Technical assistants, properly selected and in sufficient numbers, are indispensable for the achievement of a smoothly functioning and continuously improving laboratory. Specialization of the technicians in various fields of their work is productive of a greater selection of laboratory tests and a more dependable accuracy. The responsibility for the development and functioning of a department of the laboratory will bring out the best in an ambitious technician.

There is a limit to the amount of practical apparatus necessary in a laboratory. Consolation may also be had in the fact that the more expensive pieces have a long and useful life. Frequently a single instrument will be the key to a large field of diagnostic aids.

A flat rate laboratory fee which includes all but a few of the more expensive tests is of the greatest

importance. No patient should be deprived of the benefits of any laboratory aid. Once the physician realizes that there will be no additional financial burden for his patient, he will feel free to order desirable tests. Rarely is the laboratory imposed on. Routine complete blood count, urinalysis, and tests for syphilis run on all hospital admissions will justify the flat rate fee in any case.

Lack of training, ability or apparatus should be no excuse for not rendering dependable reports as desired on tests of a proved diagnostic value. This is the laboratory's first function. However, the mark of distinction of a laboratory is its accomplishments in the field of research. An efficient "routine" laboratory would fall far short of the ideal.

In the following description of a laboratory, the development of each reorganized department is revealed through a summary of the reports that have been presented to its medical staff.

DEPARTMENT OF PATHOLOGY

Necropsies—A constant effort is being made to prove the value of necropsies to physicians and interns in the hope of further developing the benefits derived from this most important branch of scientific medicine. One measure of the success of these efforts is the present average of over 80 per cent necropsies on hospital deaths. Attending physicians are being consulted as to the convenient time for performing necropsies, or, if they cannot be present, they may point out peculiarities of the case. The percentage of permissions for necropsies granted interns and their attendance at the examinations are being posted in the morgue. Nurses are encouraged to be present. A routine discussion of the history, physical examination, progress and therapy of the deceased precede each necropsy and there is a constant correlation of clinical and pathologic aspects of the case during the examination. With the necessary additions to a morgue, careful bacteriologic studies can be made without waste of time or effort. Biochemical and biologic tests can be run where indicated. Special preparation and staining of tissues is important. The stains thus far developed in this laboratory are phosphotungstic acid, hematoxylin and eosin, Mallory's eosin methylene blue, Brown-Breen's (Gram's), acid fast thionine, sudan III, Best's glucose cresyl violet, osmic acid, iron, Levaditi's spirochete and Foot's silver stains. There is on hand a sufficient amount of glassware, crocks and chemicals, so that a minimum of time is required for preserving interesting specimens. Photographs and x-ray examinations are being made in all cases where indicated.

Necropsy reports include a gross and microscopic description and, when pertinent, a brief discussion and correlation of the clinical and pathologic observations. These reports are finished within two weeks unless haste is requested or indicated, and then they may be

finished in three days. Records are sent to the attending and consulting physicians. One report is kept on the chart and another in the laboratory office. A cross index of these anatomic diagnoses is filed in the laboratory office to facilitate future investigation. Outpatient necropsies are being done without charge except for medicolegal cases. A comparison of necropsy and clinical diagnoses is being prepared and shown on a lantern slide at each monthly staff meeting. The combined errors of many physicians revealed in this way is the most effective argument for necropsies known. Another part of the mortality and morbidity report is the presentation of any outstanding case studied in the hospital during the previous month.

St. Luke's Hospital Laboratory Special Blood Report

19 LABORATORY DIAGNOSIS	
Pathologist	

Surgical Tissues — Routine gross descriptions are being made on all tissues removed at operation, and microscopic descriptions of paraffin sections are being made on all tissues except such structures as old scars, hernial sacs, normal ribs and tonsils, unless they are requested. A diagnosis by frozen section will be attempted at any time. Paraffin section preparations can be had in five hours. Routine paraffin sections are reported on by the third postoperative day or earlier if desired. Special stains, biologic tests and bacteriologic studies are used when appropriate.

An honest description of each tissue is being made, its source being designated rather than it being diagnosed as "normal." Thus it is hoped to avoid any remote possibility of legal complications. For example, if an appendix has a horseshoe shape, more lympho-

cytes than usual in the mucosa or an unusually thin wall, and yet shows no microscopic active inflammatory process, the variations will be described and the diagnosis "Appendix" will be made. With the surgeon's clinical diagnosis at the top of the report, prying eyes of those less informed will be satisfied.

A copy of the report is sent to the surgeon, one kept in the laboratory, and another put on the chart. The paraffin sections and blocks form permanent record. Unusually interesting specimens are saved for a museum. Others are being thrown out after a month until we have sufficient space and glassware to save all tissues.

DEPARTMENT OF HEMATOLOGY

A hematology department may be sadly neglected or it may follow closely the continuous advancements in the field. As a basis of our work in the study of blood, we have adopted a detailed report sheet patterned after that of Dr. Russell Haden of Cleveland (see "Special Blood Report" sheet). This is to be used for complete blood studies in cases with symptoms suggestive of blood dyscrasias.

In the interest of greater efficiency and economy in this department, the hospital has provided an excellent pipet shaking machine, Dr. Marble's differential blood counting machine, a Haden-Hausser hemoglobinometer and a binocular microscope.

Grams of hemoglobin per hundred cubic centimeter of blood is reported, as well as the usual percentage of normal. There is such a variation in the percentage of hemoglobin as determined by the several methods in common use that it would be well for physicians to become accustomed to the common basic figure expressed in grams. We are saving data on normal individuals living in this northern community and will arrive at a local relationship between grams of hemoglobin and percentage of normal.

All differential counts list neutrophils in two groups: nonsegmented and segmented. The differential blood counter makes this a simple procedure, which may become a distinct asset to some physicians. All differential counts are done on cover slip preparations so as to obtain a uniform distribution of the white blood cells.

The recently widely proved value of bone marrow studies leads me to believe that they will soon be used as a routine in certain types of cases. We have just recently proved that a patient with a normal white count was in an aleukemic phase of leukemia. Special bone marrow preparations are being made from all necropsies, and clinical studies are encouraged.

DEPARTMENT OF BACTERIOLOGY AND SEROLOGY

Bacteriology has possibly been neglected more than any other phase of laboratory work in hospitals of moderate size. With the cooperation of the hospital, we are now equipped to identify by approved methods almost any pathogenic organism.

Certain pieces of apparatus may need a brief description. Our Seitz microfilter makes it possible to isolate or work with bacteriophage, to prepare asthma and hay fever vaccines, and to study the field of filtrable viruses whenever the occasion arises. A potentiometer makes the preparation of mediums from raw material a controlled process. It is an indispensable and efficient means for accurate hydrogen ion determinations in blood and other body fluids and in certain experimental fields, especially bacteriology.

Instead of the laborious and occasionally failing method of perpetuating the many cultures used in a

modern bacteriologic laboratory by frequent subculturing, we are now using the recently discovered method of creating what might be called artificial spores of any organism. This is done by rapidly dehydrating them in a high vacuum with a special pump. The dried organisms can be kept sealed in a desk drawer for eight months or more. Preservation and concentration of antisera or complement is made possible by this method. It also introduces a new field of bacteriology as the cultures retain their virulence and original culture characteristics, enabling one to save many strains of various organisms for comparative group studies.

To give some idea of the variety of available tests and possibly some practical suggestions, a list of bacteriologic and immunologic tests will be cited. Recent improved methods for the culture diagnosis of gonorrhea have proved more accurate than the simple morphologic study of smears. A three-hour mouse method has proved quite reliable for pneumococcus typing, and we soon hope to identify all types for which there are antisera on the market. The growth of *Brucella abortus*, *Brucella melitensis*, *Brucella suis*, *Pasteurella tularensis*, *Neisseria gonorrhoeae*, and certain strains of streptococci is enhanced greatly by an atmosphere of carbon dioxide. Carriers of the organisms of typhoid epidemic meningitis and diphtheria may be located among the patient's contacts. The virulence of diphtheria-like bacilli can be tested. The determinations of total bacterial counts tests for sewage pollution, and the identification of food poisoning organisms in water and food products may become imperative in any community. Methods for the demonstration of Rickettsia bodies, the virus of psittacosis, *Leptospira icterohaemorrhagiae*, *Spirochaeta pallida*, *Bacillus anthracis*, *Clostridium botulinum*, *Haemophilus influenzae*, the organisms of gas gangrene and certain pathogenic fungi are ready for use.

Certain serologic tests may prove of practical value. Controlled agglutination tests with antigens made of *Eberthella typhi*, *Salmonella paratyphi*, *Brucella abortus*, *Brucella melitensis*, *Pasteurella tularensis*, strains Shiga, Flexner and Hiss-y of *Endamoeba dysenteriae* and *Bacillus proteus* X19 will be reported after overnight incubation. Seven cases of infectious mononucleosis have been diagnosed or the diagnosis confirmed during the last two months by using the heterophile antibody test. Frei's antigen skin test made a clinical diagnosis of lymphogranuloma inguinale a certainty. A greater use of the bacteriocytophagic index and skin tests for brucellosis is encouraged. Autogenous vaccines can be prepared in from two to seven days.

We are running the Kahn and Kline tests on all cross matched blood donors. These or other recognized tests should also be run in a routine way in all hospital admissions.

DEPARTMENT OF CHEMISTRY

The personal factor of error has recently been almost eliminated in two important pieces of apparatus used in chemistry. The photometer electrically measures the intensity of light passing through the variously colored solutions previously compared in a colorimeter. A magnetic damper on any gravimetric balance will eliminate the time consuming and difficult calculation of the zero point.

The wide variety of chemical analyses being run in this laboratory include serum albumin, globulin and fibrinogen, blood calcium, phosphorus, iodine, bromide, chloride, methemoglobin, carbon dioxide capacity, and

hydrogen ion concentration. Spinal fluid proteins, dextrose and chlorides may be ordered. Liver function tests include blood cholesterol and cholesterol esters, bromsulfalein excretion, galactose tolerance, urobilinogen in the stool and urine, Van den Bergh's quantitative test and the icterus index. Kidney function tests include the Van Slyke urea clearance, phenolsulfonphthalein excretion, Mosenthal's and Volhard's specific gravity tests, urea excretion, quantitative urinary albumin, and the quantitative determination of various protein metabolites in the blood.

All emergency chemical tests are run when ordered while routine requests are being run at 10 a. m. and 4 p. m. daily. Urinalyses are being run at 7 and 10 o'clock in the morning and 4 and 6 in the afternoon.

In toxicology we are prepared to run tests for the demonstration of the heavy metals, alkaloids, certain volatile oils and inorganic compounds. This part of the laboratory has been neglected even in many medical schools. However, a lack of training, ability or apparatus should not interfere with the isolation and identification of the more common poisons. We hope in the future to present to the staff a complete list of the poisons which we have proved our ability to identify.

TEACHING AND RESEARCH

I would like to call attention to a most important phase of laboratory work. Ideally, the pathologist should spend half of his time developing the many details of the experimental and teaching duties of his specialty. The various teaching aspects of necropsy work have already been dealt with. The continuous correlation of clinical and pathologic observations at necropsies, the permanent preservation of tissues of unusual interest, the preparation of a museum, and the frequent recording of pathologic processes by gross and microscopic photography and other methods need not be reiterated. For those interested, an opportunity to review their anatomy is being offered in the morgue in the form of group demonstrations. Staff members so requesting are notified a few hours in advance.

A clinical pathologic conference should be a part of the routine of every well organized laboratory. The benefits derived from these sessions depends greatly on the preparation of its individual participants. I might venture that no one thing has been more beneficial to the physicians of Duluth than the conferences conducted weekly during the last ten years by Drs. E. L. Tuohy and G. L. Berdez at St. Mary's Hospital. An abundance of instructive material is wasted as far as its immediate and very important application is concerned without this outlet.

It would seem that interns in many hospitals were once burdened by all the laboratory work. When the advantages of employing technicians became known, the pendulum swung, in many places, to the other extreme, so that a gesture at laboratory training became sufficient. Our intern committee has arranged for a minimum of training in this field based on several important requisites. There should be a sufficient variety and quantity of laboratory procedures for which the intern should be given full responsibility. He should not be permitted to shift his work on a technician, and there should be no interference with the laboratory's efficiency or accuracy. We feel that this has been brought about by having two interns do all the tests ordered every third Sunday under the direct supervision of a technician and the pathologist. They also have certain laboratory duties involving those

patients on their individual services, besides performing the night laboratory tests. Their attendance and assistance at necropsies is important, and the supervised complete performance of at least one examination is a minimum requirement. An intern's weekly conference provides further clinical and pathologic training.

A training school for laboratory technicians has been opened, which is planned to fulfil the requirements of the Council on Medical Education and Hospitals of the American Medical Association for acceptable schools for laboratory technicians. The number of students is strictly limited to one for each of the four teachers, and they rotate twice through the four departments during their fifteen months of training. The many assets to a laboratory offered by student technicians will not be entered on here.

The knowledge of fundamental gross and microscopic pathology in the more common disease processes would seem to be a minimum objective in the teaching of nurses. To this end, a twenty-hour lecture and demonstration course is being given by the pathologist. Nurses are being encouraged to attend necropsies at which they are treated with special consideration. It is believed that as more people become familiar with the value and procedures of necropsies there will be less obstruction encountered in this field. Ignorance, mystery and bigotry thwart progress.

A comprehensive lecture on postmortem examinations was recently given before a regional meeting of the Society of Morticians. The pathologist may be used to some advantage before other lay groups talking on medical subjects.

All the current medical journals received for the hospital's general library pass over the pathologist's desk before entering the library. One duty of the pathologist is to know of the important developments in all fields of medicine, and especially those having to do with diagnostic procedures. To this end a cross index of all such articles is being kept, and a diagnostic reference library is being developed in the laboratory office. The hospital has been quite liberal in permitting the pathologist to attend important medical meetings in other cities, which is an asset to any laboratory.

A spacious and well equipped animal house on the roof of the hospital makes animal work possible at any time. Interest in animal surgery or experimentation is welcomed. A variety of animals is being raised for this and other purposes. The hospital has offered the opportunity, there remains the necessity of time, ambition, imagination and interest on the part of the physician.

Assistance can be offered the pathologist by collaboration in experimental fields or by the editing of papers. It will suffice to list a few of the problems now being actively investigated in our laboratory: studies of bone marrow from all necropsies, comparison of retinal, cerebral, coronary and renal arteries from necropsies, development of a precipitation test for infectious mononucleosis, demonstration of the etiologic agent of infectious mononucleosis, investigation of the value of the Gordon test, performance of anaerobic cultures of the uterine cavity in cases of abortion, studies of endometrium in cases of metrorrhagia, development of a rapid, simple and practical office method of determining blood sugar, determination of the histogenesis of papillomatosis peritonei, routine studies of the hydrogen ion concentration of spinal fluid, comparison of

liver function tests, the quantitative determination of silica in the lungs, special preparations for the study of the cytology of transudates and exudates, determination of the regional relationship of grams of hemoglobin and percentage of normal, the preservation of non-pathogenic, acid fast bacilli, organisms producing green pigment, bacilli of gangrene, and other bacteria for future group studies, and the preparation of several case studies.

SUMMARY

The actual development of a hospital laboratory has been described in the form of summarized reports to its medical staff. Sufficient indication of the range of diagnostic aids offered by each department is given to define its limits of usefulness in a hospital of moderate size. Staff physicians are ultimately responsible for the development of their hospital laboratory. It would be well for them to appreciate fully its possibilities especially during the present trend toward improvement of services in many hospitals throughout the country.

THE TAKATA-ARA TEST AND ITS RELATION TO CIRRHOSIS OF THE LIVER

ROBERT C. KIRK, M.D.

NEW YORK

Clinicians everywhere are anxiously and hopefully awaiting a liver function test that will be of definite diagnostic value. The recent appearance of several American papers on a new test of liver function, the Takata-Ara test, in which it was concluded that a distinct differentiation, on the basis of this test, could be made between carcinoma and cirrhosis of the liver stimulated the present investigation.

This reaction was originally described by Takata¹ who used it to differentiate lobar pneumonia from bronchopneumonia. He found that when fluid from the chest of a patient with lobar pneumonia was added to a solution of sodium carbonate, mercury bichloride and acid fuchsin, a precipitate of mercury oxy-sol occurred. He believed that this precipitate was due to decreased stability of the serum proteins, produced essentially by an increase in the globulin fraction. Later Takata in collaboration with Ara² reported on the reaction in cerebrospinal fluid. It seemed to differentiate between syphilitic and meningitic involvement of the central nervous system. Daffinee and Grzebiemowski,³ Cameron and McCulloch⁴ and Monias⁵ have all reported favorably on this spinal fluid test. Jezler⁶ employed the test on the serum and ascitic fluid in liver disease, recognizing that a protein shift in the blood was not peculiar to lobar pneumonia. It was found to be positive in the serum and ascitic fluid in nearly all advanced cases.

of cirrhosis and usually negative in all other diseases, including cholelithiasis and carcinoma of the liver

The literature contains numerous articles of a similar nature. The data from those of Oliva and Pescoroma,⁷ Magath,⁸ Ragins,⁹ Neuweiler,¹⁰ Schindel and Barth,¹¹ Lazzaro,¹² Skouge,¹³ Crane,¹⁴ Heath and King,¹⁵ Hugonot and Sohler,¹⁶ Oefelein,¹⁷ and Hafström¹⁸ have been tabulated and presented in the accompanying chart

Positive and negative Takata Ara reactions compiled from the literature

METHOD

The method employed was that described by Jczler with modifications after Crane.¹⁴ One cubic centimeter of a 0.9 per cent solution of sodium chloride was pipetted into each of six small test tubes (agglutination tubes are very satisfactory). One cubic centimeter of the patient's serum was added to the first tube. One cubic centimeter of the patient's serum and saline solution well mixed was pipetted into tube 2 and the procedure continued until dilutions from 1:2 to 1:64 were obtained. The final cubic centimeter was thrown away. To each tube 0.25 cc of a 10 per cent solution of sodium carbonate was added, followed by 0.15 cc of 0.5 per cent mercury bichloride. The tubes were then shaken and were read in five minutes and again in twenty-four hours. A pearly flocculent precipitate filling at least one fourth of any tube and a definite precipitate in any of the first four tubes is considered

strongly positive. All other types of precipitate or lesser degrees of the pearly flocculent precipitate are considered negative. Heath's¹⁵ division of readings into five groups seems only to make interpretation difficult. Serum preserved at icebox temperature for a few days seems suitable for testing, but serum many weeks old gradually loses its precipitating properties. Slight amounts of hemolysis do not seem to alter the test. A bluish cloudiness or a brick reddish precipitate may be disregarded, as these occur occasionally in the reagents when mixed without serum. The results of the test are outlined in the tables to which reference will be made in the discussion.

RESULTS

In this series of 106 patients whose serums were tested, the clinical diagnosis was used as a basis for classification of the diseases and wherever possible was substantiated by postmortem examination or surgical biopsy. The cases are classified into twelve main groups (table 1).

In the twenty-one cases of clinical cirrhosis of the liver, diagnosis was based on a combination of several of the following: chronic alcoholism, hepatomegaly, splenomegaly, jaundice, ascites, hematemesis, esophageal varices, hyperchromic macrocytic anemia¹⁹ or shrunken liver.

The twelfth class includes all patients in whom no definite evidence of liver damage was present. In this group were seven positive and thirty-two negative

TABLE 1—Classification of Cases

Clinical Diagnosis	Takata Ara		No. of Postmortem Examinations
	+	-	
Cirrhosis of liver	15	6	1 Diagnosis confirmed 0 No deaths during observation period
Congestive heart failure	7	7	4 All with marked passive congestion of liver 4 All with less marked passive congestion
Hepatitis	2	3	2 Marked central necrosis of liver 2 Less marked central necrosis of liver
Cholecystitis with cholelithiasis	3	0	0 (Operative removal)
Liver malignancy (metastatic)	3	2	1 Diagnosis confirmed 2 One with metastasis one with normal liver (carcinoma of rectum)
Abscess of liver	1	0	0 No deaths
Congenital hemolytic jaundice	2	2	0 No deaths
Leukemia	1	1	1 Extensive leukemic infiltration of liver 1 Moderate liver cell necrosis
Tuberculosis	2	2	2 Extensive miliary infiltration of liver 1 Normal liver
Lobar pneumonia	1	4	1 Marked central necrosis of liver lobules 1 Marked central necrosis of liver lobules
Hyperthyroidism	4	0	0 One was icteric (20) no deaths
Miscellaneous	6	32	7 Normal livers microscopically
Totals	59	67	36

Takata-Ara reactions. Four of the former were chronic alcoholic cases but presented no clinical evidence of liver disease. The latter thirty-two included seven patients with nephritis, six of whom died in uremia and two patients with multiple myeloma.

COMMENT

An attempt to correlate the Takata-Ara reaction with other liver function tests has been unsuccessful. Mann

- 19 Van Duyn John. Macrocytic Anemia in Disease of the Liver. *Arch. Int. Med.* 52:839-851 (Dec.) 1933

and his co-workers²⁰ have shown that the functions of the liver vary more or less independently of one another and that disturbance of one function may be coincident with normality in the other. Yegge²¹ and Soffer²² agree that no single test can be of much value. Several authors²³ find no relation between the sedimentation rate, the galactose tolerance, the bilirubin tests and the Takata-Ara reaction. Tannenholz²⁴ found no relation between the actual Wassermann reaction and the Takata-Ara reaction but did obtain 15 per cent of positive reactions in his cases of syphilis. Analysis of his positive results shows that seven patients were jaundiced, two were chronic alcoholic addicts and three were decompensated cardiac patients, conditions which have already been shown to give positive Takata-Ara reactions. Ragins attributes his positive reactions in hyperthyroidism to liver damage, which Youmans and Warfield²⁵ and Weller²⁶ find in 50 per cent and 54 per cent respectively of such cases, as evidenced in the former's series by retention of the bromsulfalein and in the latter's series by autopsy. We have not had that experience in our clinic. Correlation with the icteric index has been almost unanimously unsuccessful.

EXPLANATION

The rationale of the Takata-Ara test is not well understood. It has been stated by Takata¹ and Jezler² that it is the decreased stability of the serum proteins of the colloid system that makes the precipitation of the colloidal solution of mercuric oxide possible and that this is due to an increase of globulin with inversion of the albumin-globulin ratio. Hugonot and Sohier¹⁰ found the Takata-Ara reaction to be positive in conditions usually brought about by severe hepatic disease, and also in protozoal infestations of the blood (kala-azar) in which a derangement of the blood proteins is found. They felt, however, that it was due to a diminution in the "protective" action of serum albumin. Oliva⁷ reached similar conclusions. Schindel²⁷ found that, by adding various concentrations of lower fatty acids (propionic and the like) to a serum which otherwise gave a negative Takata-Ara reaction, he could produce a positive Takata-Ara reaction. This confirmed experiments of Kallos-Deffner²⁸ and seemed of considerable significance to Greene, Bercovitz and Hansen²⁹. Recently Ucko³⁰ has criticized Schindel's statements on the justifiable grounds that the addition of fatty acids so alters the reaction of the tubes as no longer to meet the requirement of the Takata-Ara reaction. Zirm³¹ and others³² are able to inhibit flocculation by

the addition of small amounts of heparin to each tube but no explanation is offered. Schindel²⁷ and others³³ were unable to confirm Jezler's demonstration of reversed albumin-globulin ratios in serums which gave a positive Takata-Ara reaction.

That there is a definite relationship between a positive Takata-Ara reaction and an increase in the globulin fraction is the opinion of Jezler,³ Lazzaro¹ and myself.

Snell³⁴ writes that it has been observed repeatedly that there is a moderate reduction in the total serum proteins in advanced chronic hepatic lesions, the diminution occurring chiefly in the albumin fraction with reversal of the albumin-globulin ratio. In less advanced cases the albumin may be only moderately reduced and the globulin may be normal or increased in amount. Peters and Eisenman³⁵ state that the albumin reduction may be due to malnutrition.

TABLE 2—Percentages of Albumin and Globulin in Positive and Negative Takata-Ara Reactions

Case No	Patient	Albumin	Globulin	Diagnosis	Comment
Positive Takata Ara Reaction					
1	Ar	2.77	9.40	Multiple myeloma	
2	No	1.52	5.18	Biliary cirrhosis	Autopsy diagnosis

In an attempt to arrive at some answer to these questions, total serum proteins and fractions were determined in fifty-seven instances on fifty-six patients in this series. Total proteins in this laboratory³⁴ have a normal range from 6.8 per cent to 8.5 per cent. Wu³ obtained an average globulin figure of 2.09 per cent. Peters and Eisenman³⁵ using Howe's³ method in twenty-seven determinations on thirteen normal males obtained an average globulin of 1.89 per cent with a range of from 1.32 to 2.91 per cent. In females the average was somewhat higher—2.62 per cent with a range of from 2.02 to 3.22 per cent. On the basis of these normal figures the results in our cases were rather striking.

Serums with reversed albumin-globulin ratios were investigated. There were eighteen such cases, thirteen of which gave a positive Takata-Ara reaction, a correlation closer than Schindel and Barth¹¹ obtained (eight positives out of twenty-one serums with reversed albumin-globulin ratio), but not very definite. Mere reversal did not seem to be the important factor and absolute increases in globulin with 3 per cent as the upper limit of normal were tabulated. There were twenty-one such cases, of which nineteen gave positive Takata-Ara reactions (table 2). There were three cases of positive Takata-Ara reactions with globulin below 3 per cent for which no explanation can be offered. The total serum globulin was then calculated from the percentage figures given by Schindel and it was found that seventeen of his twenty-one positive Takata-Ara reactions were associated with globulins higher than 3 per cent.

Rowe³⁸ has found reports of globulin averages from 3 to 3.5 per cent in nephritis, pneumonia, angina pectoris, tetanus and diabetes. Bruckman, D'Esopo and Peters³⁹ report a case of gumma presenting a globulin of 6.13 per cent. Wu⁴⁰ finds globulins ranging from 3.35 to 7.06 per cent in kala-azar, and Hugonot obtains positive Takata-Ara reactions in his own cases of kala-azar. Meleney⁴⁰ reports globulin averages of 5.34 per cent in fourteen cases of *Schistosomiasis japonica*. In our sixteen cases of cirrhosis of the liver the average globulin was 3.4 per cent, while the average albumin was 3.17 per cent. In the thirty-three negative cases these figures were 2.18 per cent for globulin and 3.91 per cent for albumin (table 2).

It seems reasonable to suppose that increased globulin will give a positive Takata-Ara reaction in most instances, which, as has been shown, may occur in a variety of clinical syndromes.

SUMMARY

Reports of Takata-Ara reactions in 3,583 patients have been collected from the literature. The test was positive in 315 out of 375 cases of cirrhosis of the liver. It was negative in 2,254 out of 2,316 cases presenting no known liver involvement. Serum protein determinations and the Takata-Ara reactions were carried out simultaneously on fifty-six patients in our own series. Nineteen of our twenty patients with serum globulin of over 3 per cent gave positive Takata-Ara reactions. Only three of our thirty-six patients with globulins of less than 3 per cent gave positive Takata-Ara reactions.

The average figures for albumin of 3.91 per cent and for globulin of 2.18 per cent found in our thirty-three negative patients compares favorably with the normal figures reported in the literature. The sixteen patients with cirrhosis of the liver had an average albumin figure of 3.17 per cent and an average globulin of 3.4 per cent.

CONCLUSIONS

The Takata-Ara reaction is not diagnostic of cirrhosis of the liver.

The Takata-Ara reaction is likely to be positive in any disease within which the globulin level is elevated.

THE CLINICAL DIAGNOSIS OF AMEBIC DYSENTERY

GEORGE W. McCOY, M.D.

AND

ALBERT V. HARDY, M.D.

Medical Director and Consultant Respectively U. S. Public
Health Service

WASHINGTON, D. C.

In few diseases is the importance of specific diagnosis better illustrated than in amebic dysentery. If treated symptomatically, the illness tends to be protracted and to become progressively more distressing, if inaccurately diagnosed, therapeutic procedures hazardous to life are likely to be instituted. On the other hand, if accurately diagnosed, specific medication brings rapid relief and prompt recovery. The central problem of the effective handling of this disease is its recognition.

In the study of the Chicago outbreak the difficulties in the diagnosis of amebic dysentery frequently have been brought to our attention, commonly by impressive case records. We have ascertained that but one fifth of the active cases later reported had been identified accurately prior to the general knowledge of the occurrence of the epidemic. Concurrent and subsequent observations of endemically occurring infections also have revealed a substantial proportion of cases with long delayed diagnosis. We wish, therefore, to bring to the attention of practitioners that information which, in our opinion, serves best to facilitate the diagnosis of this condition.

As a basis for this report, we have clinical data on 1,215 cases. Our records, which vary in completeness, include reports submitted by attending physicians, questionnaires completed by patients or their representatives, and supplementary information elicited by correspondence and personal interviews. The complete analysis of these data has been presented elsewhere.¹

THE OCCURRENCE OF AMEBIC DYSENTERY

Of considerable importance in the diagnosis of any disease is a knowledge of its distribution, geographic, seasonal and in varying population groups. For the United States, evidence relative to these distributions of amebic dysentery is incomplete, but the information is adequate for clinical purposes.

During the one major epidemic outbreak (Chicago, 1933), cases were recognized in all parts of the United States, but particularly among the well-to-do of the larger urban centers of the North where the infection would be least expected. As a result of the wide interest thus engendered, endemic infections also have been widely recognized. Contrary to recent beliefs and teachings, it is now known that amebic dysentery is not limited in distribution by latitude, season or social standing.

It appears reasonable and safe to assume that variations in prevalence in different areas do occur. From a knowledge of source and modes of dissemination of amebic dysentery as compared with typhoid fever and bacillary dysentery, it is to be expected that the relative prevalence of the endemic *Endamoeba histolytica* infections will, in general, correspond. Where pollution with human excrement is known to occur, amebic

1 A full discussion of the clinical aspects of epidemic amebic dysentery as observed in the Chicago outbreak of 1933 is to be found in National Institute of Health Bulletin 166. This bulletin entitled *Epidemic Amebic Dysentery: the Chicago Outbreak of 1933* can be obtained from the Superintendent of Documents, Washington, D. C., by forwarding 20 cents to that official.

dysentery as well as the other enteric infections is to be expected. Recently in the study of water-borne epidemics of typhoid fever and acute enteritis, careful observation brought to light a few cases of amebic dysentery which probably otherwise would have gone undetected. Further observations in this line are to be desired. In such situations, judging by the Chicago outbreak, the symptoms of amebic dysentery usually will appear (in about two thirds of the cases) between the end of the first week and the end of the first month after exposure, but the incubation period may be even less than one week or, occasionally, as long as three months.

Amebic dysentery therefore must be considered in differential diagnosis at all times and in all places, but especially where the incidence of other enteric infections is high. Groups known to have been exposed to human fecal pollution should be followed with particular care for evidence of the occurrence of *Endamoeba histolytica* infection.

CLINICAL MANIFESTATION

Amebic dysentery is one of the large group of diarrheal diseases the various members of which are strikingly lacking in prominent differential characteristics. The response to *Endamoeba histolytica* invasion may be so mild that notable symptoms are lacking or there may be a minor gastro-intestinal disorder with or without diarrhea. The graver manifestations include evidences of an acute or chronic ulcerative process in the large bowel varying both in extent and in the area chiefly involved. Occasionally this may be associated

Early Inadequate or Erroneous Diagnoses in *Endamoeba Histolytica* Infection

with extensive tissue destruction. There are also the various complications, which usually, but not always, are preceded by intestinal symptoms. It is this variability in characteristics which makes difficult the accurate diagnosis of this infection.

To American physicians generally, amebic dysentery has been presented as a grave chronic disease with gradual onset and an afebrile course marked by intermittent abdominal pain and the frequent passage of stools containing much bloody mucus. As an aid in accurate diagnosis the common variations from this must be emphasized.

In 18 per cent of our cases the onset was abrupt, and in one third of all cases it was with symptoms other than diarrhea or abdominal pain. Fever and vomiting, with abdominal pain localized in the right lower quadrant and accompanied by tenderness and rigidity, often served to limit attention to the appendix. It has been demonstrated that the amebic infection frequently first establishes itself in the cecum and may involve the appendix. Thus differential diagnosis is particularly

difficult but exceptionally important. Appendectomy in this disease proved a treacherous and hazardous procedure, death resulting in thirteen (41 per cent) of the thirty-two cases in which this treatment was reported. Rectal distress with blood in the stools has provided a clinical picture interpreted as hemorrhoids. Six of these cases were treated surgically, one with a fatal outcome. In the foregoing cases it was the nature of the onset, which lacked the characteristic diarrhea, that limited attention to other than the diarrheal disorders.

Likewise, certain features of the course of the disease have proved misleading. There were the illnesses which began insidiously and were characterized by weakness, persistent abdominal distress and mild diarrhea with bloody mucus in the stools. On examination a mass was detected in the cecum or the course of the colon, or found on rectal examination. (In amebic infection this appears to be due to edema.) For obvious reasons, such cases have been regarded as due to a malignant condition. In others, the elevation of temperature was confusing. Fever in some degree was found to be present in 70 per cent of the severer infections involving Chicago residents, and this condition was reported spontaneously in almost one third of all out-of-town cases. An elevated temperature therefore does not speak against the existence of amebic dysentery.

DIAGNOSTIC ERRORS

Early diagnoses which proved inadequate or erroneous have been reported in 214 cases, as shown in the table. These are the more significant since the patients concerned were ordinarily in comfortable economic circumstances and sought relief from physicians of recognized ability.

It is noted that the most common mistake was the acceptance of nonetiologic diagnoses such as colitis or "dysentery." In fatal cases, however, the condition was more commonly designated as one of a surgical nature. In order of frequency, these erroneous diagnoses were malignancy, appendicitis or appendiceal abscess, sepsis in or near the gallbladder, and in one case hemorrhoids. In one half of the fatal cases mistaken diagnoses were reported, and in more than two thirds of these the illness had been handled as a surgical disease. As previously indicated, lack of specific diagnosis deprived the patients of effective therapy, but certain of the erroneous diagnoses subjected them to therapeutic procedures hazardous to life.

The influence of diagnosis on the prognosis has in other ways been apparent. In the total series of 1409 cases observed in the study of the Chicago outbreak there were ninety-eight (7 per cent) deaths. The highest fatality rate was in the nonhotel cases which had originated prior to the epidemic period and had progressed for months or years unrecognized. Likewise in the epidemic cases the severity of the course and the proportion of fatalities varied directly with the duration of illness prior to diagnosis. According to our report in no instance did a fatality follow early consultation, prompt diagnosis and adequate specific therapy. Thus the prognosis was directly dependent on the promptness of diagnosis and the institution of specific therapy.

MAJOR DIAGNOSTIC CONSIDERATIONS

In arriving at a correct diagnosis of this disease the following considerations appear to us of chief importance.

1. There should be a more consistent endeavor to arrive at an etiologic diagnosis of the diarrheal disease.

This is of importance not only in the identification of amebic dysentery but also for *Bacillus dysenteriae* infections

2 As an intestinal parasite, *Endamoeba histolytica* is widely disseminated in all parts of the United States. Though unknown as to prevalence still clinical disease from this cause is now known to occur sporadically in all regions of this country. Amebic infection therefore must be more commonly considered in differential diagnosis.

3 Disease caused by this parasite varies widely in clinical manifestations simulating among others "simple diarrhea," minor gastro-intestinal disorders and major surgical conditions. Hence the possibility of amebic infection must be weighed in the diagnosis of a wide variety of clinical disorders.

4 Confirmation of clinical diagnosis may rest on either the identification of the etiologic agent or the prompt response to specific therapy. Concerning the former it is to be emphasized that undue weight must not be given to negative laboratory examinations. Even by experienced workers the organism cannot always be found in the discharges, and by the less experienced they may not be recognized. The more frequent use of a therapeutic test with one of the newer amebicides would we believe, be of material aid in the more prompt and accurate identification of this disease.

THE USE OF STANDARDIZED MOUSE BRAIN ANTIGEN

FOR THE PERFORMANCE OF THE FREI TEST
FOR LYMPHOGRANULOMA INGUINALE

ARTHUR W. GRACE, M.D.
AND
FLORENCE H. SUSKIND, M.S.
NEW YORK

The recent appearance of an article by Strauss and Howard¹ condemning the use of lymphogranulomatous mouse brain antigen for the routine performance of the Frei test has necessitated the publication of our results with the use of this material for a period of two years at the New York Hospital. Since May 1934, 595 tests have been made with mouse brain materials in an attempt to establish the efficacy of lymphogranulomatous mouse brain antigen for Frei testing. The tests included those performed with lymphogranulomatous mouse brain antigen, both our own (New York Hospital) and commercial in patients infected with lymphogranuloma inguinale and control tests which were carried out with normal mouse brain antigen in the same subjects and with normal mouse brain and lymphogranulomatous mouse brain antigens in individuals who have never had the disease. In Strauss and Howard's paper the only results that are strictly comparable with ours are those which they obtained after observing three positive and eleven control tests with commercial antigen. Commercial and New York Hospital antigens are prepared and standardized by the same method, from the same strain of virus and with the same strain of mice. The remainder of

their paper deals with results obtained by the use of totally different mouse brain emulsions. Their conclusions as to the value of mouse brain Frei antigen of the type that is distributed commercially—an entirely new product—are therefore based on too slender experience to be of any significance.

Prior to the introduction of lymphogranulomatous mouse brain antigen the only material available for the performance of the Frei test was antigen made from human pus as first described by Frei.² Human pus antigen, however, is limited in supply and is an unsatisfactory material for several reasons, viz:

1 Cases of suppurating buboes due to lymphogranuloma inguinale from which pus may be obtained are encountered relatively infrequently.

2 Only that pus can be used which is uncontaminated with other organisms. Secondary infection following sinus formation and the coexistence of other venereal diseases occur often enough to make suitable pus scarce.

3 When a suitable case presents itself, the pus is usually available only in small quantities.

4 Specimens of pus taken from different cases vary in antigen content.

Previously we³ have shown that lymphogranulomatous mouse brain antigen has none of these disadvantages. Thus:

1 With a sufficiently virulent strain of the virus which is susceptible of being transmitted indefinitely through mice, the supply of antigen is unlimited and readily available.

2 By use of mice known to be free from spontaneous diseases and by careful laboratory technic, contamination with other organisms is unlikely.

3 By proper dilution and dosage, the exact details of which depend in the first place on the virulence of the virus and finally on the degree of reaction in known lymphogranuloma inguinale cases, a standardized product may be obtained the sensitivity and specificity of which are equal to that of human pus antigen.

It is our purpose in this paper to present evidence that standardized lymphogranulomatous mouse brain antigen is an excellent material for the routine performance of the Frei test.

METHODS AND MATERIALS

Antigens—1 The Source of Lymphogranulomatous Mouse Brain Antigen. All the specimens of lymphogranulomatous mouse brain antigen employed in this work have been prepared from a single strain of virus which was isolated in April 1934 from the pus and glandular tissue of a Negro who had the inguinal type of the disease.⁴ Each of the ninety-five of our antigens and the forty-one commercial antigens represented a single passage of the virus except in six instances in which brains from several passages were pooled to make a single antigen. There have been 111 passages to date.

2 Preparation and Standardization. It was seen that with successive transmission through the brains of mice the virus increased in virulence. It was also noted that with the same volume and concentration of inoculum the greater the virulence of the virus the greater the antigen content of the infected brains. In order to obtain standardized lymphogranulomatous mouse brain antigen it first became necessary to obtain

brains of approximately the same antigen content. This was accomplished by adjusting the volume and concentration of inoculum to the virulence of the virus. The details of preparation and standardization of our lymphogranulomatous mouse brain antigen follow. The Frei antigens which are distributed commercially and which were used in this paper were made in approximately the same way.

Healthy mice weighing 20 Gm. were inoculated with a suspension of virus of such concentration that 0.03 cc. of the inoculum caused the death of from 85 to 100 per cent of the animals in five to seven days. On the seventh day a dying mouse was killed and its brain removed aseptically and emulsified in a sterile mortar with sterile physiologic solution of sodium chloride. Sufficient diluent was used so that 0.05 or 0.1 cc. of the heated resultant product produced in individuals with lymphogranuloma inguinale a papule not less than 7 mm. in diameter, usually from 7 to 10 mm. This figure was chosen in accordance with Frei's original work, in which it was stated that a good positive test manifested itself as a papule from 0.75 to 1 cm. in diameter. It was found that 0.05 cc. of a 1 in 10 dilu-

TABLE 1—Summary of Frei Tests Performed with Mouse Brain Antigens at the New York Hospital from May 1934 to April 1936

Meaning of symbols: LI, lymphogranuloma inguinale; non LI, not infected with lymphogranuloma inguinale; LI M B, lymphogranulomatous mouse brain antigen prepared and standardized according to the authors' method; N M B, normal mouse brain antigen prepared in the same manner as LI M B; N Y H, New York Hospital.

tion or 0.1 cc. of a 1 in 13 dilution produced such a reaction. It has been our practice since the eighty-eighth passage of the virus to perform the Frei test with 0.1 cc. of a 1 in 13 dilution.

Heating of the emulsion was carried out in ampules in a water bath at 60 C. for two hours on one day and for one hour on the next. Sterility tests were performed before and after heating and any material that showed aerobic or anaerobic growth within seven days was discarded. The finished product was placed in sterile rubber-stoppered vials and stored in the refrigerator. Sterility tests were repeated at intervals when the material was kept over a long period.

3 Control Antigens. These were prepared from normal mouse brains in the same dilution as the test antigens.

Subjects Tested.—1. Individuals with Lymphogranuloma Inguinale. Fifty different individuals known to have or have had lymphogranuloma inguinale were used. The group was composed of thirty-four white and sixteen colored persons, of whom thirty-seven were males and thirteen females. Twenty-three individuals

presented the inguinal type and twenty-seven the anorectal type of the disease, fourteen patients of the latter type were white males.

Forty-two individuals received 118 tests with ninety-five different specimens of our own lymphogranulomatous mouse brain antigen and thirty-nine received fifty-seven tests with our own normal mouse brain antigen. The forty-one commercial antigens were employed for a total of fifty-three tests in twenty individuals, while commercial normal mouse brain antigen was used for eight tests in seven persons.

2 Individuals Not Infected with Lymphogranuloma Inguinale. One hundred and twenty-eight persons made up the group of control individuals, all of whom were obtained from the general medical and surgical services. There was no history or clinical suggestive of lymphogranuloma inguinale among the group. Two asthmatic individuals were included and neither showed untoward local or general reaction to inoculations with normal mouse brain antigen or lymphogranulomatous mouse brain antigen. The entire group was tested with our lymphogranulomatous mouse brain antigen for a total of 217 tests, while 107 of them received 118 tests with our normal mouse brain antigen. Commercial lymphogranulomatous mouse brain antigen was used in twenty of these individuals for a series of twenty-four tests.

Performance of the Frei Test.—The tests were made by intradermal inoculation in the usual manner and the results read at the end of forty-eight and seventy-two hours.

SIZE OF POSITIVE AND CONTROL REACTIONS

An analysis of the size of the reactions which appeared from forty-eight to seventy-two hours after intradermal inoculation with lymphogranulomatous mouse brain antigen and normal mouse brain antigen in subjects with and without lymphogranuloma inguinale follows.

Measurements of the papules only were used in the analysis, since the size of the surrounding zone of erythema which usually was present in positive test varied within wide limits and was therefore regarded as a less reliable indicator of the degree of reaction. Accurate measurements were easily made with a thin flexible scale and were facilitated by indenting the periphery of the papule at 90 degree intervals with the nail of the palpating finger. Measurements were recorded in millimeters, and it was our custom to take two diameters of the papule, each at right angle to the other.

Reactions to Lymphogranulomatous Mouse Brain Antigen in Subjects with Lymphogranuloma Inguinale.—The size and appearance of reactions produced by use of our own and of commercial antigens in subjects with lymphogranuloma inguinale agreed very closely. The true average diameter of the papules given by our antigens in the series of 118 tests was 10 mm. and that given by commercial antigens in the series of fifty-three tests was 9.3 mm. The distribution of papule size obtained in both groups of tests was practically the same. Of the total 171 tests performed with both New York Hospital and commercial antigens, 129, or 75 per cent, showed papules from 7 to 10 mm. in diameter; thirty-two, or 19 per cent, showed papules from 10 to 15 mm. in diameter; and the remaining ten, or 6 per cent, were larger. Eight of the ten large reactions were from 16 to 20 mm. papules, and one

measured 30 by 22 mm. The largest reaction observed resulted from the use of one of our antigens in a white woman who had anorectal lymphogranuloma of twenty years' duration following an inguinal infection nine years previously. The reaction consisted of an erythematous indurated area 37 mm in diameter, which contained a central black necrotic portion 25 mm in

Fig. 1—The distribution of papule size in 424 control tests and 171 positive Frei tests following the use of thirteen normal and 136 standardized lymphogranulomatous mouse brain emulsions. The ten largest reactions are omitted because of difficulty in representing very small percentages. It must be remembered that just as occurs with human pus antigen the papular reaction to lymphogranulomatous mouse brain antigen in certain cases of lymphogranuloma inguinale may be smaller than that regarded as positive. Thus in the early stage of the disease before cutaneous allergy is well developed and in debilitated or cachectic individuals the Frei reaction may be weakened or entirely negative. Six individuals not included in the chart or paper fell into this group.

diameter covered with minute vesicles. The distribution of papule size in positive tests is shown in figure 1.

Forty of the fifty individuals with lymphogranuloma inguinale received two or more tests with different specimens of our and commercial lymphogranulomatous mouse brain antigen. The same person showed approximately the same size of reaction at each test. Thirty seven of the fifty subjects, or 74 per cent, produced papules from 7 to 10 mm in diameter, nine or 18 per cent, gave papules from 10 to 15 mm in diameter, and the remaining 8 per cent showed larger responses. We feel, therefore, that the variation in papule size among the 171 tests occurred by virtue of differences of degree of individual hypersensitivity. There was no apparent relation between the degree of reaction produced with lymphogranulomatous mouse brain antigen and that produced with normal mouse brain antigen in the same individual with lymphogranuloma inguinale. The reactions to control tests with normal mouse brain antigen will be dealt with later.

Figure 2 shows the variation in size of papules produced in different individuals with lymphogranuloma inguinale by the use of lymphogranulomatous mouse brain antigen and normal mouse brain antigen.

It is common knowledge that the papule in a strongly positive Frei test is often surmounted by vesicles or pustules which may later break down to form an ulcerated area. Of the 171 reactions to lymphogranulomatous mouse brain antigen, seventy were of this type.

We have also observed unusual reactions in twelve individuals in which an erythematous indurated area studded with pinhead-size papules replaced the usual single erythematous papule. These reactions which are not included in table 1 or figure 1, ranged from 7 by 7 mm to 35 by 33 mm. They were regarded as positive in all cases, as each of the twelve subjects on other occasions showed the usual type of positive response. Similar diffuse reactions were sometimes observed when human pus antigen was used.

Control Tests Reactions to Normal Mouse Brain Antigen in Subjects With Lymphogranuloma Inguinale and to Lymphogranulomatous Mouse Brain Antigen and Normal Mouse Brain Antigen in Subjects Without Lymphogranuloma Inguinale—In order to prove that the reactions dealt with in the previous section were susceptible of being produced only with lymphogranulomatous mouse brain antigen in subjects with lymphogranuloma inguinale and that they could not be evoked by the use of normal mouse brain antigen or lymphogranulomatous mouse brain antigen in subjects not infected with lymphogranuloma inguinale the following tests were done.

A total of 424 control tests were performed in 128 individuals not infected with lymphogranuloma inguinale and forty-six individuals with lymphogranuloma inguinale with our and commercial antigens. The reactions obtained in the sixty-five tests with normal mouse brain antigen in individuals with lymphogranuloma inguinale the 241 tests with lymphogranulomatous mouse brain antigen and the 118 tests with normal mouse brain antigen in persons not infected with lymphogranuloma inguinale resembled each other closely. They all, with a few exceptions, produced small papules, which occasionally were surrounded by a small area of erythema. Some papule formation was to be expected since the material injected contained a considerable proportion of foreign substance (10 per cent mouse brain). The true average size of reactions for each group of tests is given in table 1. It will be noted that the average papule size in these tests was well below that of the positive tests. We have observed, however, that the responses to normal mouse brain antigen in subjects not infected with lymphogranuloma inguinale tended to be slightly

Fig. 2—Reactions to lymphogranulomatous mouse brain antigen and normal mouse brain antigen in individual subjects with lymphogranuloma inguinale. Ordinate. Shaded section of each bar represents reaction to normal mouse brain antigen, whole bar represents reaction to lymphogranulomatous mouse brain antigen. Abscissa. Individuals are arranged according to degree of reactivity to lymphogranulomatous mouse brain antigen.

smaller than the reactions to lymphogranulomatous mouse brain antigen in the same subjects or to normal mouse brain antigen in patients with lymphogranuloma inguinale.

An analysis of individual reactions showed that in 374, or 88.6 per cent, of the control tests there was either no reaction or the formation of papules rang-

ing from 1 to 4 mm in diameter. In forty-two, or 99 per cent, the papules were 5 mm in diameter, and in eight, or 15 per cent, the papules attained a 6 mm size (fig 1). We feel, however, that although the 6 mm papule approached a diameter that might be confused with a positive test, the confusion was more apparent than real. It was our impression that the 6 mm papule of a negative test did not extend above the surface of the skin as markedly as did the 7 mm papule of a positive test, nor was it as erythematous.

Two individuals showed reactions to normal mouse brain antigen and lymphogranulomatous mouse brain antigen that were suggestive of the presence of hypersensitivity to mouse brain protein. While the papules produced with either normal mouse brain antigen or lymphogranulomatous mouse brain antigen were no larger than those seen in the usual negative tests, there was a considerable surrounding erythematous zone, which was studded with pinhead size vesicles and was extremely pruritic. No history of sensitivity to other substances could be obtained in either of these persons.

1 *Reactions to Lymphogranulomatous Mouse Brain Antigen of Various Ages in Subjects with Lymphogranuloma Inguinale*—The tests with our lymphogranulomatous mouse brain antigen in individuals with lymphogranuloma inguinale were made over a period of one through 251 days after preparation of the antigens. Twenty-eight of the tests were performed within the first month after preparation or before the time when, according to Strauss and Howard, changes in the properties of mouse brain antigen take place. Of the tests carried out with older antigens thirty-one were made with materials that were from 29 to 60 days old, and fifty-nine with antigens that were from 61 to 251 days of age.

There was practically no difference in the reaction produced with antigens that were used within one month after preparation from those produced with antigens that were used as long as eight months after preparation. The distribution of papule size and true average size of papule were about the same for each time interval considered.

TABLE 2—Reactions Produced in Positive and Control Free Tests by the Use of Lymphogranulomatous Mouse Brain Antigens and Normal Mouse Brain Antigens of Various Ages

EFFECT OF AGE OF LYMPHOGRANULOMATOUS MOUSE BRAIN ANTIGEN AND NORMAL MOUSE BRAIN ANTIGEN ON SIZE OF REACTIONS PRODUCED

Strauss and Howard¹ object to the use of Frei antigens made from mouse brains on the basis of a few experiments which they feel demonstrated that "some change occurs in antigens made from mouse brains within a few weeks after preparation which, when injected intradermally, gives rise to a reaction almost indistinguishable from a true positive reaction." The nature of this change is unknown to them but they believe that it occurs in antigens made from normal as well as lymphogranulomatous mouse brains and that the reaction may be induced in subjects not infected with lymphogranuloma as well as in subjects with lymphogranuloma inguinale.

In order to discover whether such a change actually takes place with antigens prepared according to the method previously described, the results obtained with normal mouse brain antigen and lymphogranulomatous mouse brain antigen in subjects with lymphogranuloma inguinale and subjects not infected with lymphogranuloma inguinale were divided into a number of groups, each group representing an interval of time which had elapsed between the date of preparation and the use of the antigen.

The results obtained with commercial antigens were analyzed from the same aspect. The shortest interval that elapsed between preparation and use of antigen was ten days, and the longest was 382 days. A separation of the tests into groups depending on the age of the antigen employed revealed results similar to those obtained by the use of our antigen. The true average size of reactions obtained with antigens used from 121 through 382 days after preparation was a little larger than those given by fresher antigens. The difference was due, however, to the presence of two large reactions in the former group that were given by unusually strong reactors. The same antigen that produced these large reactions gave papules from 2 to 4 mm in diameter in subjects not infected with lymphogranuloma inguinale when tested on the same date as in the subjects with lymphogranuloma inguinale.

2 *Reactions to Lymphogranulomatous Mouse Brain Antigen of Various Ages in Subjects Not Infected with Lymphogranuloma Inguinale*—Our lymphogranulomatous mouse brain antigens which were used in the tests in subjects not infected with lymphogranuloma inguinale ranged in age from 9 to 636 days. In twenty tests the antigens were employed within two weeks after preparation, and in thirty-two others from ten to twenty-eight days after preparation. The remainder

of the tests were made with antigens more than four weeks old of which seventy-one were carried out with antigens from 29 to 60 days old, sixty-six with material that was from 61 to 251 days old, and eight with antigens that were prepared almost two years previously. Antigens used within two weeks after preparation gave practically the same size of reaction as

To sum up the work dealt with in this part of the paper, it can definitely be said that no appreciable change demonstrable by the performance of an intradermal test in individuals with lymphogranuloma inguinale or not infected with lymphogranuloma occurred in normal mouse brain antigen or standardized lymphogranulomatous mouse brain antigen at any period up to two years after preparation of the antigens.

COMMENT

Any suspension of a foreign substance, particularly protein when injected intradermally into a human subject will produce an inflammatory response at the site of inoculation. The reaction will occur despite the fact that the material may be chemically inert and free from living or dead micro-organisms. The severity of the reaction will be influenced by the nature of the material and the presence or absence of hypersensitivity to the material in the individual inoculated. These facts must be considered in the interpretation of the cutaneous response in a Frei test regardless of whether the test is performed with mouse brain antigen or with human pus antigen.

The Frei reaction is an allergic phenomenon and occurs only when material containing the killed virus of lymphogranuloma inguinale is inoculated intradermally into individuals who have or have had the disease. Thus far it has not been found possible to separate the virus from the tissue in which it is found, therefore Frei antigen of necessity contains a large proportion of dead disintegrated tissue. This is true both for

Fig 3—Seventy-two hour reactions to normal mouse brain antigen and commercial lymphogranulomatous mouse brain antigen in a colored male who had suppurating inguinal adenitis of three and one-half years' duration due to lymphogranuloma inguinale. The papules and areas of erythema are ringed. One half natural size. 1 Control reaction to normal mouse brain antigen. 2 Positive reaction to lymphogranulomatous mouse brain antigen. Note the pustule surmounting the papule.

those which were almost two years old. No reactions that could be interpreted as positive were observed in these control tests.

Analysis of the effect of age on lymphogranulomatous mouse brain antigen revealed that there was neither an increase nor a diminution in the size of reactions produced by our antigens within 636 days and by commercial antigens within 382 days after preparation.

3 Reactions to Normal Mouse Brain Antigen of Various Ages in Subjects Not Infected with Lymphogranuloma Inguinale—In only sixty-seven of the 118 tests made in individuals not infected with lymphogranuloma inguinale with our normal mouse brain antigen were the dates of preparation of the antigen known. These sixty-seven tests were performed in as many different individuals with emulsions of normal mouse brain antigen which were prepared from five to ninety-three days previously. Although the smallest average size of reaction was obtained with antigens used less than ten days after preparation the increase in size over this given by the older antigens was negligible and could not be regarded as an indication of a change in the properties of the antigen sufficient to produce false positive results.

4 Reactions to Normal Mouse Brain Antigen of Various Ages in Subjects with Lymphogranuloma Inguinale—The results obtained by the use of our and commercial normal mouse brain antigen of varying ages in subjects with lymphogranuloma inguinale closely paralleled the results observed in subjects not infected with lymphogranuloma inguinale with the same material.

Fig 4—Seventy-two hour positive reactions to two other commercial lymphogranulomatous mouse brain antigens in the same subject as figure 3. Sloughing of the central portion of the papules is present. The papules and areas of erythema are ringed. One half natural size.

mouse brain and human pus antigens. The products of tissue disintegration are capable of producing an inflammatory response on intradermal inoculation.

5 Except to a certain degree in the antigen prepared according to the method of Tamura J. T. Cultivation of Virus of Lymphogranuloma Inguinale and Its Use in Therapeutic Inoculation J. A. M. A. 103: 408 (Aug. 11) 1934.
6 Wells H. G. Chemical Pathology Philadelphia W. B. Saunders Company 1925.

Unless one is familiar with the type and degree of such responses errors may be made in evaluating the reaction to a Frei test.

Lymphogranulomatous mouse brain emulsions prepared and standardized according to the methods described in this paper produced in 75 per cent of the tests in individuals with lymphogranuloma inguinale high well defined papules from 7 to 10 mm in diameter. The remaining 25 per cent of tests showed papules larger than 10 mm in diameter. In no instance was the diameter of the papule less than 7 mm. All the papules were erythematous and were usually surrounded by a zone of erythema as well. Frequently they were surmounted by pustules or vesicles which were sometimes followed by ulceration of the central portion of the papule.

Fig. 5—Seventy-two hour control reactions to normal mouse brain antigen and lymphogranulomatous mouse brain antigens of various ages in a subject not infected with lymphogranuloma inguinale. One half natural size. 1 Reaction to lymphogranulomatous mouse brain antigen used 636 days after preparation. 2 Reaction to lymphogranulomatous mouse brain antigen used 633 days after preparation. 3 Reaction to normal mouse brain antigen used ninety-three days after preparation. 4 Reaction to lymphogranulomatous mouse brain antigen used thirty-five days after preparation.

Determination of the degree of the nonspecific response caused by the presence of the broken-up brain tissue in mouse brain antigen was made in the series of control tests. In no instance was this response equivalent to a positive test. Usually a papule was produced which was from 1 to 4 mm in diameter and of varying degrees of erythema. In a small percentage of the reactions (15 per cent) 6 mm papules were obtained but these were less erythematous and lower than the smallest 7 mm papule produced in positive reactions. The formation of pustules and vesicles was never observed in control tests except in two cases in which there was vesiculation accompanied by marked pruritus.

It was felt that the latter reactions were possibly due to hypersensitivity to mouse brain protein. The reactions of subjects not infected with lymphogranuloma inguinale to inoculation of antigens prepared from mouse brains infected with lymphogranuloma inguinale were practically the same as the reactions to normal mouse brain material.

In a small series of unpublished tests we attempted to determine the quality and size of nonspecific reactions produced by the extraneous material present in human pus antigen. Fourteen subjects not infected with lymphogranuloma inguinale were inoculated intradermally with three different specimens of human pus antigen of various ages for a series of twenty-six tests. In twenty-one of these tests papules were obtained which ranged from 1 to 4 mm in diameter and the remaining five tests merely showed small areas of erythema. The papules differed from those obtained in control tests with mouse brain antigens chiefly in that they were somewhat less erythematous and were on the average slightly smaller. The difference however may be explained on the basis that human pus is a less foreign substance than mouse brain, and consequently a less severe inflammatory response would be expected to accompany its use.

It is the larger size and more erythematous nature of nonspecific reactions to lymphogranulomatous mouse brain antigen that may lead those familiar only with reactions produced by human pus antigen into erroneous conclusions as to the specificity of the former material. On this account we advocate the use of normal mouse brain antigen as a control concurrently with lymphogranulomatous mouse brain antigen in the performance of the Frei test.

Our experience has convinced us that there is a large enough difference between the specific and nonspecific reactions to standardized lymphogranulomatous mouse brain antigen to make this material with all its advantages over human pus antigen the most suitable for the performance of the Frei test. Furthermore we have shown that no changes occur in the antigen standing for at least one year which alter the quality or size of the specific or nonspecific reactions produced by it.

SUMMARY

1 Lymphogranulomatous mouse brain antigen prepared and standardized according to the method described [L. I. M. B.] possesses none of the disadvantages of human pus antigen for the performance of the Frei test.

2 Ninety-five specimens of our lymphogranulomatous mouse brain antigen and forty-one specimens of commercial lymphogranulomatous mouse brain antigen were employed for a series of 171 tests in fifty individuals who were known to have had lymphogranuloma inguinale.

3 The same antigens were also used in 128 persons who never had lymphogranuloma inguinale for a group of 241 control tests. One hundred and eighty-three tests were carried out in subjects both with and without lymphogranuloma inguinale with antigens made from normal mouse brain [N. M. B.].

4 A typical positive reaction resulted from every test with lymphogranulomatous mouse brain antigen in subjects with lymphogranuloma inguinale in which the erythematous papule produced was never smaller than 7 mm in diameter and in 75 per cent of the tests was from 7 to 10 mm in diameter.

5 In none of the 424 control tests was a papule produced as large as 7 mm in diameter. The greater number of control reactions (88.6 per cent) showed papules from 1 to 4 mm in diameter.

6 The difference between positive and control tests was readily recognizable. The use of a control test with normal mouse brain antigen concurrently with lymphogranulomatous mouse brain antigen was advocated.

7 No change was observed to occur in either our or commercial lymphogranulomatous mouse brain antigen and normal mouse brain antigen on standing for any length of time up to two years after preparation which would make lymphogranulomatous mouse brain antigen unsatisfactory material for the performance of the Frei test.

8 Consequently, it is felt that standardized lymphogranulomatous mouse brain antigen is the most suitable material for the routine performance of the Frei test.

TULAREMIA WITH PLEURAL EFFUSION

CASE IN WHICH BACTERIUM TULARENSE WAS
ISOLATED FROM PLEURAL FLUID
DURING LIFE

FREDERICK C WARRING JR MD
AND
VICTOR F CULLEN MD
STATE SANATORIUM MD

During the thirty years that tularemia has been recognized, interest has increased in the pleuropulmonary manifestations of the disease. Blackford¹ recently reported a series of thirty-five consecutive cases of tularemia, of which approximately half showed clinical evidence of involvement of the thoracic viscera and more than 90 per cent showed x-ray abnormalities that might be attributed to the disease; he concluded that intrathoracic infection was frequent in patients who recover. He classifies the clinical signs in the chest as (1) tularemic pneumonia, (2) tularemic bronchitis and (3) tularemic pleural effusion. Archer, Blackford and Wissler² describe the roentgenologic observations in the same series of cases. Tularemia with pleural effusion seems to be the least frequent of the three, appearing in Blackford's series in three cases, compared with seven each of tularemic pneumonia and bronchitis. Since tularemia with pleural effusion in the weeks following the acute onset, so closely resembles both clinically and roentgenologically the wet pleurisy of tuberculosis, diagnosis, especially in the typhoidal type, may be rather difficult. It would be of great assistance in establishing the final diagnosis in doubtful cases if the causative organism could be obtained by culture or inoculation, but strangely enough *Bacterium tularense*, like the tubercle bacillus, is not easily isolated from the pleural fluid. In only three cases of tularemic pleurisy has the isolation of *Bacterium tularense* from the pleural effusion during life been reported. Gudger³

describes a case in which the organism was found in the pleural fluid, evidently before death. This patient succumbed in thirty-one days and the report includes the necropsy. In two instances the organism was found by Francis: the first a case of Blumberg and Russell⁴ and the other a case of Schrieber and Cajigas.⁵ The case about to be described is the fourth.

REPORT OF CASE

R A, a white man aged 55 a truck driver had enjoyed excellent general health until the present illness. His family and past histories were negative for tuberculosis. Sometime between Nov. 1 and 15, 1935, he shot and skinned a wild rabbit. He recalls that the rabbit seemed lively before being hit (no abnormality of the meat was noted) and there were no cuts or abrasions on his hands or fingers at the time. Likewise November 15 he skinned two more wild rabbits that had been shot by some one else. His good health continued until November 26 when a rather severe headache developed which became so intense on the following day that he was forced to stop work. In addition he felt extremely weak, lost his appetite and had fever to 103.5 F and chills. The patient was put to bed by his family physician but continued to have a fever and in one or two days pain developed on deep inspiration in the right side of the chest, relieved by strapping. There were also night sweats, some dyspnea and a slight cough but no expectoration or hemoptysis. No ulcerations could be found on the extremities, no adenopathy nor any eye signs, the liver and spleen were not palpable. The temperature returned to normal in two weeks, with evening elevations to 99.5, but the symptoms of pleurisy continued. On the twelfth day the right side of the chest was tapped and 700 cc of clear, amber fluid was withdrawn, smears of which were negative for tubercle bacilli. The urine at that time showed slight albumin and numerous white blood cells. December 10 he was taken to the local hospital where a roentgenogram showed pleurisy at the right base. Examination of the blood revealed red blood cells 4,250,000, hemoglobin 90 per cent and white blood cells 7,800 with 62 per cent polymorphonuclears and 38 per cent lymphocytes. The headache, chills and anorexia had disappeared although he was still weak and because of the pleurisy with effusion he was admitted for observation to the Maryland Tuberculosis Sanatorium, December 20.

Physical examination revealed signs of pleurisy at the right base i. e. impaired note anteriorly and posteriorly below the third rib and fourth vertebral spine with suppressed breathing. No rales were heard. The only other finding of interest was a moderate dental caries. Roentgenograms of the thorax showed clouding of the right apex with dense clouding from the fourth rib to the base (fig 1). Although there was an old slight fibrosis above the first rib on the left, there was nothing in the visible parenchyma that could be interpreted as an active tuberculosis. The urine contained white blood cells ++ and no albumin. After several weeks of bed rest it was noticed that the temperature, while remaining normal for periods of about six days, would rise on the evening of the sixth or seventh day to 100 or 101 returning to normal on the following day (fig 2). The sputum was negative for tubercle bacilli on nine examinations, Kahn and Kolmer tests for syphilis were negative. Because of the persistently negative sputums and the peculiar temperature curve,

Fig 1—Tularemic pleural effusion one month after onset. *Bacterium tularense* was recovered from the pleural fluid two and one half months later.

From the Maryland Tuberculosis Sanatorium.

The authors are indebted to Drs. Edward Francis, A. T. Brice and Elizabeth R. Wilkins for their assistance in preparing this paper and to the Bureau of Bacteriology of the Maryland State Department of Health which isolated the organism.

⁵ Personal communication to the authors.

it was thought advisable to do agglutination tests on the blood, and Feb 25, 1936 (three months after onset), the serum showed positive agglutination for *Bacterium tularensis* in dilutions of 1:320 with no cross agglutination for *Brucella melitensis*. The history of handling a rabbit was first elicited at this time. Further blood studies showed hemoglobin 79 per cent (Sahli), red blood cells 4,000,000, white blood cells 8,200 with 47 per cent polymorphonuclears, 2 per cent eosinophils, 2 per cent basophils, 16 per cent monocytes, 32 per cent lymphocytes and 1 per cent unclassified. Platelets were normal with some macrocytosis and pallor of the red blood cells. There was an unusually rapid blood sedimentation rate 27 mm in one hour. Mantoux tests were performed with purified protein derivative. No reaction occurred with the first strength (0.00002 mg) but there was a strong reaction to the second strength (0.005 mg).

March 3 (three and one-half months after onset) a third roentgenogram having revealed the pleurisy slightly more dense the right side of the chest was tapped posteriorly and 300 cc of a slightly cloudy yellowish brown fluid was aspirated which formed a heavy coagulum inside of half an hour. The specific gravity of this fluid was 1.026. It contained 5,575 white blood cells and an equal number of red blood cells (probably from operative trauma). A differential count on the white blood cells gave 96 per cent lymphocytes, mostly large, and 4 per cent polymorphonuclears. Gram and acid-fast stains on centrifuged specimens revealed no bacteria. The pleural fluid strongly agglutinated *Bacterium tularensis* in dilutions of 1:640 even higher than the blood serum. Some of the exudate was inoculated into guinea pigs from which *Bacterium tularensis* was isolated in twelve days. A subculture was sent to Dr. Francis in Washington, D. C. who confirmed the organism. No guinea-pigs were inoculated for tubercle bacilli.

Four days later another attempt was made to secure pleural fluid. This time, however, aspiration was difficult; the needle frequently clogged and only 50 cc could be secured for culture and, unfortunately, that tube was broken before reaching the laboratory. Aspiration was tried for the third time March 24 but no fluid was obtained.

The treatment up to the time of aspiration had been palliative with bed rest and washroom privileges. The only symptom, weakness, which the patient had had on admission to the sanatorium had gradually disappeared. After aspiration of the pleural fluid the temperature, which up to that time had continued to evidence rises at intervals of six or seven days, dropped to normal and showed no more of this peculiarity. There was a single rise to 100 F the afternoon of the last aspiration since then it has not gone above 99 F. He gained 23 pounds (10.4 Kg).

The pleurisy appeared slightly less dense in a roentgenogram taken March 21. Blood studies done a few days later were

Fig 2—Tularemic pleural effusion. Periodic rises in temperature during the chronic stages of the illness.

comparable to those of the previous month. Red blood cells were 4,320,000, hemoglobin 83 per cent and white blood cells 6,800 with polymorphonuclears 54 per cent, eosinophils 4 per cent, basophils 1 per cent, monocytes 11 per cent and lymphocytes 28 per cent unclassified, 2 per cent. The blood sedimentation rate continued to be rapid at 24 mm in one hour.

Four and one-half months from onset the blood serum titer for *Bacterium tularensis* had risen to positive in 1:2,560, doubtful to 1:5,120. Never has it or the pleural fluid shown any cross agglutination for undulant fever. The urine returned to normal. In the final x-ray film (fig 3) there were still residual pleuritic shadows at the right base but these were less dense than previously. He was discharged April 12 as greatly improved to continue rest at home.

COMMENT

Clinical and roentgenologic evidence in this case resemble closely the appearance of the usual tuberculous pleurisy. Only after numerous negative sputum examinations was the blood serum examined and found to agglutinate *Bacterium tularensis*. Of course there was the typical history but without ulceroglandular or glandular involvement. Neither the patient nor the physicians thought of this until after the results of the agglutination tests were known.

Fig 3—Tularemic pleural effusion four and one-half months after onset. The pleural fluid has absorbed leaving residual clouding.

With the history of the positive agglutination of the blood and pleural fluid and the isolation of the organism from the pleural fluid it can be definitely said that the pleurisy was the result of infection by *Bacterium tularensis*. Unfortunately guinea-pigs were not inoculated with the pleural fluid for tuberculosis but the negative sputum

the inability to stain tubercle bacilli in the centrifuged pleural fluid and absence of any definite parenchymal lesion in the x-ray film support the belief that we are here dealing with a manifestation of tularemia alone.

When in cases of pleural effusion the organism, either the tubercle bacillus or *Bacterium tularensis*, can not be isolated by culture or inoculation although the blood and the pleural effusion agglutinate for tularemia, is it safe to make a diagnosis of the latter disease? In the ulceroglandular, glandular or oculo-glandular case it probably is, but in the typhoidal type let it be remembered that agglutinins for tularemia have been shown to remain present in the blood serum for years and it is quite possible to have a tuberculous effusion develop in a patient who has a blood serum with positive agglutination to a tularemic infection incurred months or years before. Until we can discover better clinical or roentgenologic means of differentiating tuberculous pleurisy and tularemia with pleural effusion the isolation of the organism remains the deciding criterion for diagnosis during life in the typhoidal type of case.

The clinical, laboratory and x-ray examinations on this patient agree essentially with those reported in similar cases with some slight differences. For two and one-half months following the subsidence of the acute symptoms the case had a peculiar febrile course during which there would be normal temperature for a period of six or seven days followed by a sharp evening rise to 100 or 101 F, falling again the following day. Others have reported relatively low pulse rates in cases of tularemic pleural effusion. It is not known whether this was so in this patient during the first three weeks but the pulse was not relatively slow in the succeeding months at the sanatorium. Blackford reported normal leukocyte counts in his three cases. While this patient had total white blood cell counts within normal limit the differential counts showed a slightly increased percentage of lymphocytes and monocytes and a decrease of polymorphonuclears in the chronic stages. In cases of tuberculosis this blood picture, according to Medard

would indicate resistance with some hyperplasia. Of particular interest was the blood sedimentation rate which on three occasions during residence dropped 27, 27 and 24 mm in one hour. The tularemic pleural effusion on examination had the usual characteristics of a tuberculous effusion.

During the chronic stages of the disease improvement in the patient's condition seemed to take place immediately after aspiration of some of the pleural fluid and was manifested by disappearance of the peculiar temperature and of the remaining symptom weakness. Parallel with the improvement in the patient was a sharp rise in the agglutinating titer of the blood serum.

A RAPID CULTURAL METHOD FOR THE DIAGNOSIS OF TINEA INFECTIONS

FRANZ L. BLUMENTHAL, M.D.

AND

JAMES S. SNOW, M.D.

Research Professor of Dermatology and Syphilology and Instructor in Dermatology and Syphilology, respectively, University of Michigan Medical School

ANN ARBOR, MICH.

The dermatomycoses can usually be diagnosed by the clinical picture or the effect of therapy. It is desirable, however, to verify the clinical diagnosis by bacteriologic and specific biologic examinations. In this paper we shall deal only with the bacteriologic aids in diagnosis. There are two methods in general use, first the direct examination with the microscope after macerating the material with sodium or potassium hydroxide, and, second, the culture on Sabouraud's or other special agar mediums. The first is frequently inadequate and the second requires at least a week before a growth appears. For diagnostic work a more rapid cultural method would be very desirable.

For several years one of us (F. L. B.) had used a simple method employing a liquid medium of similar composition to Sabouraud's but without the agar. This consisted of placing the suspected material on an ordinary slide adding a few drops of the medium and covering this with a cover slip which was then surrounded by wax to prevent drying. The fact that this produced a relatively anaerobic condition was of no importance as it had been demonstrated¹ that the growth of mycelia was not hindered by anaerobic conditions. Grutz² found this method useful in studying sporotrichosis. Later we employed a hanging drop slide similar to that used recently by Hruszek³ for the microscopic study of mycelial colonies. Davidson and Gregory⁴ have also used a similar *in situ* preparation and emphasize the importance of microscopic study in classifying the dermatophytes.

METHODS

We have compared the results obtained with the hanging drop or *in situ* culture method in ninety cases with those obtained by the direct microscopic exami-

nation and culture on Sabouraud's original medium. These cases have all been followed for a sufficient period of time to establish the final diagnosis. The clinical material included forty-eight cases of tinea among which there were (1) seven cases of tinea of the scalp or beard, four of which were of kerion type, (2) ten cases of tinea of the glabrous skin, (3) four cases with involvement of the groin or axillae, (4) twelve cases of tinea of the hands which were eczematoid or pustular in character, (5) six cases of tinea of the feet, which were of an eczematoid or intertriginous nature and (6) nine cases of onychomycosis.

Forty-two cases of conditions other than tinea were used as controls. These consisted of (1) six scalp cases such as alopecia areata, syphilis vulgaris, seborrhea and pyoderma, (2) fourteen cases of generalized eruptions of the smooth skin including seborrheic dermatitis, contact dermatitis, atopic eczema, psoriasis and stasis dermatitis, (3) four cases of seborrheic dermatitis of the axillae or groin, (4) seven cases of contact dermatitis of the hands and nine scrapings from the palms of normal individuals, and (5) two cases with dystrophy of the nails secondary to contact dermatitis.

The lesions were first cleansed and scrapings were carefully taken with a sterile scalpel. These were usually selected from the periphery of flat lesions, from the under surface of pustules, or if hairs were being

Fig. 1—Eighteen hour culture showing early growth from scale of patient with tinea corporis.

examined broken off ones were used. First a fresh preparation was made by placing a portion of the material in a drop of 20 per cent potassium hydroxide in the usual manner. This was warmed gently, allowed to stand for thirty minutes and then examined microscopically. Second Sabouraud's agar⁵ slant was inoculated kept at room temperature and observed daily for a month. Third a hanging drop preparation was made, using a liquid medium of the following formula: crude maltose of Chanut 4 Gm., peptone of Chassaign 1 Gm. and distilled water to make 100 cc.

A deep hanging drop slide was washed thoroughly, allowed to dry and flamed. Cover slips were kept in an alcohol-ether solution and were dried by being put in the flame. With a sterile loop a small drop of medium

was then carefully placed in the center of the upturned cover slip, scrapings or hairs were added and the cover slip was quickly turned over and put in place on the slide. If only a small amount of medium was used

Fig. 2—Twenty four hour growth

it would remain suspended in the center of the ring and not run around the margin. The cover slip was then sealed in place with melted paraffin applied to the edges with a heated knife blade. The preparation was incubated at room temperature and examined twice a day with the microscope.

RESULTS

The accompanying table shows a summary of the comparative results obtained by the three methods of mycologic diagnosis for each of the lesions studied. In forty-eight cases of tinea infection mycelial filaments or spores were demonstrated in sixteen cases by the direct microscopic examination. On Sabouraud's agar medium a definite growth was obtained in thirty-one cases in an average time of 6.1 days. With the in situ

medium in an average time of 3.4 days and in five cases in the hanging drop in an average time of 1.5 days.

In the cases of tinea infection the two cultural methods agreed in all except four cases while in the other conditions positive growths occurred with only one method in each individual case and most of these could be readily identified as a common fungus such as the mucor or aspergillus.

COMMENT

The direct microscopic examination was found to be satisfactory for the diagnosis of tinea infections of the scalp and beard if the hairs were selected with care. In the preparations from other areas however the chance of finding mycelia was less and mistakes may

Fig. 3—Two day old culture

be made owing to the presence of so-called monie structures and other artefacts. In every case it is desirable to have a culture of the micro organism to establish the diagnosis.

Results Obtained by Three Methods of Mycologic Diagnosis

Final Clinical Diagnosis	Number of Cases	I		II				III			
		Direct Microscopic Examination (20% Potassium Hydroxide)		Sabouraud's Agar Medium				Hanging Drop Preparation

culture mycelial growth was demonstrable in thirty-five cases in an average time of 1.8 days. In at least half of these it was clearly visible in twenty-four hours with the aid of the microscope. The growth usually occurred from a number of different points and this fact is of value in distinguishing a false positive due to chance contamination.

Of the forty-two control cases of other conditions none showed mycelia by the direct procedure. Mycelial growth occurred in six cases on Sabouraud's agar

The in situ culture method has permitted microscopic examination of the hyphae and in those cases in which spores developed these could also be studied in their natural growing relationship. No attempt has been made in this study to classify the organism found as we were interested here primarily in developing a cultural method suitable for early diagnosis. If exact classification is desired culture on Sabouraud or other special agar mediums will be necessary. Recently we have found it a convenient workman-

to prepare two hanging drop cultures from each case when first seen. If these showed growth one was then inoculated on Sabouraud's agar medium for further study.

A relatively small percentage of positive cultures was obtained from the control groups of cases. This was contrary to the observations of Bloch⁵ and of Benham and Hopkins⁶ who reported the finding of fungi on the skin of the majority of normal individuals examined. Perhaps the difference may be explained by the fact that we cleansed the skin thoroughly with soap and water before taking the scrapings.

The final clinical diagnosis was open to question in a few cases, especially those of the pustular lesions of the hands. Some of these may have been trichophytids and others bacterial infections.

SUMMARY

1 Of the forty-eight cases of tinea infection studied direct microscopic examination demonstrated mycelial filaments or spores in 33 per cent.

2 Culture of Sabouraud's agar medium gave a positive growth in 64 per cent of the cases in an average time of 61 days.

3 The hanging drop culture method described in this paper showed a positive growth in 72 per cent of the cases in an average time of 18 days.

Fig 4—Four day old culture of a hair

4 The hanging drop culture was found to be the most useful laboratory aid in the diagnosis of tinea infections, not only because it is dependable but also because it is simple, inexpensive and requires a very short time to demonstrate growth of the organisms.

The First Accurate Description of the Pelvis—We are indebted to Andreas Vesalius (1543) for the first accurate description of the pelvis. Prior to the publication of his observations it had generally been believed that the birth of the child could not be effected until the pelvic cavity had become increased in size by the separation and gaping of the pelvic bones. Vesalius demonstrated the fallacy of this conception and showed that the pelvis for practical purposes should be considered as an unyielding bony ring.—Stander H J Williams Obstetrics New York D Appleton-Century Company 1936 page 1

DIAGNOSIS OF UNDULANT FEVER

THE OPSONOCYTOPHAGIC, ALLERGIC AND AGGLUTINATION REACTIONS

ALVIN E KELLER, M.D.

CRIT PHARRIS, M.D.

AND

W. H. GAUB, C.P.H.

NASHVILLE, TENN.

The diagnosis of *Brucella* infections in man has usually been confirmed by a positive agglutination test or a positive blood culture. The agglutination reaction is of especial value, usually during the febrile stage of the disease, and for varying periods after the temperature has become normal. There may be marked variations in both the regularity and the titer of this reaction. A positive agglutination reaction is of great significance, but a negative reaction cannot be relied on particularly in this disease. A positive blood culture is diagnostic of undulant fever but there are certain difficulties which have not been overcome by the average laboratory in obtaining growth of the organism so that at the present time only a small percentage of cases are diagnosed by this method.

The allergic skin reaction is considered to be a dependable test to determine whether or not an individual is or has been infected with *Brucella*. It may be used in active cases or as an epidemiologic procedure in population groups to determine the incidence of infection. Although infected persons can be detected by the skin test, it does not give any information as to whether the infection is active or whether the individual is immune. The symptoms that the patient shows may be due to some other cause and a positive skin test may be an incidental observation.

In 1933 Huddleson, Johnson and Hamann¹ reported the results of their studies on the opsonocytaphagic activity of the blood and the allergic skin reaction in brucellosis. They stated that in vitro the phagocytosis of *Brucella* by the polymorphonuclear leukocytes in whole citrated blood is an expression of immunity to *Brucella* and an indication of the progress toward recovery in active infection. They also stated that a low phagocytic activity in conjunction with a negative allergic skin test is evidence of susceptibility to *Brucella* infection and that a positive allergic skin test in conjunction with a negative or low opsonocytaphagic activity of the blood is evidence of infection with *Brucella* without immunity.

Since *Brucella* infections are being discovered more frequently and are probably present to an appreciable extent as asymptomatic infections, any method that can be used to determine the immunity status of an individual or of a group of persons to undulant fever will help either to confirm the diagnosis or to rule out infection with this group of organisms.

Our purpose in this discussion is not to point out either the sources of infection, modes of transmission or the clinical manifestations of *Brucella* infections but

to evaluate the results obtained by means of the agglutination, allergic and opsonocytophagic tests on certain groups of individuals under varied conditions.

The technics for the skin test and the opsonocytophagic test employed in this investigation were those described by Huddleson, Johnson and Hamann. The material used for the skin test was supplied by Dr. I. Forest Huddleson and was the same that he employed

infiltration following the injection which should be interpreted as a nonspecific reaction. In certain individuals who are markedly hypersensitive to the Brucella protein, the positive skin reaction may be associated with fever, general malaise and chilly sensations, symptoms of which the patient described as being similar to those which were present when he had active clinical manifestations of the disease.

Various degrees of phagocytosis of Brucella. A marked B moderate C slight D negative

in his own work. This material consists of a soluble nucleoprotein fraction of the three species of Brucella in 1:1000 dilution in slightly alkaline physiologic solution of sodium chloride. In the performance of the test, 0.1 cc. of the solution is injected intracutaneously. The allergic test should be read forty-eight hours after the injection is made in order to allow nonspecific or pseudopositive reactions to subside.

A positive skin reaction depends on the occurrence of edema of varying degree at the site of injection. There is usually erythema associated with the swelling, but erythema without edema should not be considered as a positive reaction. There may be a small area of

It was found by Huddleson and his associates that in the blood of normal individuals the polymorphonuclear leukocytes showed phagocytic activity. These investigators also found that by the addition of sodium citrate in varied amounts to whole blood phagocytosis could be inhibited, retarded or unaffected and that a concentration of sodium citrate of 0.8 per cent is satisfactory for differentiating the phagocytic activity of individuals who may be susceptible to infection with Brucella.

In the performance of the opsonocytophagic test the bacterial suspension should be fresh and contain a sufficient number of organisms. In our experience a con-

centration of not less than six billion *Brucella* per cubic centimeter is necessary. Owing to the small size of *Brucella* organisms it is necessary to differentiate between the normal granulations found in polymorphonuclear leukocytes and the phagocytized bacteria. The strain of *Brucella* used for our suspensions was

The term "opsonocytophagic" was used by Glynn and Cox² in 1910 to indicate the phagocytic activity of blood in the presence of serum opsonins and homologous leukocytes. To perform the opsonocytophagic test, 5 cc of venous blood is obtained. This is placed in a tube containing 0.2 cc of 20 per cent sodium citrate in physiologic solution of sodium chloride. The final dilution of sodium citrate is 0.8 per cent, which according to Huddleson, Johnson and Hamann has two purposes—to prevent clotting of the blood and to inhibit the *Brucella* opsonins, which may be present in the serum of normal individuals. The test consists of mixing 0.1 cc of the patient's citrated blood with an equal quantity of a live twenty-four hour saline suspension of *Brucella* organisms. This mixture is shaken and then incubated at 37 C for thirty minutes, after which the tube is shaken again and a small amount of

the mixture withdrawn and placed on a clean slide. A smear is made and stained with Hasting's blood stain. Twenty-five polymorphonuclear neutrophilic leukocytes are then examined and the degree of phagocytosis is recorded for each cell according to the classification given in table 1.

In uninfected or normal individuals it is not unusual to find some of the polymorphonuclear neutrophils showing slight phagocytosis. As many as ten or fifteen of the twenty-five cells examined may show this degree of phagocytosis and there also may be an occasional cell showing a moderate or marked degree of phagocytosis. The accompanying illustration shows photomicrographs of polymorphonuclear neutrophilic leukocytes with slight, moderate and marked phagocytosis, and also cells without phagocytosis.

To determine the status of individuals with regard to infection with *Brucella*, Huddleson has proposed the system given in table 2.

The present investigation was conducted to determine the accuracy and specificity of these tests under certain conditions, namely, (1) in patients in the active stage or who have recovered from undulant fever, (2) in individuals exposed either through drinking infected cow's milk or through routine laboratory work, and (3) in patients with other diseases. In the first group there were four patients, two of whom were considered to be in the active stage of the disease or in the stage of recovery. The other two patients had been afebrile from six to fifteen months before the tests were conducted. The second group consists of twenty-nine patients with positive skin tests among a group of 576 persons. Of this number 560 were in an institution in Tennessee which, owing to a breakdown in the pasteurization plant, were served raw milk for approximately one month. This milk was obtained from a herd of 127 cows, of which 44 per cent were found to have positive agglutination tests for Bang's disease. The

remaining sixteen in this group were technicians performing routine laboratory procedures. The third group consists of forty-four patients with other diseases in the wards of the Vanderbilt University Hospital. A skin test, an opsonocytophagic reaction and an agglutination test were performed on each individual in these three groups.

² Glynn, E. E. and Cox, G. L. Variations in the Inherent Phagocytic Power of Leukocytes. *J. Path. & Bact.* 14: 90-131, 1910.

Table 3 shows the results in patients who had either recovered from undulant fever or who were showing symptoms. The results indicated in the table are those obtained at the time the tests were performed. In patient 1 the diagnosis of undulant fever was based on a positive agglutination test (1:640) four months previously. In patient 2 the agglutination test was positive (1:640) fifteen months before the present tests. The diagnosis in patient 3 was based on a positive agglutination test (1:80) and suggestive clinical history. It was afterward found that this patient had a positive skin test and an opsonocytophagic test which showed marked phagocytosis in 60 per cent of the polymorphonuclear leukocytes examined. The diagnosis in patient 4 was based on a history of recurring attacks of

at the same time at which the other tests were done, showed titers varying from 1:20 to 1:160 in three of the four patients.

In the second group examined there were 576 individuals who were not ill but who were living or working under conditions favorable for infection with *Brucella*. In 547 persons in this group the agglutination reactions and skin tests were negative. All the opsonocytophagic tests in these 547 persons showed phagocytosis in no greater degree than would be found in the blood of normal or uninfected individuals.

In the remaining twenty-nine persons in this group positive skin tests were found. In all skin tests the area of edema was measured in two diameters at right angles to each other. The skin reactions varied in size

fever over a period of seventeen months. A diagnosis of undulant fever was made by her physician.

It will be seen from this table that all the patients who had had undulant fever or who were in the active stage of the disease exhibited positive skin tests. Following the skin test, two of the four patients (1 and 4) developed constitutional symptoms, such as increase in temperature, chilly sensations and general malaise. In three of these patients (1, 2 and 3) 60 per cent or more of the twenty-five polymorphonuclear leukocytes examined showed marked phagocytosis, which would indicate immunity. There has been no recurrence of symptoms in any of these patients since recovery from the original attack, except in patient 4, and in this instance the opsonocytophagic picture was indicative of an active infection. This patient was having an exacerbation of undulant fever at the time the tests were made and had been ill periodically for approximately seventeen months. The agglutination reactions performed

from 24 to 36 cm in one diameter and from 36 to 98 cm in the other diameter. Following the skin test four persons developed a marked systemic reaction and two developed a moderate systemic reaction. All these skin reactions cleared up rapidly and in no instance was ulceration noted. Twenty-seven of the twenty-nine individuals in this group were retested and in each case the results of the opsonocytophagic, skin and agglutination reactions were in agreement with the original tests.

In three of the twenty-nine persons with positive skin tests the agglutination titers varied from 1:20 to 1:160.

The results of the opsonocytophagic tests according to the interpretation of Huddleson et al. showed that in ten of the twenty-nine patients 60 per cent or more of the polymorphonuclear leukocytes examined showed marked phagocytosis, indicating immunity to *Brucella*. Of the remaining patients in this group twelve had opsonocytophagic tests in which a majority of the leukocytes examined showed phagocytosis of varying

degrees, which would indicate either infection or a developing immunity to *Brucella*. The seven other patients in this group had opsonocytophagic tests in which no phagocytosis could be seen in a majority of the polymorphonuclear leukocytes examined, indicating infection but no immunity to *Brucella*. Table 4 shows the results of these tests.

To determine the specificity of these tests, forty-four patients suffering from a wide variety of diseases were tested in a similar manner as the individuals in the other groups. Most of the patients in this group were febrile at the time of testing. Table 5 shows the results.

There was a complete correlation in the results of the three tests in forty-two of the forty-four patients tested in this group. In forty-one of these patients the three tests were negative. Patient 1 was admitted to the hospital with a questionable diagnosis of bronchopneumonia. The pulmonary signs cleared up but fever persisted. The *Brucella* skin test was found to be positive, after which positive agglutination and opsonocytophagic tests were obtained. This patient made an uneventful recovery. Four weeks after she was discharged from the hospital another agglutination reaction in a titer of 1:160 was obtained. The opsonocytophagic test was also repeated and all the polymorphonuclear leukocytes examined showed marked phagocytosis.

In two patients in this group the agglutination reactions showed titers of 1:20 and 1:40, which were not considered diagnostically significant. One of the patients (1:40) had pellagra and had been having fever of undetermined origin for several weeks. The other patient was afebrile and had had bronchitis. These observations may have been accidental or the agglutination reactions may have resulted from infection with *Brucella*, in which case there was no complete agreement of the various tests. In these two cases the skin tests were negative.

COMMENT

The data presented agree with those reported by Huddleson and his associates for individuals who are either in the active stage of undulant fever or who have recovered from *Brucella* infections and in persons who are living or working under conditions of exposure to this group of organisms.

The results of the intracutaneous and the opsonocytophagic tests in a group of forty-four patients with a wide variety of febrile and nonfebrile conditions indicate that the tests are probably specific for *Brucella* infections. In one patient in this series a diagnosis of undulant fever was made by means of these tests. In all but two patients, who had agglutination titers of 1:20 and 1:40, these tests were negative.

In evaluating the three tests as to their usefulness in the diagnosis of undulant fever, the results obtained indicate that the agglutination test is most dependable in patients who are in the active stage of the disease or who have recently recovered. In individuals who have been infected with *Brucella* the agglutination test may or may not be positive. Under these conditions results obtained from the examination of serums from groups of individuals to determine the incidence of undulant fever would not be reliable. It is also possible that in patients suffering from other diseases a low titer agglutination may be obtained which may be suggestive of infection with *Brucella* but which is not diagnostically significant.

The intracutaneous test is probably the most dependable procedure in determining an allergic state resulting

from *Brucella* infection. It was positive in each of the four patients with undulant fever and in twenty-nine, or 5 per cent, of 576 persons living or working under conditions favorable to infection with *Brucella*, while only one of the forty-four patients diagnosed originally as having conditions other than undulant fever showed a positive skin test. The intracutaneous test indicates a state of allergy resulting from infection with *Brucella* and may be used as an epidemiologic procedure to determine the incidence of *Brucella* infection. A positive skin test may indicate infection or may be found in an individual who has been infected but who has developed an immunity to *Brucella*.

To determine the immunity status of individuals, the opsonocytophagic test may be employed in conjunction with the intracutaneous test. The absence of marked phagocytic activity of the polymorphonuclear leukocytes in a patient with a positive skin test indicates infection and a lack of immunity. The presence of marked phagocytic activity would indicate either a developing or an established immunity. If marked phagocytic activity and a positive skin test are demonstrated in a patient with fever, it is likely that the fever is due to some disease other than undulant fever. These tests, therefore, may be used as valuable aids in differential diagnosis.

CONCLUSIONS

The results of these observations indicate that the intracutaneous test may be used to determine a state of allergy resulting from *Brucella* infection. This test alone may be useful in determining the presence of infection with *Brucella* in individual patients or the incidence of this infection in groups of the population. However, it gives no indication of the immunity status of the patient. This may be determined by means of the opsonocytophagic test. It is possible with the use of these two tests to determine whether individuals are susceptible, infected or immune with regard to undulant fever.

This discussion presents our experience up to the present time with these procedures. Further studies are planned in order to confirm the observations represented in the data covered in this paper.

ABSTRACT OF DISCUSSION

DR W S LEATHERS, Nashville, Tenn. The prevalence of undulant fever in the United States is of importance especially from the standpoint of the usually prolonged attack and the marked debilitating effect on the patient. This disease is not at present a major public health problem as related to the human being, although it is exceedingly important from a medical as well as from a preventive point of view. The average duration of an attack of undulant fever is about four months. However, there may be several recrudescences. The fever may recur at long intervals over a period from one to two years. Only 2 to 3 per cent of the patients die. It is also of interest to note that it occurs much more frequently among males than among females. The ratio is about two to one. The principal reason why undulant fever is not more prevalent is the low infectivity or degree of susceptibility of the population. Obviously an immunity has been established as a result of individuals obtaining small doses of infection chiefly through milk. Moreover, the strain *Brucella* probably does not multiply in milk, therefore if the milk from one cow is infected and is mixed with a large quantity of milk for distribution to a community the dosage becomes diluted and as a consequence serves only to stimulate immunity in the individual who drinks the milk. Dr Keller and his associates have presented a discussion with particular reference to the accuracy and specificity of the agglutination, allergic and opsonocytophagic reactions as procedures which may be effectively applied in differential diagnosis and in the epidemiologic study of this disease in the

individual and in groups of the population. The agglutination reaction is of particular value in the diagnosis of undulant fever in the acute stage. Although the blood culture is also of great importance as a confirmatory procedure, the agglutination reaction cannot be used to determine the incidence of infection in groups of the population, owing to difficulties involved in culturing the organism. It is, however, of much value in locating the infection among cows. It has also been pointed out that this test cannot be used to determine the immunity status of the individual. The allergic reaction, or skin test, is of particular importance to determine this infection in an individual, in the study of immunity and especially in clearing up obscure cases of the disease. The opsonocytophagic reaction is conclusive in determining the immunity status of a person. The degree of immunity in an individual may be indicated roughly by the number of phagocytized bacteria by the polymorphonuclear leukocytes. The authors have shown the relative clinical and public health value of these tests, and the facts presented apparently confirm the work that has been done by Huddleson and his associates. It has been shown in this investigation that the allergic reaction of undulant fever does not occur in other diseases, therefore this fact makes this test more valuable as a diagnostic procedure.

DR. J. N. BAKER, Montgomery, Ala. The diagnosis of undulant fever is often most difficult. In many cases the symptomatology either is indefinite or may resemble that of other diseases. Recently in Montgomery there was a series of cases in which the chief complaint was a severe pain in the lower right quadrant. Before the true nature of the disease was recognized, surgical intervention was practiced in one case (appendix operation). More careful and extended examination revealed that all the patients were suffering from undulant fever. The agglutination test, because of its ease in performance and its specificity, has been the reaction of choice in most laboratories. Here the matter of technic, which involves the choice of strain to be used, the preparation of the antigen, the time of incubation and other details, are of extreme importance. The question of the proper titer to be obtained before a positive diagnosis can be made is a perplexing one. Some workers think that any case showing a titer of 1:80 or above should be considered positive, while others assert that titers of less than 1:500 have little or no significance. On the other hand, by cultural methods it has been shown that certain patients may have the disease and yet never exhibit a titer over 1:15 or 1:30, furthermore, when the results of any agglutination test are considered, the question of past or present infection becomes paramount. Carpenter and Boak (1930) are of the opinion that the agglutinins usually remain for a long time, hence, in the interpretation of positive agglutination reports, the persistence of reacting bodies from a previous infection must always be considered. The blood culture method, besides its inherent technical difficulties, takes too long for an ordinary diagnostic or public health procedure. The same criticism applies to the culture of urine and feces from suspected patients. The intracutaneous test has been used with success by Giordano (1929) and others. In 1934 Huddleson reported a more refined antigen designed to eliminate a certain percentage of the nonspecific reactions, nevertheless, if the test is to be used alone, the following statement of Keller and his colleagues must be borne in mind. The intracutaneous test indicates a state of allergy resulting from infection with *Brucella*. A positive skin test may indicate infection or may be found in an individual who has been infected but who has developed an immunity to *Brucella*. In 1933 Huddleson and his associates developed the opsonocytophagic test, which is really a modification of the old opsonic index test. They recommended its use in conjunction with the skin reaction and stated that valuable information as to the status of the patient could be obtained if the results were properly interpreted. Also the agglutination test was employed. The results of Keller and his associates corroborated those of Huddleson and his co-workers. They indicate the specificity of the combined tests, intracutaneous and opsonocytophagic in individuals who have or have had undulant fever and the lack of response in those who have other febrile conditions.

DR. JOHN B. YOLMANS, Nashville, Tenn. These procedures have been a great help in our clinic since they were introduced there by Dr. Keller. In the past we have felt that some cases

of undulant fever were being missed because of the unreliability of the agglutination test, which sometimes has been negative even in the presence of positive cultures. We have been particularly concerned about mild or chronic cases with positive agglutination tests of such low titer that their significance was questionable. With these newer procedures we have been able to use the skin test extensively as a screen, quickly detecting those with evidence of the disease, past or present, and determining the presence of active disease by means of the opsonocytophagic test. By this means the use of the more difficult cytophagic test may be confined to those cases in which there is a likelihood of active infection. I would, however, stress the danger of mistaking a pseudoreaction for a positive skin test. We have had a number of patients with sharp local reactions in twenty-four hours which had cleared completely on the second day. The true reaction is present, even maximum, in forty-eight hours, and unless precautions are taken to follow this criterion, many mistakes will be made. This is the more important because the skin test is the crucial test in distinguishing between noninfected (susceptible) and the infected (nonimmune) groups. In using the combined results of the agglutination, skin and opsonocytophagic tests in individual cases, it must be appreciated that the criteria are not absolute and that borderline stages between susceptible and infected, and between infected and immune, must occur. It is in connection with the former that the skin test is so important. As always, such tests must be interpreted in the light of all the clinical observations, nevertheless, these tests are a great help in the diagnosis of an important but often illusive disease.

THE PARADOXICAL BEHAVIOR OF THE WASSERMANN TEST IN LATENT SYPHILIS

LOUIS CHARGIN, MD

AND

THEODORE ROSENTHAL, MD

NEW YORK

It is well known that, in early syphilis, treatment by any of the modern intensive methods reverses the Wassermann test from positive to negative in a period of about three months in approximately 85 per cent of the cases and that, in the majority of instances, continued treatment by an intensive method insures a continued negative serologic reaction. This behavior of the Wassermann test under treatment in early syphilis is so consistent that it can serve as an experimental criterion of the efficacy of any plan of therapy. By the same token it may be stated that in a given case of syphilis, if the Wassermann test is reversed promptly under therapy and remains negative, the patient is probably suffering from early syphilis. This is so in at least 85 per cent of the cases. This behavior of the Wassermann test, however, does not hold true in the case of latent syphilis. Those experienced in the treatment of large numbers of syphilitic patients are, indeed, well aware of the vacillating character of the Wassermann test in latent syphilis, but the general practitioner is not so informed and is frequently chagrined by the failure of the Wassermann test to exhibit results identical to those observed in early syphilis.

To examine this phase of the subject and to examine the behavior of the Wassermann test in latent syphilis, a series of 500 consecutive case records was studied. By far the majority of these patients was treated by the chronic intermittent type of therapy (Nei'er) which, as is known, includes the use of arsphenamine and mercury or bismuth compounds given alternately in courses. No case was evaluated unless the patient

From the Central Syphilis Clinic, Department of Health, City of New York.

had had at least two years of treatment, most, however, were under treatment and observation for much longer periods, some ten years or more. The amount of treatment that was administered necessarily varied with the time the patients were under care. As is well known, the chronic intermittent method includes short periods of rest between courses of treatment, and accordingly our patients had varying rest periods, but in addition there were many instances of unauthorized absences on the part of the patients. The analysis, so far as the behavior of the Wassermann test is concerned, reveals that the cases fall into three groups:

(a) Those in which the Wassermann test was reversed and remained so during the entire period of treatment and observation.

(b) Those in which the Wassermann test remained persistently and consistently positive (two plus or over), in other words, so-called Wassermann fast cases.

(c) Those in which the Wassermann test fluctuated while under treatment at will from various grades of positive to negative or the reverse without apparent relation to the amount and frequency of treatment or rest periods.

It is this paradoxical behavior of the serologic test in this type of case (c) that forms the particular object of this presentation.

While the last mentioned fact must be known to the syphilologist, it was surprising to note its strikingly high incidence. For this reason alone, it merits wider publicity, particularly among those who treat syphilis only occasionally. It is necessary to emphasize that in this presentation we are concerned chiefly with calling attention to the peculiar and totally unpredictable behavior of the Wassermann test in latent syphilis under treatment or observation.

The serologic tests in all the cases were done in a single laboratory and by a constant technic, and accordingly their evaluation is on the same basis.

SUMMARY OF ANALYSIS

1 In a series of 500 patients with latent syphilis, the Wassermann test was reversed to negative in approximately 10 per cent, remained persistently positive (Wassermann fast) in 23 per cent, and showed a paradoxical behavior in 67 per cent. These patients were treated by the chronic intermittent method (Neisser). It is possible that treatment by the continuous method as outlined by the Cooperative Clinic Group would yield better results, such a study is now in progress.

2 In latent syphilis, while the Wassermann test following treatment is frequently reduced in its positivity or even reversed to negative, almost as frequently it remains uninfluenced by treatment or is found to be of a higher degree of positivity after treatment than before.

3 During rest periods, authorized or unauthorized, the Wassermann test often fluctuates without any apparent reason.

4 In a considerable number of patients the Wassermann test, negative at the beginning of treatment, unexpectedly becomes two plus or over at the end of treatment, this unusual behavior cannot be looked on as a provocative test, since these were syphilitic patients, with many positive Wassermann tests just prior to the paradoxical reversal.

5 Even when large amounts of treatment were given, the Wassermann test fluctuated between negative and positive, almost at will.

6 In a number of patients it was observed that at the outset of a course of treatment the Wassermann

test was positive, remained positive at the completion of the course, and after a rest interval of weeks or months would suddenly become negative.

7 In a number of patients in whom treatment was discontinued, for one reason or another, but subjected to repeated Wassermann tests subsequently, the test again showed paradoxical behavior, progressing from positive to negative unexpectedly.

CONCLUSIONS

1 The behavior of the Wassermann test in latent syphilis under therapy cannot be predicted with any degree of certainty in a given patient.

2 The Wassermann test in latent syphilis is an unreliable guide to therapy.

3 As a corollary, one should treat the patient and not the serologic reaction.

4 The physician should be cognizant of this paradoxical behavior of the Wassermann test in latent syphilis and should utilize this knowledge in discussing treatment and prognosis with the patient.

SCHISTOSOMIASIS

REPORT OF TWO CASES

AMANDA HOFF, M.D.

NEW YORK

Schistosomiasis is usually classified as a tropical disease, but while it is true that the condition is unusual in the United States a case is encountered occasionally. Although the literature on this disease in the United States is scarce, there have undoubtedly been cases occurring in foreigners from the tropics which have been overlooked, owing to lack of specific information.

Briefly, there are three types of schistosomiasis—*Schistosoma mansoni*, *S. haematobium* and *S. japonicum*—which occur in various tropical countries. The infestation takes place through intermediary hosts, various species of fresh water snails which have become infested with the ova from the excreta of patients suffering with the disease. After a stage of development in the snails the infected larvae or cercariae enter the patient by penetration of the skin. The infestation must therefore take place either through the patient's bathing in infested waters or, in rare cases, through the swallowing of the cercariae, which penetrate the mucous membrane. The early symptoms consist of a skin eruption. Later symptoms may arise, varying according to the specific localization of the parasites in the bladder veins (*S. haematobium*) or in the rectal veins (*S. mansoni* and *S. japonicum*). Cystitis or mucosanguineous diarrhea occur at this stage, later the parasites and their ova find their way to the liver and mesentery and may cause a very severe liver cirrhosis, with splenomegaly. The latter, and usually fatal, stage may often be prevented if the diagnosis is made in the early stages of the infestation and treatment immediately instituted.

The presence of schistosomiasis may be especially suspected in cities of both coasts of the United States, where shipping from all parts of the world is the means of importing the disease. As far as is known at present, the snails that serve as specific intermediate hosts for the various schistosomes are not found in the United States. The public health aspects of the disease may therefore safely be ignored in this country,

From the First Medical Division, Bellevue Hospital

as the spread of the malady is impossible where the intermediate host is absent. The importance of the recognition of the disease lies in the fact that the introduction of the specific treatment has resulted in the complete cure of many cases, and that, if untreated, the condition progresses to the stage of liver cirrhosis and various other frequently fatal complications. Cutler¹ reports a case of urinary schistosomiasis in 1926 and reviews the literature up to that time. According to him, twenty-two cases have been reported in the United States up to 1926. In addition to these cases, two *S. japonicum* infestations were reported by Bovard and Cecil.² One of these is the only case reported in the United States in which autopsy studies were included. In Bellevue Hospital the records of the four medical divisions show that there have been but five cases of schistosomiasis since 1913. Most of them were merely incidental manifestations in patients suffering from other conditions. The patients were discharged after a short period of hospitalization. Only two of these cases were treated with antimony and potassium tartrate until found to be egg free, since specific treatment for schistosomiasis was unknown until 1918. There were no deaths or serious complications among them during their hospital stay. All the cases reported in the literature as well as the Bellevue Hospital cases invariably occurred in foreigners of various nationalities who had lived in the United States for a comparatively short while. They include all the varieties of schistosomiasis, depending on the country from which the patient had emigrated.

The diagnosis of schistosomiasis rests mainly on the finding of specific ova in the stools or urine, as the case may be. The symptomatology must be carefully studied and usually provides a clue to the correct diagnosis. Recently, however, diagnosis has been materially aided by the elaboration of specific skin sensitization and complement fixation reactions.³ The antigen for the skin test is derived from the livers of snails infested with schistosome cercariae. A filtered saline extract of the dried powdered livers is sometimes used, the intradermal test is easily made and the reaction consists of an urticarial wheal with pseudopodia and erythematous margins, which usually appears with a half hour.

A delayed type of reaction may also occur in from three to twenty-seven hours. The reaction is a group reaction for all types of schistosomes, as is the case in most of the parasitic skin tests. As there is a high percentage of positive reactions in known cases of schistosomiasis, the test is of great clinical value. The complement fixation test, in which the antigen is made from an alcoholic extract of infected snail livers or of adult schistosomes, has also been used by Fairley,⁴ mainly to determine the true end point of the disease, as the reaction has been found to exist several years after treatment and definitely indicates the presence of living schistosomes.

The prognosis of schistosomiasis varies with the type of infestation. In the haematobium variety the lesions are usually fairly well localized and a fatal outcome is rare. The mansoni and japonicum varieties, however,

as has already been mentioned, progress to liver cirrhosis and usually to a fatal outcome due to hemorrhage from ruptured varices, as in the first case to be reported or to intercurrent infections, such as pneumonia, which are extremely common at this stage.

Up to the introduction of antimony and potassium tartrate for the treatment of schistosomiasis, no effective or specific remedy was available. Among the substances tried had been emetine, calcium chloride, thymol, arsphenamine and innumerable other drugs. None of these were found satisfactory and they have all been discarded. McDonagh first used intravenous antimony for schistosomiasis from 1911 to 1915, but the treatment did not begin to attract wide attention until he and Christopherson in 1918 definitely demonstrated its value.⁵ Antimony and potassium tartrate was the remedy of choice until the introduction of fuadin (neo-antimosan) in 1929-1930. Antimony and potassium tartrate is injected intravenously, usually in a 1 per cent solution. It is often diluted with 60 cc. of physiologic solution of sodium chloride to lessen the irritative effects. A course of twelve injections is usually found sufficient to cause the disappearance of the schistosome ova. The dosage is usually one half 1 and 1½ grains (0.03 to 0.1 Gm.) on alternate days the first week, and 2 grains (0.13 Gm.) thereafter for two further weeks, given on alternate days. Extreme care is necessary during the administration of the drug as leakage into the tissues is apt to cause extensive necrosis. Toxic symptoms that have been noted are cough, nausea, rheumatic pains, vomiting and collapse. Sudden death has occurred from time to time and has been ascribed to the toxic effects of the drug on the heart muscle. The treatment is effective in a large percentage of cases if it is vigorously pursued, and the effect on the ova can be checked by microscopic examination of the stool, when it will be found that they become shriveled and brownish (dead) and finally disappear altogether.⁶

Fuadin,⁶ a trivalent sodium antimony compound, has been recently introduced. It has certain advantages over antimony and potassium tartrate and has been found to be fully as efficacious. The drug may be injected intramuscularly or intravenously, and the total of 40 cc. of a 7 per cent solution is usually administered as follows: first day 15 cc., second 35 cc., third 5 cc., fifth, seventh and ninth 5 cc. each, and eleventh, thirteenth and fifteenth 5 cc. each, a total of 40 cc. None of the toxic symptoms usually encountered in treatment with antimony and potassium tartrate are noted. A slight bradycardia, reduction of pulse by twelve beats at the most has been the only abnormal finding noted. There was only one death in the 2,041 cases reported by Khalil and Betache in 1930. Owing to its ease and safety of administration and the shorter time required for its effect, fuadin should be employed whenever obtainable.⁷

REPORT OF CASES

CASE 1—History.—E. L., a French chief aged 45 a native of Guadeloupe, French West Indies, admitted to the hospital Aug. 7, 1933 complained of swelling of the abdomen of one month's duration.

The past history was negative except for the important fact of his having lived in an area well known as a focus of

schistosomiasis and of his habit of frequent bathing in the fresh water streams of the island. He gave no history of skin irritation nor of any suspicious diarrhea either during his stay in Guadeloupe or after his removal to New York six years before his present illness appeared. He had always been in perfect health except for one attack of grip. There was no history of a venereal infection and he was a moderate but never excessive drinker of rum. His present illness began July 2, when he noted progressive swelling of the abdomen and legs accompanied by weakness and loss of weight. He went to the City Hospital, where a paracentesis was done. This was repeated after five days, and he then left the hospital because of failure to improve and came to Bellevue Hospital.

Examination—Physical examination showed that the patient had apparently lost some weight. There were many dilated vessels and angiomas on the skin. The pupils were equal and reacted. The conjunctivae were pale, and there was some sclerosis of the retinal vessels. There was no general glandular enlargement. The lungs showed some diminished breath sounds and a few crepitant rales at both bases. The heart was displaced upward and to the left but was otherwise normal. The abdomen was rounded and the flanks bulged. A fluid wave and shifting dullness were present. The spleen was felt as a large, firm mass occupying half of the left lateral part of the abdomen. The liver percussed and was felt three finger-breadths below the costal margin. Pitting edema of both lower extremities was present.

Laboratory tests The blood Wassermann reaction was reported anticomplementary. A Kahn test was not done. The first blood count, August 9, showed red blood cells 4,100,000, hemoglobin 80 per cent, white blood cells 6,500 polymorphonuclears 25 per cent, lymphocytes 24, eosinophils 50, basophils 1. The x-ray examination was essentially negative. The temperature was 98 F, pulse 60 respiration rate 18 and blood pressure 108 systolic, 76 diastolic. The urine and sputum were normal. Stool examination, September 1, disclosed the presence of the lateral spined ova of *Schistosoma mansoni*. Proctoscopic examination was negative.

Course—Ascites and edema continued. Paracentesis was performed ten times during his stay in the hospital, the fluid removed varying in amount from 5,500 to 10,000 cc. The course of his illness was mainly afebrile but was marked by several episodes in which the temperature rose to 103 F. This on one occasion was accompanied by swelling and redness of the right leg, which was diagnosed as erysipelas. The attack subsided in four days. The patient vomited a small amount of blood on one occasion but otherwise the symptoms were those of the dyspnea and discomfort attendant on the ascites. Treatment was started September 11. A course of antimony and potassium tartrate was given as follows. One per cent solution was administered intravenously in doses of 0.5, 1, 5, 5 and 5 cc. on alternate days, followed by a final dose of 10 cc., a total of 26.5 cc. On several occasions the administration of antimony and potassium tartrate was followed by a violent attack of coughing, but no other ill effects were noted. At the end of this course of antimony and potassium tartrate the eosinophils were 38 per cent and a secondary anemia of red blood cells 3,700,000, hemoglobin 70 per cent had developed. Stools following this course of treatment showed a few disintegrated ova and the patient was therefore started on a course of fuadin. This was administered intravenously in doses of 1.5, 3.2, 5, 5 and 5 cc., a total of 19.7 cc. No ill effects of any kind were noticed following the administration of fuadin. The eosinophils dropped to 18 per cent and the stools became free and remained free from *S. mansoni* ova. Owing to the ascites, which recurred at increasingly short intervals and necessitated repeated paracenteses it was thought advisable to resort to operative measures in an effort to relieve the condition. Omentopexy and splenectomy were performed, December 28, under spinal anesthesia. However the patient became very lethargic following the operation and finally lapsed into coma and died, December 31.

AUTOPSY REPORT

The primary anatomic diagnosis was atrophic cirrhosis of the liver.

The heart showed some coronary sclerosis and there was some atherosclerosis of the aorta.

The lungs showed congestion and edema, and there was evidence of acute purulent bronchiolitis.

When the abdomen was opened, 500 cc. of serosanguineous fluid was found in the peritoneal cavity. The stomach was dilated and showed hemorrhages and the intestine was distended. There were petechial hemorrhages in the colon. Ruptured esophageal varices were present. Microscopic sections showed infiltration of the mucosa and muscularis, with scattered groups of eosinophils. The subserosa showed interstitial collections of groups of lymphocytes and eosinophils. There was perivascular lymphocytic infiltration.

The kidneys were normal except for a small adenoma of the left kidney.

The left testicle was normal. The right one was absent.

The liver was shrunken and well up under the costal margin and adherent to the diaphragm. It weighed 1,500 Gm. The capsule was thick and dull. The surface was diffusely nodular, the nodules being firm and greenish. They were bounded by pinkish cords of stroma, the whole giving the liver a bright, variegated pink and green color. On section, the liver showed increased resistance to cutting. The cut surface was firm and presented a brownish, diffusely granular appearance. On microscopic section the parenchyma was divided into irregular masses by overgrowth of connective tissue stroma in which were proliferated bile ducts and scattered areas of lymphocytic infiltration. Some masses were lobulated with distinct central veins, others were irregular. The liver cells were hypertrophic. A section about a large branch of the portal vein showed areas of more dense fibrosis in which were deposited remnants of schistosome ova each about the size of a giant cell. There was very little tissue reaction about the ova. In one section there was a granuloma in the wall of the portal vein in which there was a large giant cell containing a well preserved ovum with a definite lateral spine. About this giant cell there was a lymphocytic and eosinophilic reaction. The vasa vasorum were dilated.

The spleen, which had been removed at operation, showed diffuse fibrosis. It showed considerable enlargement. There were several areas of calcification, which on section were a mottled yellowish gray. The section showed marked dilation of the endothelial sinuses. These sinuses were filled with red blood cells and many eosinophils. There were several scattered, moderately large areas of dense fibrosis in which there was evidence of interstitial hemorrhage, in and about which were scattered foreign body giant cells. The reticular stroma was thickened by connective tissue. The lymph follicles were hyperplastic. No schistosome ova were present.

The final diagnosis was schistosomiasis, cirrhosis of the liver, chronic interstitial splenitis with eosinophilia, and chronic interstitial inflammation of the large intestine with eosinophilia.

CASE 2—History—R. R., a Puerto Rican youth, aged 19, was admitted to the hospital June 1, 1934 with an infection of the upper respiratory tract. His past and present history in no way suggested parasitic infestation, except for the fact that he had recently come from Puerto Rico and had frequently bathed in fresh water streams of the island. At no time had he had an attack of diarrhea. His present respiratory condition cleared up rapidly and it was only on stool examination that he was shown to be harboring *Schistosoma mansoni*. The stools showed characteristic *S. mansoni* ova as well as ova of hookworm and *Trichiuris*. The physical examination was entirely negative. The liver and spleen were not enlarged. The urine and Wassermann examinations were negative. The blood count showed hemoglobin 85 per cent, red blood cells 4,200,000, white blood cells 8,200, polymorphonuclears 67 per cent, lymphocytes 20 per cent, monocytes 1 per cent and eosinophils 12 per cent. Except for the eosinophilia there was nothing striking in the blood count.

Treatment—A course of fuadin was begun, starting with 15 cc intravenously, and was continued as in case 1 until 40 cc had been given. The hookworm ova were eliminated by treatment with carbon tetrachloride following the completion of the fuadin course.

Course—The stools became egg free early in the treatment and there were never any unpleasant reactions. The temperature ranged from 97 to 102 F (infection of the respiratory tract). He was discharged, August 10, free from the parasites as well as the infection of the upper respiratory tract. The patient was followed for several months in the gastro-intestinal clinic and remained egg free and in excellent health. He was seen again recently (April 1936) and was in perfect health.

COMMENT

The first case well illustrates the unfortunate end results of either lack of treatment or equally ineffective belated treatment of schistosomiasis. The absence of the usual dysenteric symptoms in this patient evidently caused the condition to be overlooked for many years, for after the initial warning signals the existence of schistosomiasis may be entirely compatible with perfect health until damage to the liver initiates the secondary phase, that of cirrhosis. This patient's symptoms were entirely referable to his cirrhosis; however, the high eosinophilia and of course the finding of schistosome eggs in the stool pointed to the parasitic cause for his disease. Treatment was instituted, although it was realized that the case was a late one and the prognosis extremely unfavorable, but the finding of live schistosome eggs indicated that even greater damage was possible. This additional damage could at least be eliminated by treatment that results in removing the cause of further liver trauma. The use of antimony and potassium tartrate in this case was fairly satisfactory, but the persistence of schistosome eggs and the unpleasant reaction, i. e., severe coughing, that followed its administration on several occasions made fuadin the next choice. The fuadin was administered intravenously without the slightest discomfort or reaction, and the treatment was apparently efficacious, and no schistosome eggs were subsequently found.

The second case in contrast to the first was luckily in a very early stage of parasitic invasion and there were no signs of liver involvement. This case illustrates the comparative ease with which the parasite is eliminated by specific treatment, and there is every reason to believe that this boy will remain egg free and will escape the fatal outcome that occurred in the first case.

Clinical Notes, Suggestions and New Instruments

A METHOD FOR RESTORING THE BODY AFTER AUTOPSY

FLMUS D. PEASLEY, M.D.

Pathologist and Director of the Laboratory, the Truesdale Hospital,
FALL RIVER, MASS.

In the course of modern medicine few things have contributed more materially to progress than postmortem examinations. They have provided physicians and surgeons with knowledge that could have been obtained in no other manner, by the layman, unfortunately, necropsy has been feared not favored. So important have been the results of such investigations that it is essential to make every effort to secure permission for an autopsy from relatives.

Gruesome ideas fostered by hearsay and regrettable pseudo-scientific publications have been largely responsible for the unwillingness of the public to grant authority to make post-mortem examinations even when the benefits to be derived from them are well outlined by the attending physician. The undertaker has often been equally opposed to granting permission. As a mortician he makes it his business to protect his interests. He has objected to the condition of bodies when transferred to him by the pathologist which has been such as to make satisfactory preparation difficult.

The duty and responsibility of preparing the body for viewing by relatives and friends lie with the undertaker. Certainly his professional reputation rests squarely on the results that he is able to achieve. His clients are frequently in the depths of emotional despair; he must fulfil his obligation and restore the body to a semblance of its lifetime appearance.

Although it must be admitted that embalmers who thoroughly understand the principles as well as the technique of embalming, are able to prepare a body regardless of its condition on arriving at their table, many embalmers find themselves at a loss to restore a body properly when routine practices are made impossible by dissections at autopsy.

A well conducted postmortem examination in which the pathologist restores the body to the best of his ability, should be welcomed by the undertaker in preference to beginning work on a body that has not been so examined. The undertaker is justified in opposing autopsies when bodies are returned to him with important arteries carelessly severed or wantonly destroyed. There is no necessity for such lack of care.

Diagram of glass and rubber tubing used by pathologist after autopsy in restoring body for undertaker.

Cooperation between pathologist and undertaker is necessary then if hospitals are to secure the desired permissions and if undertakers are to be able to restore bodies to the required standards after an autopsy has been performed.

In September 1933 this laboratory began experimenting with methods that would rid the undertaker of the greatest of post-mortem cares, that of restoring the circulatory system. Methods of tying off arteries were unsatisfactory. There was always the chance of slipping or failure to tie a vessel. Contemporary with our efforts, Williams and Henderson¹ of the Taunton State Hospital began the use of glass cannulas in the aorta from which rubber tubes were passed to the surface through the stitching of the restored body. This method offered the embalmer a direct entrance to the arterial system and enabled him to complete his work in a shorter period of time and with a maximum of certainty of results.

Our experiments on the restoration of bodies after autopsy established a technique which has been highly satisfactory. For some time an attempt was made to preserve the arch of the aorta ligating it proximal and distal to the origins of the innominate, the left common carotid and the left subclavian arteries. By leaving this segment of the arch circulation to the head and both upper extremities could theoretically be established by embalming in the usual manner into either axillary artery. This procedure however is not practical because of the difficulty encountered in securing leak-proof ligations of the aorta. There is the further disadvantage that the arch of the aorta cannot be examined a procedure which should not be omitted.

The first use of the present method was in October 1933. By dividing from the aorta separately the three great vessels to the upper extremities and head, namely the innominate, the left common carotid and the left subclavian arteries and tying into each a glass cannula of the proper size it became possible by means of glass connecting U tubes and rubber tubing to establish access to these arteries by a single rubber tube extending through the incision of the restored body. The vessels

¹ Williams, H. W. and Henderson, D. C. Restoration of A Bodies. *New England J. Med.* 211: 371 (Aug. 23) 1934.

to the lower extremities, namely, the external iliac arteries, were similarly canalized.

In the accompanying illustration *B* shows the two sets of tubing and *A* shows the tubes in place. The glass cannulas are made in the laboratory from glass tubing of varying diameters. Scrap glass tubing furnishes most of the supply. Experience with the method is the best guide to the sizes of tubes required by the exigencies of the case at hand. After insertion into the respective arteries the cannulas are secured by tying them with heavy cotton string. Fine string or twine will invariably cut through the arterial wall. It is customary for the knowledge of the undertaker to tie a simple knot in the tube leading from the head. The internal mammary arteries are also tied.

Should it be necessary to cut the carotid arteries when the neck is examined these can readily be canalized and attached to the tube system by a longer segment of rubber tube, or another U tube can be inserted, thereby making the circulatory system intact again.

After postmortem examination there is relatively little blood left in the body. What remains, however, is allowed to drain into the body cavity by not ligating the veins. This material is easily taken care of by the undertaker's cavity fluid.

The results in the first case were all that could be desired and the undertaker in charge was enthusiastic in his praise of this newer method of restoration. Since October 1933 more than 100 bodies have been so restored. Opposition from the undertaker has been replaced by an agreeable cooperation.

The objection has been raised that this method is expensive and caters unnecessarily to the desires of the undertaker. The expense is approximately 50 cents a body, which does not seem an exorbitant price for the object achieved.

With the undertaker's honest objections to autopsies removed by this method, there still remains one of the greatest problems that of converting physicians to lead the way to obtaining permission for more postmortem examinations by example, that is, by granting permission for autopsies on their own relatives. Until this is accomplished, sincerity is lacking no matter how much the scientific value of autopsies is praised.

THROMBOLYMPHANGITIS OF THORACIC DUCT CASE PRESENTING ABDOMINAL SYMPTOMS NECESSITATING EXPLORATORY LAPAROTOMY

S H POLAYES M.D. BROOKLYN

Thrombolympangitis of the thoracic duct is rare. The current literature contains but little information on this subject and the textbooks contain less. Pappenheimer¹ refers to a total of ten cases in the English, French and German literature up to 1921, adding two cases of his own. Von Glahn,² in a similar review in 1924, describes another case and calls attention to a case reported by Warthin³ and another by DeForest,⁴ both of which, the author states, were omitted from Pappenheimer's collection. The rarity of this condition is again emphasized by Kryloff⁵ and Wurm,⁶ each of whom reports an additional single case. This makes a total of eighteen cases, including the present case report.

The absence of clinical signs and symptoms pointing to the existence of a thrombolympangitis of the thoracic duct has been explained by the previous observers to be due to the deep course of the duct. All agree that it is most difficult to diagnose the condition clinically. That the disease may simulate closely an acute surgical condition in the abdomen has been illustrated in some of the previously reported cases as well as in the present case.

From the Department of Pathology, Cumberland Hospital.

6 Wurm, H. Zur Kasuistik der Entzündungen des Ductus thoracicus. Thrombolympangitis des Halssteils mit Halsvenenthrombose nach hämorrhagischen Lungeninfarkt. Centralbl. f. allg. Path. u. path. Anat. 39: 545 (May 15) 1927.

Regarding the etiology of this acute condition, nothing definite can be stated except that in three of the ten cases collected by Pappenheimer the streptococcus was isolated from the contents of the thoracic duct, which was true in Von Glahn's case and the case reported here. More than three fourths of the cases described occurred in men.

REPORT OF CASE

History—A D., a man, aged 55, a Puerto Rican, admitted to the Cumberland Hospital in the surgical service of Dr. J. E. Jennings (to whom I am indebted for the clinical history), Nov. 6, 1934, at 3 p. m., complained of severe abdominal pain. He had been drinking the night before and at about 4:30 a. m. the day of his admission he was suddenly seized with a sharp pain in the umbilical region. The pain, which was persistent, radiated to the rest of the abdomen and was accompanied by vomiting.

The past history revealed that for the last three months he had been having vague abdominal pains, which were relieved by solution of magnesium citrate. Several years previously he had had an attack of epididymitis and for the last few months he had been having a pink discharge from the urethra.

The family history was irrelevant.

Examination—The patient was acutely ill, suffering from severe colicky pains in the abdomen. The vital signs were as follows: temperature 102° F., pulse 108, and respiration rate 22 per minute. The blood pressure on admission was 94 systolic, 72 diastolic.

Auscultation revealed heart sounds of poor quality and the presence of scattered moist rales over the right upper and left lower lobes of the lung posteriorly. There was also diminution of the breath sounds over these areas. The abdomen was distended and moderately rigid. The point of greatest tenderness was located in the epigastric region. Rebound tenderness and dulness in the flanks were both absent. Rectal examination failed to show any abnormalities.

Analysis of the urine showed an alkaline reaction, pink discoloration, the presence of numerous red blood cells and a trace of albumin.

The blood study showed the presence of 13,800 leukocytes per cubic millimeter, with 88 per cent polymorphonuclear cells and 12 per cent lymphocytes. A repeated study about twelve hours later showed a marked decline of the leukocytes to 5,850, with a rise in the proportion of the polymorphonuclear cells to 94 per cent.

The blood Wassermann test was reported negative on two occasions. The blood sugar was 120 mg. and the urine 18 mg. per hundred cubic centimeters. The blood diastase was 112.

The provisional diagnoses were (1) perforated gastric ulcer and (2) acute pancreatitis.

Clinical Course—Because of the severity of the abdominal symptoms it was decided to perform an exploratory laparotomy. General anesthesia was used. On exploration the only abnormalities discovered were marked congestion of the distal third of the ileum, the presence of old adhesions binding the omentum to loops of the small intestine in the right lower quadrant, and a cystic mass in the pelvis, considered by the operator to be dilated sigmoid.

The patient reacted fairly well but within twenty-four hours after operation his temperature steadily rose to 105° F., accompanied by a chill and increase in the signs of pulmonary consolidation. On the second postoperative day the temperature suddenly dropped to 99° F. and then rapidly rose again to 105.5° F. at which time the patient became cyanotic and comatose and died.

A definite postoperative diagnosis was not made. Influenzal pneumonia with complicating ileitis was considered to be the most probable diagnosis.

POSTMORTEM EXAMINATION

Only the important and pertinent manifestations are described.

General Description—The body was well developed but emaciated. The skin and mucous membranes were definitely cyanotic. The abdominal wall was the seat of a laparotomy wound from which turbid, red-brown fluid escaped as the sutures were removed.

Cavities—Peritoneal. The peritoneal cavity at the site of the incision was markedly congested. Only a small quantity

of serosanguineous exudate was present. The omentum was lightly adherent to the anterior abdominal wall.

Pleural Both cavities contained numerous old adhesions. The right contained in addition about 100 cc. of thin, purulent exudate, encysted at the level of the eighth rib in the mid-axillary line.

Cardiovascular System—The pathologic changes consisted essentially of congestion and cloudy swelling, usually associated with a severe toxemia.

Respiratory System—Bronchi The bronchi showed hyperemia and multiple, minute hemorrhages in the mucosa.

Lungs The lungs showed apical scars and caseous deposits of an old tuberculous process. Inter-alveolar fibrosis was found in the sections of all lobes. The left upper and lower lobes also showed conglomerated areas of consolidation (lobular pneumonia).

Gastro-Intestinal System—The esophagus and stomach were normal.

Intestine The first portion of the duodenum was the seat of a diverticulum about 3 cm in diameter and 5 cm in depth.

The proximal portion of the ileum showed no disturbance. The distal 20 cm of ileum was intensely congested and its wall markedly thickened. The mucosa, however, failed to show any gross changes other than congestion. Microscopically this portion of the ileum showed only a slight infiltration of polymorphonuclear cells involving all its layers. (This reaction might be attributed to surgical manipulation, since there was insufficient vascular response to suggest the presence of a true inflammatory ileitis.)

The mesentery at this site showed a similar degree of polymorphonuclear cell infiltration.

The appendix was bound to the brim of the pelvis by old adhesions and showed no gross or microscopic changes.

The spleen weighed 110 Gm and presented the usual appearance of toxic splenitis.

The pancreas weighed 90 Gm and showed no abnormalities.

Biliary System—The liver weighed 1,800 Gm and showed the usual cloudy swelling of a severe toxemia.

The gallbladder and bile ducts were normal.

Urinary System—The kidneys weighed approximately 110 Gm each and showed cloudy swelling, cortical cysts and very small areas of arteriosclerotic infarction.

The urinary bladder was dilated and its wall thickened by increase in fibrous tissue, congestion and edema.

The ureters were normal.

Endocrine System—The thyroid, adrenals and pituitary showed no pathologic changes.

Genital System—The penis, prostate and seminal vesicles were normal.

The right testis and epididymis were normal. The left testis and epididymis were each about one and a half times as large as those on the right and the diameter of the spermatic cord was about twice that of the right.

Sections through the left testis proper showed no gross or microscopic changes, but those of the epididymis presented numerous distended ducts, which were filled with amorphous, granular material. The rete testis was the seat of chronic inflammatory changes with replacement fibrosis and marked varicosities, many of the vessels showing marked perivascular round cell and plasma cell infiltration. Some of the blood vessels were hyalinized, others were occluded by organized thrombi and still others were the seat of marked, acute inflammatory infiltrate.

Sections removed from various levels of the spermatic cord as it proceeded to the inguinal canal showed the varicosities already described to be more marked, presenting a suppurative character to the thrombophlebitis. The process became diminished at the termination of the pampiniform plexus, leaving the rest of the spermatic veins only slightly involved.

The ductus deferens, although the seat of fibrous thickening of its wall showed no other pathologic condition.

Lymphatic System—The left lateral and pre-aortic lymph nodes were enlarged and soft and were the seat of purulent changes. A number of these nodes were reduced to mere capsules filled with frankly hemorrhagic and purulent exudate. Several of such nodes were connected with the cisterna chyli which was itself markedly distended by coagulated as well as fluid exudate of purulent character. From here on the entire thoracic duct, as far as could be traced, was filled with similar

exudate. At various levels along the duct, sacculations were found which markedly accentuated its usual varicose appearance. Its course in the posterior mediastinum between the aorta and the azygos veins was marked by brawny discoloration of the lymph nodes and of the connective tissue of this region, both of which were found to be the seat of marked polymorphonuclear cell infiltration, edema and hemorrhagic extravasation. Its course through the superior mediastinum was marked by similar changes. Although the duct could not be traced to its termination into the subclavian veins, the portion of it that arched in the root of the neck was traced to a suppurative mass of fat and lymph nodes. Sections of the duct at various levels showed purulent infiltration of its wall and suppurative thrombosis, which in the sacculated areas completely occluded the lumen. The predominating elements of the thrombus consisted of disintegrated leukocytes although here and there were also found clumps of bacteria and red cells.

Bacteriology—The direct smears of the contents of the thoracic duct and of the exudate from the lymph nodes showed a pure growth of long chains of streptococci. On culture of the contents of the thoracic duct these organisms were found to be *Streptococcus haemolyticus*.

The same organisms were found in the pleural mediastinal and peritoneal cavities, as well as in the exudate of the surgical wound of the abdominal wall.

Cultures and smears as well as guinea-pig tests were negative for tubercle bacilli. (The late Dr. Charles Norris, chief medical examiner of New York City, who examined the specimen, was of the impression that the condition strongly suggested a tuberculous origin. At his suggestion the search for tubercle bacilli was repeated several times, each time yielding negative results.)

The anatomic diagnoses were as follows:

- 1 Chronic epididymitis
- 2 Suppurative thrombophlebitis of the pampiniform plexus
- 3 Acute suppurative lymphadenitis (lumbar, thoracic, mediastinal and cervical)
- 4 Suppurative thrombolympangitis of the thoracic duct
- 5 Suppurative mediastinitis and pleuritis
- 6 Confluent lobular pneumonia and healed apical tuberculosis
- 7 Laparotomy wound with local peritonitis
- 8 Cortical cysts of the kidney (arteriosclerotic)
- 9 Diverticulum of duodenum

COMMENT

The chain of events in this case may be stated as follows:

A dormant source of infection existed in the thrombophlebitis of the pampiniform plexus. This was complicated by a streptococcal infection (the respiratory tract being a possible portal of entry) and invasion of the organism into the adjacent lymphatics. This region being drained by the lumbar lymph nodes, the latter became purulent and the process extended to the cisterna. From there the suppurative thrombolympangitis ascended, causing a suppurative mediastinitis, which was fatal.

Kryloff's case was similar to the present case in many respects. The onset of the condition was acute and the patient presented symptoms referable to an inflammatory condition in the right lower quadrant, with localized tenderness in the ileocecal region. A clinical diagnosis of grip was made which was also true in this case, and autopsy revealed changes similar to those described here, i. e., acute tracheitis and bronchitis, purulent pleuritis, bronchopneumonia, and thrombolympangitis of the thoracic duct, with marked purulent lymphadenitis of the thoracic, abdominal and inguinal nodes. As in this case the course was very rapid, the condition terminating fatally within five days of the onset.

In Kryloff's case the organism was believed to have invaded the lymphatics from an area of cellulitis in the left leg, while in this case the original source could not be determined with certainty, the inflammation of the epididymis and the thrombophlebitis of the pampiniform plexus undoubtedly led to the involvement of the thoracic duct. According to Pappenheimer death in these cases is due to peritonitis and septicemia rather than to the thrombolympangitis of the thoracic duct. In the present case, however, it is difficult to believe that so purulent a process and so marked an invasion of streptococci into the thoracic duct could be anything other than an important factor in the cause of death.

NEEDLE (ASPIRATION) BIOPSY

ROBERT P. BALL, M.D., CHATTANOOGA, TENN.

Director of Laboratories, Baroness Erlanger and Children's Hospitals

Needle aspiration has been a much used therapeutic and diagnostic procedure in general practice. The diagnostic possibilities are much greater when the macroscopic and bacteriologic examination of the aspirated material is extended to include sectioning and staining solid elements present. In the last few years various workers¹ have demonstrated the practical application of this method in obtaining tissue for biopsy. It has been used in every part of the body including the prostate², bone,³ lung,⁴ breast⁵ and vertebral column.⁶ Klinger and Burch⁷ have used aspiration biopsy to obtain specimens of the endometrium. Others have modified the needle so as to use a punch⁸ method.

The diagnosis of bone lesions is materially aided by the use of needle (aspiration) biopsy. The procedure is relatively painless and not expensive, and the patient will often permit the insertion of a needle when he would refuse an open incision. The osseous system is characterized by compactness and denseness. However, in pathologic conditions it loses its denseness and compactness so as readily to permit the insertion of a needle. Particularly is this true of localized destructive lesions due to inflammations or neoplasms.

Bone lesions are well demonstrated by roentgenography but in many cases there are not sufficient pathognomonic alterations to make a positive diagnosis. Since treatment and prognosis are dependent on the diagnosis, it is important to establish this with accuracy.

The following technic has proved satisfactory for obtaining biopsy material. It should be unnecessary to emphasize attention to every detail, for without doing so any technical procedure is liable to give unsatisfactory results.

TECHNIC

The skin is prepared with iodine and alcohol and anesthetized with procaine hydrochloride, and a number 18 needle is inserted into the lesion from which the material is to be obtained. A 50 or 100 cc. Luer syringe is then attached to the needle and the plunger withdrawn far enough to be grasped with the palm of the hand. The plunger is held steady in one hand and the barrel of the syringe with the needle attached is rotated from 90 to 120 degrees at the same time the needle being withdrawn or inserted a few millimeters. This maneuver should be repeated only until about 2 or 3 cc. of material is aspirated, which will usually contain blood. The needle is then withdrawn while traction is maintained on the plunger to hold the vacuum. On withdrawal, air rushing through the needle to close the vacuum in the syringe will clear it and the syringe tip of the tissue fragments. The plunger is then withdrawn care being taken not to force any material back into the syringe tip. Bacteriologic specimens or smears are taken at this time and the bits of tissue are teased from the blood clot and placed in a heap on a dry piece of paper. This is immediately dropped in 10 per cent solution of formaldehyde for fixation and then carried through dehydrating solutions cleared in xylene and embedded in paraffin for sectioning. Sections are stained with hematoxylin and eosin and mounted in balsam for permanent preservation.

Special Article

THE PHARMACOPEIA AND THE PHYSICIAN

THE USE OF HYPNOTICS

G. P. GRABFIELD, M.D.

BOSTON

This is one of a series of articles written by eminent clinicians for the purpose of extending information concerning the official medicines. The twenty-four articles in this series have been planned and developed through the cooperation of the U. S. Pharmacopeial Committee of Revision and THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION—ED

The poet's dream of a harmless sleeping potion achieved reality through a lucky accident coupled with scientific vision when Liebreich¹ noted that animals went into an apparently normal sleep when given chloral hydrate and awoke without evident harm. Since that time, enormous industry and ingenuity have been expended to improve on this drug.² In no field of pharmacology has the relationship between physiologic action and chemical constitution been more assiduously studied. And yet, in some experiments done in 1930, chloral still stood at the head of the list of efficient hypnotics.³ Most of the recent work has concerned itself with the barbituric acid derivatives introduced into medicine by Fischer and von Mering⁴ in 1904. However, not all the work has been concerned with these, and in a recent review Hjort⁵ has outlined compounds of ten chemical groups possessing sufficient hypnotic effects to have merited the study of a large number of individuals. It is perhaps sufficient to say that the ideal hypnotic drug has not been found and that the realization of the accurate correlation between physiologic action and chemical constitution or physical properties cannot as yet be made in this group of drugs, even though the effect of certain groups in the molecule has been pretty well established.

The general action of the hypnotics is that of a descending depression of the central nervous system, beginning with the cortex. There is a large difference in the dose required to affect centers below the cortex as compared with that necessary to produce only cortical depression. However, individual compounds probably act at slightly different points in the cortex and some exhibit earlier subcortical effects than others. As doses are increased, the depression deepens and gradually the action on the deeper parts of the nervous system becomes more evident until one can see in the experimental animal and in the patient definite evidence of action on one of the vital centers in the medulla—usually the respiratory center. Of course, in addition to their action on the central nervous system most of these drugs have other effects. In some, the lethal effects are associated with their metabolism in the body. For example, chloral may kill by secondary degeneration of the liver or by its direct effect on the heart. The sulfone compounds, such as sulfonethylnmethane exert their effects on the liver and kidney, signaled by

the hematuria that follows their use. This drug is also said to exert an effect on the purine metabolism, and some of the barbiturates are excreted in part as a uric acid complex. One wonders whether the purine metabolism may not be concerned with the central nervous system action of this group of drugs in some way, in view of Lennox's⁶ observation on the rise in blood uric acid in certain successful procedures in epilepsy, though he does not connect this observation with the success of the therapy.

The site of action on the cortex is probably within the cells themselves, as effects producing the changes accompanying sleep are evident long before any significant changes in pain perception can be demonstrated. Since these drugs act primarily at a point superior to the first synapse for painful stimuli within the central nervous system, it is to be expected that they could be prescribed with the analgesic drugs of the antipyretic series, which probably act in the thalamic regions where the pain stimuli arrive in the brain. Such has been found to be the case,⁷ interestingly enough, in both directions, that is, both the hypnotic effect and the analgesic effect are enhanced by the simultaneous exhibition of an analgesic and a soporific drug. It is interesting to note the variation in the effect of these drugs, the general pattern of whose action is essentially the same. Thus there is variation in absorption and excretion and in minor effects on various cortical or sub-cortical mechanisms, such as temperature, equilibrating sense and the special senses. Such actions may become apparent as idiosyncrasies of certain individuals to some of these drugs. Some act slowly after absorption, some rapidly, some act as chemical entities, whereas some are changed into active forms after absorption, some are excreted in the urine unchanged, some partly changed, and some are completely destroyed in the body. Any classification for therapeutic purposes cannot be made on the basis of such variable properties and must therefore be pragmatic in using as a basis the rapidity of onset and duration of sleep produced, with due consideration in choice of drugs to the frequency of the minor effects mentioned and the duration of action beyond actual sleep. On this basis the drugs to be discussed may be divided as follows: chloral, "Evipal," paraldehyde, carbromal (rapidly acting), sulfonethylmethane (slow acting), barbitol, pentobarbital (between these). "Evipal," carbromal and paraldehyde (especially the first) act over a shorter period than pentobarbital, barbitol, chloral and sulfonethylmethane (as to duration of action).

In addition to these, certain drugs must be considered which act primarily on the motor side of the nervous system though probably possessing some general sedative effects as well, namely, phenobarbital and the bromides. The former is an example of the variations in action that may be introduced by slight chemical changes in the molecule—the introduction of the phenol group apparently enhances the effect on the motor cortex to the point where the general sedative effects are partly masked. Before the foregoing general pharmacologic principles are applied it is necessary to consider sleeplessness in more detail.

The treatment of insomnia is a subject that can be considered from many angles. It seems wise to limit the discussion to certain phases of the subject in order to avoid excursions into the realm of psychiatry. Text

books of internal medicine do not recognize such a condition. Yet all know what is meant by the term, though from an etymological point of view it simply means lack of sleep from any cause. It may be due to pain, discomfort, dyspnea, frequency, diarrhea, itching or any symptom that forces itself on the sensorium. However, the usual idea of insomnia as a medical problem is that of sleeplessness unconnected with somatic symptoms. If sleeplessness is due to some definite cause such as one of those enumerated, treatment is necessarily directed to the relief of the underlying symptom. True insomnia, therefore, may be defined as sleeplessness due to no underlying stimulation preventing sleep or awakening the sufferer. The condition may assume different forms.

First, and most common, is difficulty in going to sleep, second, awakening early and inability to sleep again, third, periods of wakefulness in the middle of the night, and, finally, a reversal of the sleep mechanism with wakefulness at night and sleep by day. The cause of the first three types usually is habit or some emotional disturbance, either acute or as a manifestation of a psychoneurosis. The last, most distressing form is almost exclusively found in cerebral arteriosclerosis and usually is accompanied by other manifestations of senility.

Since it is axiomatic that the treatment of any symptom should be directed to its cause, and since the usual cause of insomnia is either habit or a psychoneurosis, it is obvious that treatment must be directed against these underlying conditions.

However, in connection with the foregoing, the indications for the use of hypnotic drugs may be concisely formulated. The following four indications for the use of soporific drugs seem clear: 1. When sleeplessness can be foreseen as the result of an acute situation of short duration. 2. When wakefulness is clearly due to an obvious cause, and the symptomatic relief will aid in the treatment. 3. When the cause is unclear but relief is urgently demanded, and no danger of masking night symptoms is present. 4. In the reversal of the sleep mechanism in cerebral arteriosclerosis.

The first group includes such situations as the near relatives of a deceased person before the funeral, the first night in the hospital, and others that will readily come to the reader's mind. In the second group are such cases as discomfort from any of the causes previously enumerated. Even though the cause is unclear and definite somatic symptoms are present, immediate relief of the third group of sufferers may aid subsequent therapy, especially if the cause is psychic. Finally, relief for the fourth group demands the utmost care in the use of drugs to change the mechanism without intensifying it by the late action of the soporific.

To connect these two classifications will provide the appropriate therapy.

Considering first those with rapid action over a comparatively short period of time suitable for patients unable to get to sleep, one finds first of all paraldehyde and chloral, both of which have stood the test of time. The obvious disadvantage of paraldehyde lies in its odor on the breath the following day, but this is often more than compensated by its efficacy and above all by the practical absence of toxicity. It must be remembered, however, that the combined use of morphine and paraldehyde is highly toxic. Chloral is undoubtedly the most useful of all the hypnotics and the cheapest. Given well diluted in water it produces sleep within an hour, and in proper doses (from 0.3 to 0.6 Gr.)

⁶ Lennox, W. G. and O'Connor, Marie. *J. Biol. Chem.* 66: 521 (Dec.) 1925.
⁷ Reitz, E. *Arch. f. exper. Path. u. Pharmacol.* 161: 379 1931.

5 to 10 grains) is entirely harmless even in heart disease. There is no doubt that in toxic doses it kills by its effect on the heart, but the fear of this side action has been engendered by the large dosage that has always been recommended up to the last few years. None the less, it is not the hypnotic of choice in heart disease, though it may be used if for some reason the barbitals and paraldehyde are contraindicated in a given patient. For quick action of short duration, two of the barbiturate series recommend themselves. Pentobarbital (from 60 to 120 mg., or 1 to 2 grains) has proved very useful.

Barbital itself is still probably the most satisfactory drug when more prolonged and less prompt action is desired. In all these drugs both intensity and duration of action are increased with increasing doses. If, therefore, more than 0.6 Gm. (10 grains) of barbital is found necessary to produce the effect desired, another drug should be used. Comparable to barbital, but of another chemical constitution, is "Sabromin," considerably more expensive than barbital, carbromal also may be tried. Sulfonethylmethane has fallen into disuse on account of the long period before it acts and because of its prolonged stay in the body. However, these very qualities can be utilized in selected cases. It is usually effective from five to seven hours after administration and is particularly useful in the second group of patients. Its action, however, is prolonged and it may leave a certain amount of drowsiness the next day. Furthermore, repetition over a comparatively short period, even in ordinary doses, is said to lead to liver damage. In occasional selected cases for short periods it may be extremely useful, especially in supplementing the action of some of the shorter acting drugs. Thus the combination of barbital with sulfonethylmethane given an hour or two before bedtime may prove more satisfactory than double the dose of barbital for producing a deep sleep throughout the night. This evidence of synergism suggests that other combinations might prove equally useful. The unfortunate one between paraldehyde and morphine has been mentioned and another between chloral and alcohol is well known, even to the underworld, in the form of "knock-out drops." "Synergism" between the hypnotics and antipyretics (analgesics) has been fairly well studied in some instances. This should be utilized when pain or discomfort is associated with insomnia. While the antipyretic drugs of the types acetylsalicylic acid, aminopyrine and acetophenetidin have almost no hypnotic actions, the soporifics discussed have equally little effect on pain. Yet combinations of these two groups of drugs enhance the effects of each. In this connection it is well to remember that both morphine and codeine are inefficient hypnotics as compared with the drugs discussed. Finally, on certain occasions sleep is disturbed, largely by motor restlessness, "the fidgets," not directly associated with cerebral activity. Under such circumstances, phenobarbital ("lumnal") and the bromides are most useful, but their effects are prolonged on a comparatively low level of intensity. Both are poor hypnotics in the strict sense of the term and produce their quieting effect by their depression of the motor side of the central nervous system, neither should be used as a simple soporific. It seems hardly necessary to caution against the use of morphine when pain is not a factor, and, while scopolamine alone or with morphine may be useful in states of great motor excitement, it should not be considered as an ordinary hypnotic.

It should be understood that the foregoing remarks apply primarily to the use of these drugs for simulating normal sleep. The problem of preanesthetic medication is an entirely different one. The purpose here is to find a drug that will relieve the apprehensive attitude of the patient, have no untoward effect in combination with the anesthetic about to be used, and produce partial anesthesia, to be completed by a lesser amount of inhalation anesthetic. It is noteworthy that historically the drugs that have been suggested for preanesthetic medication were originally introduced as anesthetics. They have all the objections of any fixed anesthetic. Many accidents have occurred, particularly with tribromethanol. Some drugs so introduced have come subsequently to be recommended as hypnotics, but most present no advantages over those in common use.

Apparently for preanesthetic medication and for a partial anesthetic in obstetrics,⁸ pentobarbital sodium has proved to be most satisfactory in that it is quick acting and fits well with all the inhalation anesthetics.

Since the use of soporifics for this purpose has become common, a tendency has arisen of giving them as hypnotics in larger doses than is warranted for simple sedation. This has led to the use of drugs that are actually not very efficient in doses that are sufficiently large to produce some of the untoward toxic symptoms, such as delirium and ataxia. It should be repeated that in doses which produce simulation of normal sleep the group of drugs that is being discussed has little, if any, pain relieving qualities. This fact is to be emphasized, since too often the physician exhibits large doses of hypnotics when the use of one of the analgesic drugs would be more efficient in producing sleep. When sleeplessness is due to pain or discomfort, one of the analgesic drugs, such as acetylsalicylic acid, acetophenetidin or aminopyrine, should be used either alone or in combination with hypnotics. The drugs of these two groups have been shown to have a synergism with each other and skilful mixtures of barbital or chloral with one of this group are frequently surprisingly efficient, even in pain as severe as that of spinal metastases.

This leads to the consideration of the opium group, which should not be exhibited except for certain very definite indications, owing primarily to their habit forming qualities.⁹ Morphine itself, though hypnotic, is more efficient in the relief of pain, whereas codeine is not very efficient for the relief of pain or for the production of sleep, its particular field being in the depression of the cough center. As to habit formation, of course, this is primarily a property of morphine, but, unfortunately, the newer derivatives of morphine appear to offer no improvement in this respect. Codeine apparently does not furnish sufficient euphoria to be habit forming. It is probable that the continued use of any of these drugs produces certain tolerance, but from a practical point of view this is not significant and habit formation from the hypnotics is psychic rather than otherwise.

A discussion of sleep producing agents would not be complete without the mention of their use with suicidal intent. The readiness with which these drugs can be purchased by the public makes them ideal agents. Fortunately the lethal doses are larger than the layman thinks, so that the attempts are often unsuccessful. It should not be forgotten that occasionally delirium is a symptom of poisoning with these agents, especially

⁸ Irving F. C. Berman S. and Nelson H. B. Surg. Gynec. & Obst. 58:1 (Jan.) 1934.
⁹ Gunn I. A. Physiol. Rev. 3:41 (Jan.) 1923.

with the bromides¹⁰ Many treatments have been advised for patients under the influence of these narcotics Analeptics of all sorts have been used both logically and illogically¹¹ The use of strychnine is not desirable because its action is primarily on the spinal cord,¹² and while these drugs can control the convulsions from strychnine poisoning from above, the converse obviously cannot hold true "Coramine"¹³ has been tried with favorable results However, the most striking results have been obtained by the use of picrotoxin,¹⁴ owing to the stimulating effect of this drug on the vital centers of the medulla in keeping the patient alive until the toxic drug can be removed from the body However, the difficulty lies in having the picrotoxin when it is needed and in the fact that picrotoxin is a dangerous drug¹⁵ In addition, the fluid intake must be high and introduced by all routes, as a percentage of many of the drugs is excreted through the kidneys Diuretics may also prove of value¹⁶ Care should be taken to prevent chilling of the patient Nutrient enemas or even feeding by nasal tube may be necessary if stupor is prolonged

In exhibiting the hypnotics, the physician does well to follow the fundamental principle of sound therapeutics, which is to learn thoroughly all the possibilities of a few drugs before adding to his armamentarium many substances hastily introduced and inadequately tested

319 Longwood Avenue

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
PAUL NICHOLAS LEECH Secretary

GADOMENT NOT ACCEPTABLE FOR N N R.

Gadoment is the coined, proprietary name under which E. L. Patch & Co markets a preparation stated in the firm's house organ, *Patchwork* to contain "70% Cod Liver Oil in a wax base with Zinc Oxide Benzoin and Phenol" According to a trade package it is proposed for use in the treatment of burns, cuts and minor skin irritations The composition is not declared on the trade package

Early in 1935, E. L. Patch and Co inquired of the Council's Secretary what would be the attitude of the Council on the use of the trademarked name "Gadoment." The firm did not at that time present the product for the Council's consideration, nor has Gadoment since been presented The Council's secretary asked the firm on what premises it would base the claim for the use of a proprietary name.

Some further correspondence was carried on between the firm and the Secretary concerning the name "Gadoment" the firm stating that the name does not suggest diseases, pathologic conditions or therapeutic indications and that it simply indicates to physicians the potent ingredients The firm also stated that Gadoment is the first of this class of preparations and therefore

is entitled to a special name In the end the Council held the firm's right to the use of a proprietary name for this product was not established

In a later communication the firm stated that it was gathering data on this preparation The Secretary explained to the firm that a product should not be submitted to the medical profession for use until evidence for such use had been established and that it would not be keeping faith with the profession if, on the one hand, the product was advertised to the profession for certain indications, and on the other hand the Council was informed that the firm did not have sufficient evidence

As long ago as November and December 1934 in the firm's house organ sent to physicians and dentists *Patchwork* (Vol. 1, No. 6, p. 4), there was an entire page devoted to cod liver oil in the treatment of skin diseases and an advertisement for the new cod liver oil treatment for burns and other skin injuries, "Gadoment-Patch"

Further, in *Patchwork* (Vol. 18, No. 6, p. 2 1935) there is comment on Gadoment entitled "Gadoment Clinical Studies and illustrations of varicose ulcer of six years duration with the same case discharged after ten weeks' treatment Mentions is also made of "descriptive literature" on Gadoment This has not been submitted for the Council's consideration.

The firm offered no further argument but apparently proceeded with the marketing of the product with the label claims already pointed out.

From its consideration of the evidence from the literature the Council concluded that the whole subject of cod liver oil treatment of burns and wounds is still in an experimental stage Lauber finds that vitamin A produces no acceleration in the process of wound healing, and in the case of concentrated application he even noted a slight retardation He noted that vitamins B₁ and C produced slight retardation in wound healing, when given in comparatively large doses and that vitamin D produced a slight acceleration when administered in low concentration, but in moderate doses it had no effect on the healing of wounds, and in concentrated doses it even retards healing Löhner found that addition of petrolatum reduces the bactericidal power of cod liver oil and calls for careful examination as regards sterility Moreover, Lauber apparently disagrees with the observations of Löhner in regard to the value of these local applications of cod liver oil, and he even states that acceleration of the healing process is never as convincing as following oral administration in small doses of vitamin A, and that oral administration of vitamin D had no effect whatever on the wound healing process Lauber also deplores lack of definite statements regarding the vitamin contents of vitamin ointments in the treatment of wounds and considers it inadvisable to use ointment with various components

The package cover for Gadoment indicates to the user its purpose for treatment of certain diseases This is in conflict with the Council's rules concerning indirect advertising of products It also states that "A special base which physicians have found most desirable as a dressing for skin injuries is used. This is in conflict with the Council's rule providing for unambiguous declaration of composition of a product.

The Council desires to emphasize the fact that E. L. Patch & Co., which has for years had relations with the Council and should thus be conversant with proper procedure has in the case of Gadoment gone precisely contrary to the accepted way of introducing a new preparation Instead of collecting evidence for claims and then presenting this to the Council the firm went ahead promoting the product with the uncorroborated claims The Council therefore found it necessary to consider the preparation on its own initiative and to inform the medical profession concerning it and the claims made for it

The Council declared Gadoment unacceptable for Nonofficial Remedies because it is an unoriginal preparation insufficiently declared composition marketed under a proprietary name with unwarranted therapeutic claims and indirectly advertised to the public

PHYSICIANS SPECIALIZING IN PATHOLOGY AND CLINICAL PATHOLOGY

PREPARED BY THE COUNCIL ON MEDICAL EDUCATION AND HOSPITALS

For the past ten years the Council on Medical Education and Hospitals has actively promoted the practice of pathology and clinical pathology by qualified physicians. A list of approved laboratories was maintained until 1931, when for obvious reasons the system was changed to one of certifying individual pathologists according to a minimum standard of qualifications.

The results of the Council's work are gratifying. Increasing numbers of hospitals throughout the country have employed qualified physician-pathologists, where previously this service was in the hands of technicians under nominal supervision or under no supervision. The number of commercial laboratories under lay direction has been reduced. Interns, nurses and technicians are receiving better training in pathology and clinical laboratory work. More and better necropsies are being secured. The organized profession has been constantly reminded that the practice of pathology and clinical pathology is the practice of medicine, and as a result the patronage of lay laboratories has been steadily withdrawn and the patient is better served. The following list contains the names of 902 physicians who were found to meet the "Essentials" and were recommended by the Council's advisers.

Those engaged in teaching, research and other activities are admitted, as well as those in active practice. For the list of pathologists in government service, see page 1389.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

535 NORTH DEARBORN STREET • • CHICAGO, ILL.

Cable Address

Medic, Chicago"

Subscription price

Seven dollars per annum in advance

Please send in promptly notice of change of address giving both old and new always state whether the change is temporary or permanent. Such notice should mention all journals received from this office. Important information regarding contributions will be found on second advertising page following reading matter.

SATURDAY, OCTOBER 24 1936

CLINICAL APPLICATION OF HORMONES OF ANTERIOR PITUITARY AND GONADS

Many important advances have been made by clinicians without help from laboratory workers. On other occasions new facts have been determined in the laboratory without aid from the clinicians. Confusion often results when clinicians attempt the premature application of studies begun in the laboratory and not carried to completion.

These remarks are prompted by the confusion now existing in the field of endocrinology, particularly with regard to knowledge of the hormones of the pituitary body and sex glands. This knowledge had its inception only a few years ago, its progress has been slow and uncertain, yet already it is receiving wide clinical application. Workers in research laboratories with every facility at their command have been able to isolate certain active principles, but even when exerting every effort to conduct a controlled experiment there have been disturbing variations in their results. For example, a pituitary fraction that had produced hypertrophy of testes of rats on repeated occasions suddenly and inexplicably produced atrophy of the testes. While disturbing this was not serious—rats have no lawyers to sue for malpractice. However, workers in this laboratory report that it was, and is, besieged with requests for such extracts for injection into man, and that the clinicians in the community where the laboratory is situated are openly critical of the director of the laboratory because "with all that work being done right on our campus we must send elsewhere for extracts for patients." The director of the research laboratories of one of the largest American pharmaceutical houses is much upset by this insistence on the part of clinicians for extracts to be used in the treatment of patients. Recently he remarked, "I have repeatedly sent extracts marked 'for veterinary use only' to men who I thought had good judgment and later received letters reporting 'encouraging results in patients' and requesting an additional supply."

This is regrettable, of course, but perhaps the gentleman protests too much. It may be the boomerang effect of the policies of many commercial laboratories. They are in a highly competitive field wherein the organization that first gets its product into general use is most likely to profit handsomely. Therefore they equip personable and intelligent detail men with a satchel full of new hormones and send them forth to call on members of the medical profession. In many physicians they find men who may feel that they cannot permit the physician across the corridor to learn of new substances which can be injected hypodermically, their wonders to perform while they stand by without a syringe or a new hormone. Thus these physicians demand the hormones as rapidly as they can be separated from the tissues, blood or excreta of animals or man and proceed to inject them into patients for a variety of conditions that have not responded to less dramatic therapy.

Another disturbing feature is that the medical literature is being filled with articles which are almost unanimously enthusiastic and which often give evidence of lack of critical consideration. When a clinician of large experience suggests that these glowing reports have not produced miracles in the treatment of his patients he is referred to as a "mossback" or a "nihilist." For example, it is somewhat difficult to find an article reporting the failure to produce descent of the testes by injection of gonadotropic substance, yet many such failures occur.

The existence of such a discrepancy between the brilliant laboratory observations and their clinical application does no particular harm to a clinician who is well grounded in fundamental knowledge and gifted with critical acumen. It does immeasurable harm to the clinician who relies on the written word as always representing the well digested opinion of an intelligent observer and who regards such opinions as accepted facts worthy of clinical application. A physician engaged in a busy practice who reads these glowing reports tends to undergo a transition from amazement to general interest, to acceptance, to clinical application. What he does not often see in print are the conservative reports or the reports of failure. What he never sees in print, for example, is the report of an experience like that of an endocrinologist who injected an extract into a 15 year old girl for dysmenorrhea. The size of her ovaries seemed normal before the injections were given, at the conclusion of the injections acute appendicitis developed and at operation the surgeon found bilateral cystic ovaries the size of oranges.

These reflections are not intended to inhibit chemical and biologic studies in accredited laboratories. Neither do they apply to the carefully controlled clinical application of accepted knowledge by competent observers. This is necessary. Rather are they intended (1) to emphasize that there is a great discrepancy between laboratory knowledge of the hormones and their clinical

ical application, (2) to suggest that for the present only those clinicians with facilities for critical study be encouraged to administer the newer endocrine preparations to patients and that these clinicians be urged to publish their negative as well as their positive results, and (3) to suggest that a large group of physicians not represented in either of the groups mentioned cease their indiscriminating injection of unknown substances into unsuspecting patients

HYPOCHROMIC ANEMIA AND ALKALI THERAPY IN PEPTIC ULCER

Loss of blood for long periods usually leads to a slow depletion of iron stored in the body and frequently to the subsequent development of a hypochromic anemia. Obviously, successful treatment of the uncomplicated anemia depends on the arrest of the hemorrhages and on the replenishment of the reserve supply of iron. One of the frequent causes of this type of anemia is the chronic loss of blood resulting from peptic ulcer. Since one of the more common methods of treatment of this disease is the use of rather large amounts of alkaline powders daily and since the utilization of iron is known to be unfavorably affected by the presence of alkali in the upper part of the gastro-intestinal tract,¹ questions arise regarding the possible prolongation of periods of anemia in patients with bleeding peptic ulcer because of alkali therapy.

In a recent study at the University of California,² the results of an investigation dealing with the question of the utilization of iron during alkali therapy in patients with peptic ulcer have been described. Four adult male patients with a history of prolonged loss of blood from the gastro-intestinal tract and with an accompanying hypochromic anemia were subjected successively to three different types of treatment: a modified Sippy regimen, a period during which the diet was supplemented by iron in the form of iron-containing foods, as spinach, eggs or beef, and a period during which the alkali therapy was suspended entirely but the supplement of iron-rich foods was continued unchanged. In two of the patients, large doses of inorganic iron in the form of ferrie ammonium citrate were subsequently administered. Although there was some variation in the response obtained from the various patients, the general trend of the results was consistent and unmistakable. During the period of unsupplemented alkali therapy there was no significant change in the hemoglobin content, the erythrocyte counts or the percentage of reticulocytes in the blood of the patients. Likewise there was little or no change in the pigment concentration of the blood following the addition of the iron-containing foods to the diet, even though the amounts

given were sufficient to satisfy the daily requirement of normal adults. There was a slight but consistent increase in the number of erythrocytes in the blood, however, which the authors attribute to the absorption from the food ingested of some substance necessary for the formation of cell stroma or for the maturation of erythrocytes. In contrast to these results, the cessation of alkali therapy was followed promptly by a significant reticulosis and a subsequent increase in the concentration of hemoglobin and cells in the blood. In the two cases treated with large doses of inorganic iron further increases in cells and pigment toward normal values were observed. These results appear to warrant the conclusion that the administration of alkali to patients with hypochromic anemia due to prolonged loss of blood from peptic ulcers interferes with the utilization of dietary iron for hemoglobin formation and thus delays recovery from the anemia.

The foregoing investigation emphasizes anew the importance of normal gastric acidity in providing a favorable environment for the proper utilization of dietary iron for the formation of hemoglobin. Other examples are well known, such as the impairment of iron utilization in patients with achlorhydria³ and in experimental animals in which total gastrectomies have been performed.⁴

From a practical standpoint the study indicates that patients given alkali therapy for peptic ulcer complicated by an iron deficiency anemia will remain anemic until alkalinization is discontinued or until large amounts of iron are administered. According to the California investigators the method of choice is to give large doses of inorganic iron, since many foods that are rich in iron favor a recurrence of peptic ulcer, particularly in the absence of alkali therapy.

THE SOVIET UNION REVERSES ITS STAND ON LEGALIZED ABORTION

On May 26 the Central Executive Committee and the Central Peoples' Health Committee of the Soviet Union published the draft of a new law prohibiting abortion except in the presence of stringent indications, thus it completely reversed its stand of 1920, when it legalized artificial abortion. With the interdiction of artificial abortion, except when the life or health of the woman is threatened, a number of measures calculated to lighten the burden of child bearing and of the rearing of large families were proposed. The number of available obstetric hospitals, beds, consultation stations and creches were to be increased so as to make this service universally available. The new law likewise proposed to raise alimony fees, to make divorce more difficult

and to encourage the rearing of large families. The legislative bodies responsible for the bill asked the people for a free and fearless discussion of the proposed legislation. Opponents of the bill, chiefly women, advanced a number of social reasons, such as the still existing lack of housing facilities, the difficulty in prosecuting study or work and rearing many children at the same time, the ill effect of oft repeated pregnancies on one's health and, last but not least, the encroachment on the woman's right to determine whether she chooses at a given moment to become a mother or not.

The attitude of the medical profession and in particular of the obstetricians and gynecologists is in sharp contrast to these views. The medical profession in the Soviet Union had an unusual opportunity to observe the harmful effects, both early and late, of artificial abortion. Prof. G. A. Baksht,¹ the head of the First Gynecologic-Obstetric Clinic of the Leningrad Medical Institute, states: "The accumulated experience since 1920 furnishes abundant proof that artificial abortion is a serious evil and that the operation, even when performed *lege artis*, leads to a number of injurious effects." Trauma and infection have always constituted a real danger in operative interference with the normal process of labor. The same holds true with even greater force in the case of artificial abortion. The organism of the woman in the first months of pregnancy has not acquired those protective properties which guarantee it a physiologic puerperium. In discussing the operative trauma, Baksht states that the incidence of perforation of the uterus amounted to from 0.01 to 0.11 per cent. This accident not infrequently calls for an immediate laparotomy in order to ascertain probable injury to the intestine, the urinary bladder or the mesentery. Occasionally the uterus has to be sacrificed in a young woman. According to Ulyanovsky (quoted by Baksht), tears of the internal os occurred in 10.5 per cent and led to cicatricial contractures and even to a complete atresia, or served as a portal of infection of the parametrium. Too energetic curettage of the uterine mucosa traumatizes the basal membrane, with the consequent atrophy and depression of the menstrual function.

While micro-organisms enter the uterine cavity after the fourth day in the normal puerperium, about the time of the formation of the protective granulation zone, bacteria were found to be present in the uterine cavity after an artificial abortion on the second day after the operation and their number rapidly increased on the third and fourth days. This is manifested clinically by the frequency of "mild" fever. The high incidence of postabortive fever (40 and 50 per cent according to Rusin) depends on the considerable number of repeated abortions with the attendant subinvolution and latent infection. Chronic pelvic infection

was present in 12.8 per cent in a follow up study of 1,500 cases of artificial abortion.

The extent of biologic trauma is rather difficult to estimate. The introduction of two new glands of internal secretion, the corpus luteum and the placenta, undoubtedly call for especial adaptation on the part of the rest of the endocrine-vegetative system. The effect of the sudden interruption of pregnancy must be to upset the new equilibrium and to lead to endocrine vegetative upsets and to disturbance of the menstrual function and the libido. This is of particular significance when interrupting the first pregnancy in women with an asthenic-hypoplastic constitution. It tends to stabilize infantilism and result in sterility even in the absence of a pelvic infection. Artificial abortion is an important etiologic factor in extra-uterine pregnancy.

The advocates of the bill likewise stress the salutary effect they believe the new law will have on the relations of the sexes, on the irresponsible and frivolous attitude toward the sex problem and on the building of character in the growing generation.

The bill was passed, June 27.

Current Comment

THE DECLINE OF TUBERCULOUS INFECTION

In the September issue of the *American Journal of Diseases of Children*, Beaven¹ discusses the results of tuberculin tests made on 4,982 children between 1 and 14 years of age admitted to the Children's Division of the Strong Memorial Hospital and Rochester Municipal Hospital during the years 1926 to 1934 inclusive. Four hundred and eighty of these children (9.6 per cent) had positive reactions, the majority being in the early age group. As has been frequently found elsewhere, the number having positive reactions to old tuberculin increases as age advances. The significance of the positive reaction is therefore greater in the younger child. Fifty-two per cent of all children from 1 to 14 years of age with a positive reaction to old tuberculin had clinical or roentgenologic evidence of tuberculosis. Similar evidence was present in only 41.2 per cent of the children from 6 to 14 years of age. A positive reaction to old tuberculin in a child appears approximately equal in the two sexes, but boys are more likely to succumb to the infection than are girls. In the series studied, tuberculous children without signs or symptoms of the disease had an incidence of 13.8 per cent of known exposure, while those with clinical or roentgenologic evidence of the disease had an incidence of known exposure of 38 per cent. The decline, and it is perhaps the most significant section of the report, is the proportion of children with positive reaction to old tuberculin during the course of this survey was 62 per cent. This decline in the incidence of tuberculous infection in children has not been accompanied by a change in the relative incidence of the disease.

¹ Baksht, G. A. Regarding the Prohibition of Abortion. *Sovetskoy Vracheyev Zhurnal*, June 1936, No. 12.

¹ Beaven, P. W. Extent and Nature of the Decline of Tuberculous Infection in Children. *Am. J. Dis. Child.* 52: 565 (Sept.) 1933.

studies suggest that in the last three or four years infection with the tubercle bacillus has been more likely to result in positive clinical or roentgenologic signs than earlier in the survey. During this period, however, the mortality among infected children has changed little if at all. Beaven's analysis furnished credible evidence that tuberculosis among children is decreasing rapidly. This result is apparently due to a lower rate of infected persons rather than to any attenuation in the virulence of the organism causing tuberculosis.

Association News

RADIO BROADCASTS

The American Medical Association and the National Broadcasting Company are presenting the second series of dramatized health broadcasts under the title *Your Health*. The first broadcast in the new series, the thirty-second dramatized cooperative broadcast under the title *Your Health*, was given October 13. The theme for 1936-1937 differs slightly from the topic in the first series, which was "medical emergencies and how they are met." The new series is built around the central idea that "100,000 American physicians in great cities and tiny villages who are members of the American Medical Association and of county and state medical societies, stand ready day and night, to serve the American people in sickness and in health."

The program will go out on the Blue network instead of the Red, as originally announced. The announcement cards that were sent out when the program was planned for the Red network can be changed simply by substituting the word 'Blue' for 'Red' where it occurs. Stations to which the program is available are as follows:

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH)

ALABAMA

Clinical Meeting—The Gulf Coast Clinical Society held its first annual meeting in Mobile, October 16-17. The speakers included Drs. Leon J. Menville, New Orleans, John A. Lanford, New Orleans, Willis C. Campbell, Memphis, George R. Livermore, Memphis, Winchell McK. Craig, Rochester, Minn., Fred H. Albee, New York, Raymond W. McNealy, Chicago, James S. McLester, Birmingham, Lloyd Noland, Birmingham, Louis A. Bue, Rochester, Minn., Orion O. Feaster, St. Petersburg, Fla., Harvey F. Garrison, Jackson, Miss., and Francis E. LeJeune, New Orleans. The Mobile County Medical Society was host at a banquet Friday evening. Dr. McLester gave the address. The society was organized early this year and is composed of physicians from Biloxi, Gulfport, Mobile and Pensacola.

ARKANSAS

Society News—Dr. James Ogden, Fort Smith, discussed trachoma before the Sebastian County Medical Society recently. —The Tenth Councilor District Medical Society was addressed at Fort Smith, September 15, among others, by Drs. Charles T. Chamberlain, Fort Smith, on "The Patient with Heart Disease as a Surgical Risk," and Harry Wilkins, Oklahoma City, "Practical Management of Cranio-cerebral Injuries." —At a meeting of the Arkansas County Medical Society in Stuttgart, September 8, the following members of the state hospital staff in Little Rock spoke: Drs. John Stathakis, North Little Rock, treatment of syphilis, Elizabeth D. Fletcher, San Antonio, Texas, history of insanity, and Alice C. Kolb, Little Rock, the problem of caring for the mentally abnormal.

CALIFORNIA

Dr. Dock Named Professor of Pathology—Dr. William Dock, associate professor of medicine, Stanford University School of Medicine, San Francisco, has been appointed professor of pathology, effective September 1. Dr. Dock is a graduate of Rush Medical College, Chicago, and has been associated with the department of medicine at Stanford since 1926.

Southern California Medical Meeting—The ninety-fifth semiannual meeting of the Southern California Medical Association will be held in Los Angeles, October 30-31. The following program will be presented:

Dr. John Edwin Kirkpatrick, Los Angeles: Immediate Repair of Divided Nerves and Tendons of the Hand.
Dr. Alvin G. Ford, Pasadena: Normal Hematologic Standards with Discussion of Variations Due to Physiologic Changes.
Dr. Hermon C. Bumpus, Jr., Pasadena: What May We Expect from the Treatment of Tumors of the Bladder?
Dr. Charles M. Taylor, Los Angeles: Proctology in General Medicine.
Dr. Elliott P. Joslin, Boston: Insulin Protamine and the New Era in Diabetes.
Dr. Emil Bogen, Olive View: Medical Aspects of the Business Cycle.
Dr. Isaac A. Olch, Los Angeles: Results of Surgical Treatment of Hyperparathyroidism.
Dr. Francis M. Smith, San Diego: Anemia as a Cause of Angina Pectoris.
Dr. Hans von Briesen, Los Angeles: General and Neurosurgical Consideration of the Cerebral Birth Palsies.
Dr. John B. Renshaw, Glendale: Gastroscopy as an Aid in the Diagnosis of Malignant Lesions of the Stomach.
Dr. William Benbow Thompson, Los Angeles: Cesarean Sections in Los Angeles County.
Dr. George Finess, Los Angeles: Allergic Study of Feather Protein.
Drs. Merrill W. Hollingsworth and John J. Montanus: Santa Ana Relationship of Low Basal Metabolic Rates to Allergic Disease.

COLORADO

Society News—The Mesa County Medical Society was addressed in Grand Junction, September 15 by Dr. Robert J. Groom, Grand Junction, on "Diarrheas in Infants." —The Medical Society of the City and County of Denver was addressed, October 6, by Drs. Gerrit Heusinkveld on obstetrics, and Bernard N. E. Cohn on the normal and pathologic physiology of joints. —The Colorado Hospital Association will hold its annual meeting at the University of Colorado School of Medicine and Hospitals, Denver, November 4. —Dr. George E. Rice, Pueblo, addressed the Pueblo County Medical Society.

The topics are announced monthly in advance in *Hygienic Health Magazine*, and three weeks in advance in each weekly issue of *THE JOURNAL*. The topics and speakers for the next three programs are as follows:

October 27 Help for the Hard of Hearing. W. W. Bauer, MD.
November 3 Community Sanitation. Morris Fishbein, MD.
November 10 Noise. Morris Fishbein, MD.

The time of the broadcast is Tuesday afternoon at 5 o'clock eastern standard time (4 o'clock central time, 3 o'clock mountain time, 2 o'clock Pacific time).

October 6, on "The Approach to a Diagnosis in Thyroid Disease."—The Delta County Medical Society was addressed, October 2, by Dr. Albert C. McClanahan, Delta, on "Does Morphine Inhibit Intestinal Peristalsis?"

DELAWARE

Society News—Dr. George H. Cross, Chester, Pa., discussed "Magnetic and Nonmagnetic Foreign Bodies in the Eye and Their Methods of Removal" before the New Castle County Medical Society in Wilmington, September 15.

GEORGIA

District Meeting—The Fifth District Medical Society held its annual meeting at the Academy of Medicine, Atlanta, October 15. Drs. Benjamin H. Minchew, Waycross, and George A. Traylor, Augusta, president and president-elect, Medical Association of Georgia, attended the meeting. Papers were presented, among others, by Drs. Joseph Earle Moore, Baltimore, on "Management of the Wassermann-Fast Patient", William A. Smith, Atlanta, "Quinine Treatment of Myotonia Congenita" and Joseph Yampolsky, Atlanta, "Use of Stovarsol and Stovarsol and Bismuth in the Treatment of Syphilis in Children."

Changes at Medical School—Dr. Richard Torpin, clinical instructor in obstetrics and gynecology, Rush Medical College, Chicago, has been appointed associate professor of obstetrics and gynecology and chairman of the department at the University of Georgia School of Medicine, Augusta. Dr. Alfred P. Briggs, assistant professor of internal medicine, St. Louis University School of Medicine, St. Louis, has been named associate professor of biochemistry and of medicine. Fourth year medical students at the university were required to assist in making physical examinations of newly enrolled students in the various units over the state during September, in accordance with an order by the board of regents.

ILLINOIS

Personal—Dr. Brian J. Carder, deputy health commissioner of Berwyn township for the past three years, has been appointed commissioner to fill the unexpired term of the late Dr. Edward J. Farrell. Dr. Frederick A. Causey, assistant managing officer of the Chicago State Hospital, has been appointed acting managing officer of the Lincoln State School and Colony, Lincoln. Dr. Phillip S. Waters, Alton, managing officer of the Lincoln school, has been granted a leave of absence on account of illness.

Thirteen Per Cent Too Slow to Drive Fast—Tests given to 4,271 persons at the Illinois State Fair in August show clearly that large numbers of people are not physiologically able to maneuver automobiles at high speeds under emergency conditions with the split-second skilfulness that must be employed to prevent accidents, according to the state department of health. The tests revealed that 13 per cent of the men and 33 per cent of the women required more than one-half second to apply the brakes on a car after the flash of a danger signal. In addition the tests showed that a noticeably higher percentage of persons over 35 reacted slowly about 20 per cent of the older and 12 per cent of the younger group requiring more than one-half second to apply the brakes. About one-third of the men and two-thirds of the women tested made poor scores on steering ability. The state department of health points out that the worst time of the year for traffic accidents in Illinois is usually in the last three months of the year. In 1935 there were 713 deaths during the last quarter against 597, 518 and 506 in the third, second and first quarters respectively. To date this year, mortality from traffic accidents has been almost parallel with that of 1935, indicating that about 700 more persons will be killed in Illinois before January.

Chicago

Dr. Lewis Gives Bevan Lecture—Dr. Dean DeWitt Lewis, professor of surgery, Johns Hopkins University School of Medicine, Baltimore, delivered the eighth annual Arthur Dean Bevan Lecture of the Chicago Surgical Society, October 2. His subject was "Endocrinology and Surgery."

Dr. Kanner Appointed to School of Dentistry—Dr. Oscar Kanner, formerly of Vienna, has been appointed professor of general histology, bacteriology and pathology at Loyola University School of Dentistry (Chicago College of Dental Surgery). He succeeds the late Dr. Emanuel Link. Dr. Kanner graduated in medicine at the University of Vienna in 1921. He came to the United States in 1927.

Large Gift to Wesley Hospital—Securities valued at more than \$1,000,000 were given to Wesley Memorial Hospital, October 14, by George Herbert Jones, formerly president of the Inland Steel Company. The money will be used to erect the first unit of a proposed new \$5,000,000 group of hospital buildings at Chicago Avenue, Fairbanks Court and Superior Street, near Northwestern University's McCormick Campus.

Personal—Samuel J. Beck, Ph.D., recently of the department of psychiatry, Harvard Medical School and Boston Psychopathic Hospital, Boston, has been appointed in charge of the psychology laboratory in the department of psychiatry at Michael Reese Hospital. Dr. Hugh Ernest Griffiths, London, and F. A. Lyon, secretary, Seamen's Hospital Society, Greenwich, England, will spend a few days in Chicago visiting various hospitals.

Symposium on Oxygen Therapy—The Chicago Medical Society will devote its meeting, November 4, to a symposium on oxygen therapy with the following speakers:

- Dr. Ford H. Hick, associate in medicine, University of Illinois and the staff of the Illinois Research Hospital, Physiology of Oxygen, Want with Discussion of Symptoms.
- J. I. Banash, consulting engineer, Accepted Methods of Administration to Assure Therapeutic Dosage.
- Dr. M. Herbert Barker, associate in medicine, Northwestern University School of Medicine, Clinical Response to Oxygen Therapy.
- Dr. Ralph M. Waters, professor of anesthesia, University of Wisconsin Medical School, Madison, Postoperative Use of Oxygen.
- Dr. Robert W. Keeton, professor of medicine, University of Illinois College of Medicine, will open the discussion.

INDIANA

Society News—The Dearborn Ohio County Medical Society was addressed in Lawrenceburg, September 24, by Dr. Daniel J. Davies, Cincinnati, on rupture of the uterus. At a meeting of the Montgomery County Medical Society in Crawfordsville, September 24, Dr. Foster J. Hudson, Indianapolis, discussed the care of new-born infants. Dr. Charles O. McCormick, Indianapolis, addressed the Boone County Medical Society in Lebanon, September 15, on rectal ether analgesia in labor. The Fountain-Warren County Medical Society was addressed in Kramer, October 1, by Dr. Donald C. McClelland, Lafayette, on treatment of cancer. Dr. Hugh A. Cowing discussed insulin protamine before the Delaware-Blackford County Medical Society in Muncie, September 29.

Public Health Conference—The forty-second annual conference of Indiana health officers was held at the Jefferson Plaza Hotel, South Bend, October 5-6. Speakers included Walter S. Frisbie, Ph.D., chief division of state cooperation, Federal Food and Drug Administration, Washington, D. C., on "Food and Drugs in Relation to Public Health," Dr. Calvin C. Applewhite, U. S. Public Health Service, Chicago, "Toll Time, Local Health Departments" and Dr. Reginald M. Atwater, executive secretary, American Public Health Association, New York, "What Next?" A symposium on syphilis, including the following speakers, concluded the session: Drs. Arthur F. Weyerbacher, Indianapolis; Minor W. Miller, Evansville; Ernest O. Asher, New Augusta, and Alfred S. Giordano, South Bend.

IOWA

Personal—George D. Stoddard, Ph.D., professor of psychology, State University of Iowa, Iowa City, and director of the Child Welfare Research Station, has been made dean of the Graduate College of the university, succeeding Carl E. Seashore, Sc.D. On the latter's retirement he was made dean emeritus.

Health Lectures for High School Students—The Crawford County Medical Society is presenting a course in public health for all high school students in the county. A course of nine lectures, one for each month of the school year, will be arranged on a rotating schedule, so that each talk will be given to every high school during the school year. Fifteen minutes of each period will be devoted to the lecture and ten minutes at the end of the period will be allowed for questions from the students. The society plans to make this an annual course. The program to be presented this year is as follows:

- Dr. Henry D. Jones, Schleswig, Heart Diseases and How to Prevent Them.
- Dr. Dora E. Kielhorn, Zarske, Characteristic Epidemic Contagious Diseases and Their Complications.
- Dr. Thomas L. Vineyard, Dow City, Care of the Digestive Tract.
- Dr. Edward N. Mark, Manilla, Kidney Infections in Youth.
- Dr. Carl A. Soc, Manilla, Tuberculosis in High School Age.
- Dr. G. K. Fair, Denison, Immunizations That Are Successful.
- Dr. Claudius L. Sievers, Denison, Functions and Dysfunction of the Ductless Glands.
- Dr. Amandus H. Grau, Denison, Epidemic Infections of the Respiratory System.
- Dr. John James Duffy, Denison, Venereal Infections in the Female.

Society News—Drs Hamilton Montgomery and Frederick A. Figi, Rochester, Minn., addressed the Decatur County Medical Society, September 22, on "Skin Carcinomas and Related Lesions"—At a meeting of the Pottawattamie County Medical Society, September 21, Dr Charles H. Watkins, Rochester, Minn., spoke on "Blood Dyscrasias"—Dr Elliott P. Joslin, Boston, will address the Linn County Medical Society, Cedar Rapids, October 27, on "Treatment of Diabetes"—Dr Harry H. Lamb, Davenport, was elected president of the Iowa Association of Ophthalmology and Otolaryngology at its annual meeting in Marshalltown, September 16; the next annual session will be held in Des Moines—A symposium on undulant fever was presented before the Boone-Story Medical Society, September 23, at Ames—The Cerro Gordo County Medical Society was addressed in Mason City, October 13, by Drs Hiram Winnett Orr, Lincoln, Neb., on "Treatment of Compound Fractures," and Draper L. Long, Mason City, on "Indication and Methods of X-Ray Pelvimetry"—Dr George B. Eusterman, Rochester, Minn., addressed the Clinton County Medical Society in Clinton, September 3, on diagnosis and therapy of gastroduodenal disorders; and Dr Daniel L. Sexton, St. Louis, October 1, on endocrinology—The speakers before the Dubuque County Medical Society in Dubuque, September 22, included Drs Budd C. Corbus, Chicago, on "Intradermal Immunization in Gonorrheal Infections," Earl C. Sage, Omaha, "Errors Made in Obstetrical Practice," and Frederick H. K. Schaaf, Minneapolis, "Liver Function and Differential Diagnosis of Jaundice"

MAINE

Personal—Dr John F. Shaw, who resigned as superintendent of Central Maine Sanatorium, Fairfield, in 1932, has been again named to the position to succeed Dr Arthur Paul Wakefield.

MARYLAND

The Dohme Lectures—Dr Charles H. Kellaway, director, Walter and Eliza Hall Institute of Research in Pathology and Medicine, Melbourne, Australia, will deliver the Dohme Lectures at the Johns Hopkins University School of Medicine, Baltimore, November 5-7. The titles of these lectures are "Snake Venoms: Their Constitution and Therapeutic Applications," "The Peripheral Action of Snake Venoms," and "Snake Venoms and Immunity."

MICHIGAN

Graduate Instruction in Obstetrics—The bureau of child hygiene and public health, state department of health and the department of postgraduate medicine, University of Michigan Medical School, Ann Arbor, are cooperating in a graduate course on obstetrics now under way in Traverse City, Petoskey, Alpena and Grayling. Dr Alexander M. Campbell, Grand Rapids, chairman of the maternal health committee of the state medical society, is presenting the lectures. Subjects include maternal and fetal mortality, antepartum care, toxemias of pregnancy, conduct of normal labor and postpartum care. These lectures, which will continue for six weeks, are a part of the state's social security program.

Michigan's Health in 1935—With 51,051 deaths from all causes in 1935, Michigan had a mortality rate of 10.05 per thousand of population. Organic heart disease, with 9,578 deaths, again led the list of ten principal causes of death. Next in order was cancer with 5,187 deaths, apoplexy with 3,907 deaths, pneumonia, 3,805, and nephritis, 2,974 deaths. According to the state health department, these five causes occupied the same relative positions as in previous years. Coronary disease and angina pectoris replaced accidents exclusive of automobile accidents, as the sixth major cause of death, with 2,352 deaths recorded in 1935. There were 2,161 deaths from accidents in the home, in occupations and in other pursuits where automobiles did not figure, the department pointed out. Tuberculosis continued to decrease, 2,045 deaths were recorded as compared with 2,199 in 1934. Automobile accidents appeared ninth on the list of leading causes of death, while diabetes remained in tenth place with a total of 1,230.

MINNESOTA

Illegal Practitioner Ordered to Leave State—Francis Howard Punched Sr., alias J. Francis Clark, following thirty-three days in the Minneapolis City and County Jail, pleaded guilty to a charge of practicing healing without a basic science certificate, October 5. He was given a suspended sentence of six months in the Minneapolis Workhouse provided he left the state in one week and did not return for five years. Punched, who is not licensed to practice medicine in any

state, was arrested following an investigation of the state board of medical examiners, which disclosed that he had been posing as a skin and cancer specialist. Unable to furnish a bond of \$2,000, he was placed in jail.

Society News—Dr Oscar O. Larsen, Detroit Lakes, was again elected president of the Northern Minnesota Medical Association at the annual meeting in Fergus Falls, August 31-September 1. Other officers are Drs Emmett A. Heiberg, Fergus Falls, vice president, and John F. Norman, Crookston, secretary. The Stearns Benton County Medical Society was addressed in Sauk Center, September 17, by Drs Joseph C. Michael and Olga S. Hansen, both of Minneapolis, on "Some Neuropsychiatric Considerations in Cases of Trauma—Accidental Injuries" and "Cardiac Disorders of Particular Interest to the General Practitioner"—Dr Alexander E. Brown, Rochester, discussed jaundice before the Washington County Medical Society, September 8—Dr Richard H. Jaffe, Chicago, will address the Hennepin County Medical Society, Minneapolis, November 2, on "Diseases of the Reticulo-Endothelial System."

MISSISSIPPI

Society News—At a meeting of the Winona District Medical Society in Winona, September 24, speakers included Drs Wallace L. Chambers, Lexington, on Vincent's infection of the chest, J. H. Eugene Rosamond, Memphis, infantile paralysis, and Eugene J. Johnson, Memphis, local anesthetics in certain abdominal conditions—At a meeting of the South Mississippi Medical Society in Laurel, September 11, the speakers included Drs Charles J. Bloom, New Orleans, on pediatrics, Henry T. Simon, New Orleans, infantile paralysis from the orthopedic point of view, John Gould Gardner, Columbia, infection of the hand, and Henry G. McCormick and the Hon. Ellis Cooper of Laurel, the legal use of the x-ray plate—The Marshall County Medical Society has been organized with headquarters in Holly Springs. Officers are Drs Curtis R. Senter, Byhalia, president, Ira B. Seale, Holly Springs, vice president, and Herbert S. Phillips, Holly Springs, secretary.

NEW JERSEY

"Pharmacy Internship" in New Jersey—A recent amendment to the New Jersey pharmacy practice act has enabled the board of pharmacy to prescribe the conditions under which a pharmacy graduate must obtain the one year's practical experience required precedent to registration as a pharmacist. That experience must be obtained in an "Approved Training Pharmacy" which conforms to certain regulations promulgated by the board. A pharmacy desiring to be so classified must make application for registration as an "Approved Training Pharmacy," and the list of such pharmacies is to be revised annually. During his internship the pharmacy graduate must, under the supervision of a registered pharmacist personally compound at least 600 prescriptions and take part in the sale of poisons at least sixty times. He must familiarize himself with the manufacture and wholesale distribution of drugs and must visit from three to five physicians for the purpose of discussing the prescribing of U. S. P. and N. F. preparations. Complete records of pharmacy internship must be kept by the pharmacy intern and by his employer, in a book supplied by the board of pharmacy, and these records must be submitted to the board when the application is filed for registration as a pharmacist. The board rules prescribe in detail the activities in which a pharmacy graduate must engage during his internship and provide generally that he must keep abreast of developments in pharmacy by additional study, attendance on lectures, and in other designated ways.

NEW YORK

New Bulletin—The Onondaga Medical Society and the Syracuse Academy of Medicine are publishing a joint bulletin, the first issue of which appeared in September.

Personal—Dr Alvah P. Maine Webster, celebrated his ninetieth birthday, September 21. Dr Maine graduated from the University of Pennsylvania in 1870 and established his practice in Webster in 1878.

Cornerstone for New Medical Building—President Roosevelt laid the cornerstone of the new building for the University of Syracuse School of Medicine, September 29. The building, which is being constructed as a WPA project at a cost of \$1,250,909, will be completed next year. It is a unit in a medical center that now contains the City Hospital, Syracuse Memorial Hospital and the Syracuse Psychopathic Hospital.

New York City

Dr Martland Reorganizes Department of Forensic Medicine—The department of forensic medicine, New York University College of Medicine has been reorganized under the direction of Dr Harrison S. Martland, Newark. In addition to undergraduate work, the department has developed graduate instruction leading to the degree of doctor of medical science and short, intensive courses in specialized branches of medico-legal work. The Charles Norris Fellowship in Forensic Medicine has been established, which is open to candidates applying for work toward the degree. Dr Martland succeeded the late Dr Charles Norris as professor of forensic medicine in January 1936. The latter had held the position since the establishment of the department in 1933.

Lectures on the Art and Romance of Medicine—The New York Academy of Medicine has opened a series of lectures to the public on "The Art and Romance of Medicine." Dr Smith Ely Jelliffe gave the first lecture, October 8, on "The Historical Background of Psychiatry." Other lecturers will be

Dr Francis G. Benedict, director Nutrition Laboratory, Carnegie Institution of Washington, Boston, November 12. The Physiological Cause of the Circus Elephant.

Dr Charles R. Stockard, professor of anatomy, Cornell University Medical College, December 10. The Mechanisms of Heredity.

Dr Karl Vogel, associate professor of clinical pathology, College of Physicians and Surgeons, Columbia University, January 14. Medicine at Sea in the Days of Sail.

Dr Frederick Tilney, professor of neurology and neuro-anatomy at Columbia, February 11. The Evolution of the Human Brain.

Dr Henry E. Sigerist, director, Institute of History of Medicine, Johns Hopkins University, Baltimore, March 11. The History of Medical History.

Dr Victor G. Heiser, president, International Leprosy Association, April 8. The History of Leprosy.

Dr Walter Timme, professor of clinical neurology at Columbia, May 13. The Story of the Glands of Internal Secretion.

OHIO

Course in Endocrinology—The Mahoning County Medical Society is sponsoring a graduate course in endocrinology in Youngstown, consisting of ten lectures by D. Roy McCullagh, Ph.D., and Dr Ernest Perry McCullagh, Cleveland. The series began September 23 to continue on succeeding Wednesday evenings.

Advisory Health Board—With the appointment of Drs. Carl S. Mundy, Stanley D. Giffen and Paul M. Holmes, an advisory health board has been created for Toledo. It will act in a purely advisory capacity on all municipal health matters and confer with the city manager, the welfare director and the health commissioner on current problems of the health department.

Personal—Dr. Chester W. Waggoner, Toledo, has been appointed a member of the state medical board. Wilton Marion Krogman, Ph.D., Cleveland, associate professor of anthropology, Western Reserve University School of Medicine, has been awarded the \$1,000 prize of the *Readers Digest* for his article on "The Skeleton Speaks," giving an account of some of his medicolegal interpretations of crime.

Society News—Dr. Justin M. Waugh, Cleveland, addressed the Hancock County Medical Society, Findlay, September 18 on "Deep Infections of the Neck."—At a meeting of the Ohio chapter of the American Physiotherapy Association in Cleveland, October 17, Dr. Rudolph S. Reich spoke on "Supracondylar Fractures of the Elbow," and Dr. Joseph L. Fetterman, "Cerebral Palsy." A clinic was held in the morning at Mount Sinai Hospital.—Dr. Max M. Peet, Ann Arbor, discussed "The Present Status of the Surgery of the Sympathetic Nervous System" before the Toledo Academy of Medicine, October 2.

Toledo Teachers Must Have Physical Examination—In accordance with a recent ruling of the board of education, an annual health certificate will be required of all teachers and other employees of the Toledo public schools immediately prior to the opening of the schools for the fall term. Examination and health certificate forms will be furnished each teacher and these are to be filled out, signed and certified to by the examining physician, preferably the family practitioner. A code system will be used to keep the report confidential. This measure has been adopted as a safeguard to the health and efficiency of the individual teacher as well as a health protection to the school child according to the *Bulletin* of the Toledo Academy of Medicine.

Health at Columbus—Telegraphic reports to the U. S. Department of Commerce from eighty-six cities with a total population of 37 million, for the week ended October 10, indicate that the highest mortality rate (20.5) appeared for Colum-

bus and that the rate for the group of cities was 11. The rate for Columbus for the corresponding week of 1935 was 11.7 and that for the group of cities 10.5. The annual rate for the eighty-six cities for the forty-one weeks of 1936 was 12.1, as compared with 11.4 for the corresponding period of 1935. Caution should be used in the interpretation of these weekly figures, as they fluctuate widely. The fact that a city is a hospital center for a large area or that it has a large Negro population may tend to increase the death rate.

PENNSYLVANIA

Hospital Seminar—The seventh annual graduate medical seminar of the Easton Hospital, Easton, was presented October 21. The speakers were Drs. Norman M. Keith, Rochester, Minn., on "The Action and Use of Diuretics," Wallace M. Yater, Washington, D. C., "Arteriography in Peripheral Vascular Disease," and Walter E. Dandy, Baltimore, "Diagnosis and Treatment of Cranial Nerve Lesions."

Philadelphia

Hospital News—The Skin and Cancer Hospital of Philadelphia has recently added two new wards of ten beds each for treatment of cancer, especially patients in advanced stages.—The board of managers of the Germantown Dispensary and Hospital gave a garden party October 3 for inspection of the hospital and the newly opened building for research on respiratory diseases.

Society Aids in Medical Relief—The Philadelphia County Medical Society will provide medical care to persons on relief for the period September 25-December 31, according to the *Weekly Roster and Medical Digest*. This action was acknowledged in a resolution adopted by the society following the announcement by the State Emergency Relief Board that it had abandoned medical relief service as of September 19. The members of the Philadelphia Association of Retail Druggists will cooperate with the medical society by donating their services and making only the lowest possible charge covering a portion of the ingredients and container. It was believed that, on U. S. P. remedies, this fee could be kept at a minimum of possibly 25 cents for each prescription. Persons on emergency relief needing medical care are urged to go to the physician of their choice. When unable to find a physician who will treat them free, they may telephone the office of the county medical society, who will give them a list of the cooperating physicians in their neighborhood. Under the society's plan, physicians have agreed to treat free only persons who at the time of their visits are on emergency relief and are not already receiving free treatment at a dispensary.

Pittsburgh

Pediatric Institute—The second of a series of three pediatric institutes sponsored by the state department of health and the Medical Society of the State of Pennsylvania was held at the Allegheny General Hospital, Pittsburgh, October 14. The speakers were Drs. James K. Everhart on "Appraisal of the Child," James L. Foster, "Gastro-Intestinal Disturbances and Infant Feeding," and Joseph S. Baird, "Contagious Diseases with Immunology." The last pediatric institute in the county will be held October 28 at the Western Pennsylvania Hospital.

PHILIPPINE ISLANDS

Dr Calderon Retires—Dr. Fernando Calderon, J. Roca has retired as dean of the University of the Philippines College of Medicine, director of the School of Hygiene and Public Health, head of the department of gynecology and director of the Philippine General Hospital. Dr. Calderon is 70 years old and was graduated from the University of Santo Tomas College of Medicine and Surgery, Manila, in 1891.

Lepers Demand Freedom—Several hundred lepers broke out of San Lazaro Hospital in Manila, October 6, and marched through the streets to the presidential palace to protest against being held as "prisoners," the *New York Times* reported. They contended that persons suffering from tuberculosis were more dangerous to the public than those afflicted with leprosy. On the promise of the secretary to President Quezon that he would present their views to the president, the lepers were taken back to the hospital.

Association Opposes Schools of Chiropody—The council of the Philippine Islands Medical Association at a meeting in July approved a resolution protesting against a bill introduced in the national assembly "to regulate the practice of chiropody." By the resolution the council protested against

establishment of chiropody, declaring that there is no real demand for practice of chiropody and if there should be any future demand for treatment of ailments of the feet and legs "there is even now an adequate supply of qualified medical practitioners who, with more competence, can render such service." The resolution also expressed the opinion that official recognition of the practice of chiropody "will ultimately result in the exploitation of the credulous public through exaggerated claims, thereby resulting in actual harm and injury to the health and lives of our people."

GENERAL

The Military Surgeons' Meeting—The forty-fourth annual convention of the Association of Military Surgeons of the United States will be held at the Hotel Book-Cadillac, Detroit October 29-31, under the presidency of Dr. Charles M. Griffith, Washington, D. C., medical director, Veterans' Administration. The speakers will include

Dr. Philip B. Matz Washington Diabetes Mellitus Among Veterans of the World War
Dr. Frederick G. Buesser Detroit Treatment of Peptic Ulcer
Dr. Frederick A. Collier Ann Arbor Gas Bacillus Infection in Civil Life.
Leigh C. Fairbank, D.D.S. Washington Medical and Dental Liaison in the Military Forces
Stanley W. Clark D.D.S. Chicago Recent Research in Local Anesthesia with Reference to the Development of the Alkaline Solution
Dr. William W. Hall Mare Island M. C. U. S. Navy Active Immunization Against Tetanus with Tetanus Toxoid
Dr. Irwin B. March Moncton Clemens Mich. M. C. U. S. Army Aviation Medicine
Dr. George W. Crile Cleveland Eighteen Years After

Acute Accidental Poisonings—A study of the records of 298 persons insured in the industrial department of the Metropolitan Life Insurance Company who died of acute accidental poisoning during 1934-1935 reveals that ninety were children under 5 years of age, according to the *Statistical Bulletin*. The manner of poisoning was given on 84 per cent of the death records and may be roughly grouped into three classes: poisonous substances picked up and consumed by children; poisons mistaken for medicines and overdoses of medicines; and ignorant use of substitutes for alcohol and fluids mistaken for alcoholic beverages. Poisonous substances picked up and consumed by children were responsible for eighty-two deaths. Strychnine caused the deaths of thirteen children drinking kerosene caused thirteen deaths, and, in addition, there were seven deaths from gasoline, benzene and other petroleum products. Mistaking poisonous drugs for medicines or overdoses of medicines containing poisons accounted for seventy-eight deaths. Veronal (barbital), luminal (phenobarbital), allonal (allylisopropylbarbituric acid and aminopyrine) and amytal led the list, with a total of fourteen deaths. Mercury bichloride with nine deaths was next in order, lysol (saponated solution of cresol) caused six deaths, arsenic, acetanilid and paraldehyde with four deaths each were next in numerical importance. The bulletin offers suggestions and safeguards to educate the public in an effort to reduce these accidental deaths.

Radio Forum—Growth of the Child—The American Academy of Pediatrics, the National Broadcasting Company and the National Congress of Parents and Teachers are cooperating in a radio forum on the growth and development of the child. Dr. Norman C. Wetzel, Babies and Children's Hospital, Cleveland, is editor. The series, which opened October 21, will continue each week until May 19. For the next two months the program will be as follows:

Dr. George L. Streeter director department of embryology Carnegie Institution of Washington Baltimore October 28 Prenatal Growth
Dr. Harry Bakwin, assistant professor of pediatrics New York University College of Medicine November 4 Growth of Infants
Dr. Horace Gray, clinical professor of medicine Stanford University School of Medicine, San Francisco November 11 Growth of the Adolescent
Richard E. Seamon LL.D. Distinguished Service Professor Graduate Faculty University of Minnesota November 18 Growth of Organs
Earnest A. Hooton Ph.D. professor of anthropology Harvard University Cambridge November 25 Our Ancestors
Amos H. Hersh Ph.D. associate professor of biology Western Reserve University Cleveland December 2 Does Life Beget Life?
Dr. Harold C. Stuart assistant professor of pediatrics and child hygiene, Harvard University Medical School Boston December 9 Measurements of Growth
Dr. Alfred H. Washburn associate professor of pediatrics University of Colorado School of Medicine Denver December 16 Individual Variations in Infants and Children
Elmer V. McCollum Sc.D. professor of biochemistry Johns Hopkins School of Hygiene and Public Health Baltimore December 23 Foods and Growth
Dr. Samuel Z. Levine professor of pediatrics Cornell University Medical College, New York December 30 Chemical Elements and Their Part in Body Growth.

These lectures are being given over the Blue network of the National Broadcasting Company every Wednesday afternoon at 4 o'clock eastern standard time.

New Test for Estimating the Toxicity of Mineral Oils

The Manchester Committee on Cancer has just issued its report for 1935. Dr. C. C. Twort, director of the Cancer Research Laboratories, states that since the publication of the last report a new test has been devised for assessing the toxicity of mineral oils. Having found a simple method by which the approximate carcinogenicity of a mineral oil could be rapidly ascertained—by examination of its refractivity—they investigated how the animal cells reacted to oils and thus brought the new test to light. The test shows not only the probable carcinogenicity of an oil but also its probable power of causing dermatitis. It is performed by injecting a few drops of oil into an animal and recovering it for examination as to its physical characteristics. The basic principle of the test is that if the oil is toxic the animal will alter its physical characteristics, while nontoxic oil remains unaltered. When the animal reacts against the toxic oil, a fall is produced in the refractive index roughly proportional to the carcinogenicity plus the dermatogenicity of the oil.

The following conclusions have been reached: 1. The fall in refractive index is proportional to the degree of unsaturation or dehydrogenation of the oil. 2. There is no change in the refractive index of such oils as medicinal liquid petrolatum, squalene (a highly unsaturated pure hydrocarbon oil obtained from the liver of the dogfish) and cylinder stocks, all of which cause little or no reaction in the skin of an animal when placed in contact with it. 3. The refractive index fall varies inversely as the viscosity of the original oil. 4. There is a definite correlation between fall of refractive index and carcinogenic potency, viscosity and refractivity. The practical importance of these researches lies in their bearing on "mule spinners' cancer" (cancer of the scrotum due to contact with the oil used for lubrication in their work). A noncarcinogenic oil can be selected for use.

Another line of research was investigation of the oily tarry material recovered from soot emitted from the exhaust of high compression internal combustion engines. The soot contained about 3 per cent of this liquid material and when placed in contact with the skin of animals proved carcinogenic. The activity of this material was high—about that to be expected in view of the activity found by previous experiments on mineral oils cracked at different temperatures. It appears that at a certain critical temperature mineral oils regardless of their actual carcinogenicity, can be brought by cracking to a more or less constant carcinogenicity.

Research at the Royal College of Surgeons

The annual report of Dr. Beattie, the conservator of the museum and director of research of the Royal College of Surgeons, contains reports of important researches carried out during the year.

THE NERVOUS FACTOR IN TRAUMATIC SHOCK

Mr. O. Shaugnessy and Dr. Slome have continued their investigations on traumatic shock. In previous work they concluded that some other factor than fluid loss and tissue toxins was necessary to account for the shock that follows severe trauma. They therefore investigated the nervous factor and showed that in the period during which there is a marked fall in blood pressure there are continuous discharges of nerve impulses from the traumatized area. These impulses have been photographed by means of a cathode ray oscillograph. Their

investigations are proceeding along the lines of determining the exact nerve endings from which these impulses arise and the factors inducing their production. They are also concerned with the exact level in the nervous system at which these impulses produce their depressor effect on blood pressure. They have taken as the criterion of the intensity of the shock the lowering of the blood pressure in the general circulation, which seems to be the only one at present available for quantitative study. Their experiments in blocking the impulses by means of spinal anesthesia have suggested a possible line of treatment for the shock condition.

THE TOXIC FACTOR IN INTESTINAL STRANGULATION

Mr G. C. Knight and Dr David Slome have investigated the toxic factor in intestinal strangulation. They demonstrated the presence of a toxin (which caused marked depression of blood pressure and even death when injected intravenously into a normal animal) in the peritoneal fluid surrounding non-viable loops in the venous blood of the loops of all types, viable and nonviable, in the thoracic duct during absorption and in the urine. Using loops that had been completely cleared of intestinal content by irrigation, they showed that the toxin arises within the wall of the strangulated segment and passes thence into the lumen and into the venous blood and lymphatics. It appears to be a new product formed as a direct result of strangulation and not a substance previously existing in the intestinal lumen, which has merely been absorbed. Whether it arises from metabolic changes or bacterial action is being investigated. It has been demonstrated within half an hour of the onset of strangulation. Further experiments have been performed in order to assess the importance of the return of the toxic substance to the general circulation following relief of the strangulated loop. In certain cases, even of a viable type, relief of the strangulation is accompanied by a marked fall in blood pressure, and occasionally death ensues. An attempt is being made to determine the factors that govern these phenomena. Some early experiments in man show that a similar depressor substance is present in high concentration in the dialysate of the urine of patients with intestinal strangulation, whereas the dialysate of normal urine has no effect on blood pressure or contains only a minute quantity of the substance. After a period of twelve hours a similar depressor substance has been found in the peritoneal fluid in human cases but could not be found before this period in five cases. This may be of significance as the twelve hour period has been shown to be the critical time at which the mortality begins to rise from nothing to 30 per cent and thereafter to 60 or 80 per cent at the forty-eight hour period. Biologic tests with preparations of the isolated uterus and intestinal strips indicate that the toxic substance is different from histamine or acetylcholine.

NERVE GRAFTING

The late Dr A. B. Duval stated that degenerated nerve grafts, taken either from the individual in whom the graft was placed or from another of the same species, was more efficacious than grafts not degenerated. Miss Hill and Mr Bentley have completed a series of experiments which show that: 1. A nerve graft, whether autogenous or homogenous, will serve to bridge a nerve gap and allow a large number of axons to reach the distal segment. 2. There is no difference in the time of recovery of function between animals which have had fresh and which have had degenerated grafts. 3. The number of new growing axons that pass into the distal segment is determined by the amount of scar tissue formed at the junction of the nerve with the graft and the amount of scar tissue that has developed within the central end of the grafted nerve at the upper line of junction. They conclude that to reduce the production of scar tissue to a minimum and thus obtain the best results—absolute approximation and almost exact equality of size of the cut ends of the graft and the nerve—are essential

Recent Changes in Social Insurance Laws

Although the Social Insurance Law, when first enforced in 1930 was considered an ideal one by its proponents, a number of modifications have already been made. In the fall of 1930 a complete revision was legalized, but this practically revamped law did not go into effect until the spring of 1931, a delay which has caused much confusion. The law as it now stands is briefly as follows. Some recent (August 26) changes will be cited later.

RELATIONS BETWEEN THE INSURED AND THE SOCIAL INSURANCE AUTHORITIES

In addition to those employed in industrial pursuits who were obliged to be insured, those who work at home, commercial travelers, chauffeurs of all kinds of vehicles and others are now included. The right of an employee to decide whether he or she wishes to be insured is now suppressed, that is, optional insurance no longer exists except for those in agricultural pursuits.

On the employer is placed the responsibility of sending to the caisses or primary collecting and disbursement offices his own premiums and those of his employees.

Every pay day the employer deducts 3.5 per cent of the salary of each employee and, having added an equal amount, the premium thus collected must be forwarded within ten days to the nearest postoffice.

Social insurance does not include industrial accidents and diseases. According to the older law, the insured could receive an indemnity only during the first six months of an illness, but this has been changed so that after the lapse of two months during which no indemnity is received, a new period begins so that indemnity can be given for a second six months if proof can be furnished that the insured is not cured, or the indemnity is granted until the termination of the illness irrespective of the duration of the same.

The caisse or bureau must be notified now within three instead of six days after the beginning of an illness, in the form of a letter attached to the physician's certificate thus greatly simplifying the former very complicated procedure.

The free choice of the medical attendant continues, thus differing from the system in some other countries in which only a physician appointed by the social insurance organization can treat a patient.

Great latitude is permitted in the way of prescribing drugs and apparatus, but attention is to be paid to using the less expensive of these.

No physician deals directly with the social insurance offices or caisses. He is paid by the patient who is allowed a certain sum for each day of illness, or in case of operation the sum allowed is proportionate to the character of the intervention. Before the insured worker can receive any money from the caisses or offices, his or her certificate must be signed by the attending physician or surgeon.

A fee table arranged by the syndicates or medical unions governs the charges of the medical attendant.

If an insured wishes to become a hospital patient he must enter an institution having a contract with the social insurance authorities. The patient must pay the difference between the price for hospital care demanded by the institution and the amount allowed by the caisses or insurance bureau. The latter allowance however can never be higher than the minimum fee paid by patients admitted to public hospitals. This amount is 10 francs (\$2.50) a day. If the insured prefers a hospital which has no contract he or she receives an indemnity equivalent to that received for illness at home.

This applies also to maternity cases. The insured must be willing to permit a physician appointed by the caisses or bureaux to verify the diagnosis and the like but this can be done only in the presence of the attending physician of the insured.

In case any prescription costs more than 25 francs (\$1.75) or any special treatment is needed, the medical inspector must give his approval.

RELATIONS BETWEEN PHYSICIANS AND SOCIAL INSURANCE AUTHORITIES

1 Medical service. The caisses, or insurance bureaux, can make contracts with the medical syndicates or unions by which a fee table for services rendered to the insured is agreed on.

2 Hospitalization. Every public and private hospital can make contracts with the social insurance authorities according to which they care for the insured at an agreed daily rate. As stated previously, if an assured worker chooses to enter a hospital not having such a contract, he or she is allowed only a sum equal to that paid if he or she remained at their domiciles.

The caisses or insurance bureaux allow certain amounts for daily care and also for medical attendance if the insured is in a contract hospital.

LATER MODIFICATIONS PUBLISHED AUGUST 30 1936

1 Every French citizen, male or female, who works for one or more employers and earns less than 21,000 francs is obliged to become an insured according to the new law. (This annual sum was formerly lower, so that more workers are now included.)

2 If the insured cannot, after medical examination resume his or her work six days after the onset of an illness, he can be indemnified up to a period of six months. This indemnity cannot be below 3 francs nor more than 22 francs (\$1.50) per day.

Treatment of Acute Osteomyelitis of Adolescents

The question as to whether it is not better to operate on an acute osteomyelitis in adolescents at a late stage, when the process is well localized in the bone and the evidences of a generalized toxemia have subsided, was discussed at recent meetings of the Académie de chirurgie of Paris. The papers by Leveuf, who is an advocate of late operation, and of Sorrel and others, who opposed this point of view, have been referred to in previous letters.

The discussion was terminated at the June 17 meeting of the society by Leveuf himself. He stated that emergency operations on suppurative foci in general were being less often employed at present, and in place of this every effort is made to aid the resistance of the organism by nonoperative measures. The surgeon intervenes only when the pus is well localized but this does not mean that no operation at all is to be performed. To place an inflamed limb at rest in a plaster splint as advocated by Boppe, another Parisian surgeon, greatly aids in recovery.

One encounters cases of acute osteomyelitis termed the septicemic type, in which there is high fever, positive blood cultures and grave general symptoms, whereas the bone focus symptoms are minimal. No form of local treatment even amputation would be of any avail in such cases. Opposed to such hopeless cases, all other varieties are encountered in which it is impossible at the onset for the surgeon to ascertain the severity of the local infection. The operation must be one that is adapted to each individual case. It is still a debatable question as to whether an early trephining of the bone is of benefit or not. Certain recently published statistics would lead one to believe that it does more harm than good. Joint complications and secondary foci are observed twice as often after trephining as after simple incision of a subperiosteal abscess.

The operative indications in osteomyelitis are of two kinds (a) to evacuate a subperiosteal abscess and (b) to treat the bony focus. The former ought not to be opened too early, one can wait for one or two weeks without danger. With the aid of roentgenography the formation of a sequestrum can be easily ascertained and operation for its removal performed. There are other cases which are less favorable. The fever returns, the limb is swollen and roentgenography reveals extensive lesions. Here an extensive resection of the diaphysis is indicated according to Leveuf.

Heredity and Tuberculosis

Since ancient times it has been assumed that some etiologic factor based on heredity is present in tuberculosis. That view is justifiable. The heritability of a predisposition plays an important part in tuberculosis along with the danger of bacterial dissemination. This subject has been elaborated in Germany during the last few years. Münster, for example, on the basis of thoroughgoing familial examinations, has formulated tables of relationship. He came to the conclusion that a predisposition, namely, a predisposed pulmonary weakness toward tuberculosis and other infectious diseases, does exist, that it is in fact inherited and in all probability subject to the law of recessive hereditary transmission and in any case is compatible with the laws of recessive hereditary descent. Ickert,

Likelihood that a Child Will Become Tuberculous

	Percentage of Probability
1 Both parents healthy and untainted	5.3
2 Both parents healthy, siblings or grand siblings (of one spouse) tuberculous	6.0
3 Both parents healthy, one parent of one spouse tuberculous	6.5
4 Both parents healthy, one or more children already tuberculous	14.1
5 Both parents healthy, one or more children already tuberculous, siblings of the parents or parents of the spouses tuberculous	20.5
6 One parent tuberculous without further defect the other parent untainted	19.5
7 One parent tuberculous otherwise as in group 6 in addition other children already tuberculous	40.1
8 One parent tuberculous otherwise as in group 6 in addition siblings or grand siblings tuberculous	27.1
9 One parent tuberculous otherwise as in group 6 in addition one or both of this parent's parents tuberculous	39.1
10 Both parents tuberculous together with additional taint from either side	58.7

a well known research worker on tuberculosis, has come to the same conclusion. In collaboration with Benze he has investigated, by means of genealogical research, the influence of tubercle bacilli and the individual human constitution on the tuberculous process. These authors assume that all tuberculous infection is ascribable to a heritable congenital predisposition, since practically every person who presents evidence of an established recessive hereditary transmission of this nature will become tuberculous. Nothing is stated, however, as to what course the disease will take, since this is dependent on secondary endogenic and exogenic factors. Whereas Münster assumes a nonspecific predisposition (based on a lack of pulmonary resistance to infections), Professor von Verschuer believes, on the basis of research on tuberculous twins undertaken in collaboration with Diehl, in the existence of a specific inherited predisposition toward tuberculosis. After observing the interrelation of the incidence of tuberculosis and environmental factors, von Verschuer and Diehl made the remarkable discovery that an identical behavior of tuberculosis cases pre-

senting extremely disparate environmental influences could be demonstrated only in enzygotic twins. Therefore, according to the sum of these observations, the hereditary predisposition is the crucial factor in the etiology of and subsequent course pursued by the tuberculosis.

Environmental influences are to be thought of also, but the eugenic factors are still important considerations in the campaign against tuberculosis. The German writers who have treated this subject find it desirable that persons with hereditary tendencies toward tuberculosis be restrained as far as is possible from contracting marriages. These writers are furthermore of the opinion that in any such case in which the prevention of offspring is unqualifiedly indicated the tuberculous person should be sterilized at his own request. The German legislation for prevention of hereditarily defective offspring should be extended so as to include persons who present progressive and advanced tuberculosis, those who present asocial and antisocial open tuberculosis, and any pair of tuberculous marriage partners. To judge the likelihood that a child of given parents will become tuberculous, Ickert and Benze have computed the accompanying "risk table."

Result of the Examination of Lupus Patients

During the year 1935, in the province of Thuringia, all persons known to be suffering from lupus and their relatives were subjected to a thorough examination. The result was recently published in the *Münchener medizinische Wochenschrift*. Since 456 patients were examined, the results are of particular interest. Of these 456 persons, 143 were men, 278 women and thirty-five children, thus, the number of women was nearly twice that of the men. The latter fact serves to corroborate previous statements with regard to a greater morbidity among females. The occupations most commonly represented by the patients were, among men, factory workers and laborers (twenty cases), artisans (twenty-three cases) and small independent tradesmen (thirty-two cases). There were, however, only one teacher and one waiter among the male patients. Of the women the vast majority (206 of 278) were housewives, young women living at home and domestic servants, next, at a great distance, followed factory workers (twenty-nine cases). The figures for other occupational groups were insignificant.

Of the 456 lupus patients, eighty presented tuberculous alterations of the lungs, this group was composed of thirty men, forty-four women and six children. Tuberculosis other than pulmonary was found in nine patients.

In addition, 651 relatives of the lupus sufferers were examined, sixty-eight of these presented pathologic tuberculous alterations of the lungs (including two cases of pneumoconiosis) or tuberculosis at some other site. Of the sixty-eight relatives fourteen were found to present open tuberculosis and in five of these cases the disease was detected for the first time by this examination, the other nine cases being previously known to the antituberculosis centers. The outcome of this examination suggests once more the need for roentgenologic pulmonary examinations of all lupus patients and their relatives.

Dental Caries in Prehistoric Man

Dental caries is discussed by M. H. Baegé in an extensive treatise on the diseases of prehistoric man. To the men of the paleolithic age dental caries was still unknown. This refers to be sure, only to European relics of the Old Stone age. Paleolithic specimens in Africa show that dental caries had already appeared in that continent. The first European evidence that relates to the disease belongs to the mesolithic age. In the succeeding epoch dental caries seems to have increased steadily. In the neolithic period of Egypt dental caries appears still to have been a disease of rare occurrence. In later ages and especially during the period of Roman domination the incidence of the disease increased rapidly, however

From the material in hand to date it may be assumed that dental caries was still unknown to paleolithic man. The disease makes its initial appearance in the mesolithic age, occurring at first sporadically and then with ever greater frequency. By the close of the neolithic period the form of the caries approaches that of the modern disease. It may accordingly be said that the first appearance of dental caries coincides with the beginnings of human civilization. What has been said of caries is equally true of rachitis and is apparently likewise applicable to tuberculosis. With the exception of the men of the earliest paleolithic times, prehistoric man would seem according to the evidence not to have possessed that robust constitution which is popularly attributed to him.

VIENNA

Sept. 10, 1935.

Death of Prof. Julius Tandler

A few days ago the news reached Vienna that Prof. Dr. Julius Tandler, former director of the First Faculty of Anatomy in Vienna and former head of the local bureau of health, had died suddenly in Moscow. This news brought a sense of keen bereavement. His was an interesting career, not devoid of a certain element of tragedy. Born in the neighborhood of Vienna in the year 1869, the eldest of numerous children of a wretchedly poor family, Tandler attended the lower schools and the university in Vienna, graduating from the latter in 1895. He then immediately took up the study of anatomy, since three years previously he had been chosen by Professor Dr. Zuckerkandl, the head of the Faculty of Anatomy, as a demonstrator. One year later he became assistant at this institution, by 1899 he was a docent. As Zuckerkandl declined in health, Tandler, who attained professional rank in 1903, came to substitute for him both as lecturer and as examiner. After Zuckerkandl's death, Tandler was selected and appointed his successor *unco loco*. He remained at the head of the First Faculty of Anatomy from 1910 to 1933.

During this time the university repeatedly entrusted to him the highest posts of honor, then in 1919 he became under secretary of public health in the postwar Socialist ministry. In this capacity he rendered notable service. In 1920 he was appointed head of the city health department in Vienna and became reorganizer or, to put it more aptly, creator of a comprehensive public health system for the metropolis. Tandler's reputation as an anatomist was international. He was a distinguished teacher, brilliant lecturer and wit. His position afforded him abundant opportunity for scientific work and for the training of exceptional pupils. Tandler has enriched the science of anatomy with a vast amount of research. The following are only a few of his important contributions: a topographic anatomy of emergency operations that is indispensable to the practicing surgeon, fundamental work on the female pelvis in collaboration with Halban, elucidation of important gynecologic questions, work on the surgery of the brain in collaboration with Professor Ranzi, and work in the field of dental anatomy, in which he was assisted by Professor Sicher. In addition he became interested in the heart and published a notable work on cardiac embryology, and last but not least there is his great textbook of systematic anatomy. Tandler also edited the *Zeitschrift für Konstitutionslehre* in which the latest results of research on the endocrines were worked up. Well known too are his *Anatomy for Artists* and his studies of infantilism and of the effect of castration on the organism. In connection with his investigations of the last named topic he repeatedly frequented the sect of the Skoptzi in Russia. As head of the Vienna bureau of health, Tandler established a whole group of standardized procedures that have been studied by specialists the world over and adopted by many municipalities. His principal concern as a public health official

was child welfare, since after the war there was a genuine danger of depopulation. Tandler organized a system of child welfare agencies that function in the interest of an individual infant even before birth. In Vienna welfare centers were set up for expectant mothers, for new-born infants and for nursing, the school children were kept under careful control by skilled physicians and nurses, school dental clinics were instituted as well as centers for examination of the eyes, and tuberculosis was attacked on a large scale by the construction of amazingly large numbers of sanitary, sunny dwellings. As a result of Tandler's initiative, Vienna came to possess some 50,000 sanitary dwellings that were rented to the poorer classes of the population. Sports and physical culture also found in Tandler an ardent advocate. His activities brought him into contact with questions of population policy, by which his destiny was further influenced. His success as an organizer of systematic public hygiene resulted in his being called to China to organize the public health activities there. This invitation he gladly accepted, since in Vienna he had had certain differences with his friends over questions of policy. He was not involved in the political revolution that took place in Austria in 1934, as he had been absent from Vienna since 1932 and he was completely exonerated when the legal proceedings against the socialist regime were instituted. In 1933 he was dismissed from his post of professor of anatomy. Thereafter he made his home in China, whence he was called to Russia, as he had been called to China, to organize the public health service. He also managed to interpolate extensive lecture tours in Russia, Japan and North America. In the midst of his activity this distinguished man was carried off by a heart attack.

Physiology of Aviation at Great Altitudes

Prof Carlo Foà, regular professor of physiology at Milan University, in a lecture recently delivered before the physicians of the army spoke on physiology of aviation at great altitudes. The resistance that the atmosphere offers to moving airplanes increases in proportion to the square of the speed of the machine. The studies made on physiology of aviation at great altitudes were preceded by studies on the life of men at the highest spots in the Alps. The methods used in these studies were those of Angelo Mosso and, more recently those in which chambers for decompression of air are used. In these chambers it is possible to produce, by means of suction pumps a progressive decompression of the air which corresponds to the different altitudes as the ship ascends.

Professor Herlitzka, instructor in physiology at Turin University, in his experimental studies on the subject, brought rarefaction of the air to a minimal pressure of 50 mm of mercury which corresponds to 19,000 meters above sea level. The figure is of importance because of the fact that above this altitude the alveoli of the lung are able to absorb no more gases than water vapor. In case of flying to such an altitude the body temperature would rise to such a height that the body fluids in contact with the atmosphere would boil. At an altitude of 10,000 meters above sea level the atmospheric pressure is reduced to one fourth the normal atmospheric pressure. A given weight of air at 10,000 meters above sea level occupies four times as much volume as it would occupy at sea level. Therefore the quantity of oxygen contained in a given volume of air at this altitude is much less than that which is needed for respiration. Aviators at this altitude should breathe oxygen from an artificial supply. With this purpose in view the speaker advises the use of apparatus for the self administration of oxygen that is, those with a closed circuit of the type of those which are now in use in the defense against war gases.

Professor Talenti of the Turin school found that the oxygenation of the blood in the lungs in breathing in an atmosphere of rarefied air is insufficient. When breathing is made under a pressure of 130 mm, which corresponds to 12,540 meters at sea level, it is diminished to two thirds in comparison with normal respiration. When respiration is made under a pressure of 115 mm, which corresponds to an altitude of 13,320 meters at sea level, the excitability of the nervous center of respiration is greatly lowered. It is necessary to recall frequently to the aviator his need of breathing oxygen, to which a small amount of carbon dioxide should be added. The speaker in his experiments with rarefied air reached a pressure of 107 mm of mercury, which corresponds to 14,000 meters at sea level. The Italian aviator Donati reached sometime ago an altitude of 14,433 meters at sea level, which corresponds to a pressure of 96.5 mm. He was breathing a mixture of oxygen and carbon dioxide while flying. The amount of oxygen in the lungs of aviators who reach an altitude of 14,433 meters is smaller than that which existed when death of the aviators in the *Zenith* and of the alpinists at Everest took place. According to the speaker, the reasons why Donati was able to resist such altitudes were that the period of time in flying was short and that the muscular work performed by the aviator was as minimal as possible, in comparison to that performed by the former rescarchers. Professor Herlitzka says that flying can be indefinitely prolonged if it is made up to an altitude of 12,000 meters above sea level, provided the aviator's respiratory apparatus is protected against the ambient air and the aviator breathes a mixture of oxygen and carbon dioxide. If aviation is performed in the stratosphere, that is, 16,000 meters above sea level, the aviator should be entirely isolated from the external ambient air either in an air-tight cabin or in individual apparatus. Such appliances, similar to those used in diving, are being developed in France, Spain and the United States.

Fracture of Neck of Femur

Professor Pieri, in a lecture recently delivered before the Società medica di Friuli, spoke on fractures of the femoral neck. He made a differentiation between fractures of the surgical neck of the femur and those of the anatomic neck of the femur and also between recent and old cases. Reduction of the wedge of the fracture followed by traction for two months is the preferable operation in fractures of the surgical neck (retrochanteric fractures). Mobilization in old patients should be started, however, earlier than that. Curvilinear or oblique osteotomy is indicated in cases of long duration, not in old patients, in correcting the femoral deviation that usually remains under the form of coxa vara. In recent fractures of the anatomic neck, fibular nailing is indicated. In cases of long duration complicated by pseudarthrosis, it is advisable to reopen the fracture through an anterior incision, to make it bleed again, and then in the same operation to perform the fibular nailing.

Professor Devoto Is Dead

Prof Luigi Devoto, a senator and the founder and first director of the Clinica del lavoro at Milan University, is dead. Professor Devoto graduated from Genoa University and was professor of medical pathology at Pavia University and director of Milan University. In both universities he established postgraduate courses in social and industrial diseases. He was surgeon general of the army during the war, founder of the journals *Il lavoro* and *La medicina del lavoro* and president of the Società italiana di medicina del lavoro and president of the clinical institutes for postgraduate work at Milan. Professor Devoto published important articles on lead and mercury chronic poisoning, pellagra and several diseases. He also wrote books on physiologic chemistry, immunology, clinical

medicine, semeiology and medical technics. He was a collaborator to the following books: "Trattato italiano di patologia e di terapia," "Trattato di diagnostica e terapeutica per medici e studenti" and "Trattato sulla tubercolosi."

RIO DE JANEIRO

Uterine Hemorrhage in the New-Born

Dr. Barros Vianna, in a recent lecture before the Associação Paulista de Medicina, reported a case of uterine hemorrhage of two days' duration in a new-born infant. According to Halban, uterine hemorrhage in new-born infants is due to uterine changes caused by the presence of placental substances in the infant's blood. Jappert, in studies of such cases, found subepithelial hemorrhages with passage of blood into the uterus. Halban also, in studies of the internal genital organs of the infants who had not suffered from uterine hemorrhage, found uterine congestion and subepithelial hemorrhage. The uterine changes were not caused by ovarian secretions, because the ovaries in all cases were still in complete rest. Several of the hypotheses given to explain the uterine hemorrhage in infants cannot be supported. Ferraresi's hypothesis (stasis due to asphyxia) conflicts with the fact that cases of uterine hemorrhage have been observed even in infants delivered in cesarean section. That of Eroess (endometritis) is nullified by the results of Jappert's anatomopathologic studies of the uterus in that condition, in none of which was endometritis found. Schukivski's hypothesis (intestinal irritation causing congestion of the internal genitalia) is not correct because the conditions mentioned may coexist but there is no relation of cause and effect between them. Halban's theory of presence of placental substance in the infant's blood seems to be supported by the fact that Schlachke found hyperemia, hemorrhage and prostatic secretion in anatomopathologic studies on internal genitalia of new-born infants. Vianna pointed out the benign evolution of uterine hemorrhages in infants except in cases in which the hemorrhage is a symptom of septicemia or of hemorrhagic diathesis. He discussed the differential diagnosis of uterine hemorrhage in infants and said that infants suffering from the condition should not be given any treatment, not even vitamin C because of the fact that the hemorrhage disappears spontaneously in a few days.

Therapeutic Applications of Vitamin C

Dr. Vicente Baptista, in a recent lecture before the Associação Paulista de Medicina, said that Szent-Gyorgyi succeeded in isolating from certain plants and from the adrenals a substance that was identified as vitamin C (cevitamic acid). The substance can be chemically synthesized. It has oxidation-reduction properties and an action in controlling organic diseases. The speaker reviewed the work performed by Stepp and his school in the medical clinic of Munich with relation to the action of vitamin C in controlling diseases of the blood. He reviewed also the literature in which satisfactory results are reported from the use of vitamin C in the treatment of gynecologic hemorrhages. According to the speaker, the treatment with vitamin C is indicated in pigmentations of the skin, dimetrophenol toxic cataract, internal medicine and neuropsychiatric and pediatric diseases. The speaker reported satisfactory results from vitamin C in a case of hemophilia in his practice. Several vitamin C preparations ready for clinical use are in the market from some foreign countries. In São Paulo a vitamin C preparation will be in the market in the near future.

Histology of Leprous Neuritis

Dr. Vincente Grieco, in a recent lecture before the Sociedade de Leprologia de São Paulo, reported results of studies of cases of leprosy neuritis. He found in the trunks of the nerves alterations corresponding to tuberculous, pure nervous and

tuberculous forms of leprosy. The different types of neuritis that involve the trunks of the nerves are of an interstitial type. The granulomatous tissues first involve the nerve fiber and then cause its destruction. In tuberculous neuritis there is a great infiltration with presence of Virchow's vacuolized cells and of a large number of leprosy bacteria. In pure nervous neuritis there are few and small foci of infiltration containing lymphocytes. A consequent reaction of intense fibrosis with a process of calcification takes place. Leprosy bacteria are few. In neuritis of the tuberculous type the infiltration is made by epithelial cells, lymphocytes and giant cells. Frequently there are processes of caseification and calcification. Leprosy bacteria in the infiltration is rarely found in this form of neuritis. The types of neuritis caused by involvement of the fibers at the level of the cutaneous lesions show, as a rule, leprosy infiltration around the perineurium. Frequently the perineurium is entirely degenerated.

Marriages

- HOLLAND STEVENSON, Pelham, N. Y. to Miss Kathleen Elizabeth Brady of New Rochelle, in Trout River, August 20.
DONALD MORRISON BALDWIN, Jacksonville, Fla., to Miss Rowena Virginia Mann of Lawrenceville, Ill., September 1.
ALLEN MARSTON BOYDEN, Portland, Ore., to Miss Margaret French Davis of Ann Arbor, Mich., September 19.
LOUIS DE ANGELIS to Miss Mae Carmela Cavalier, both of New Haven, Conn., in Richmond, Va., June 2.
COLUMBUS HERSCHEL BARNWELL, Asheville, N. C., to Miss Esther Ireland of La Fayette, Ill., September 19.
L. EDWARD GIOVINE, Woodside, N. Y., to Miss Anne Sheridan of East Elmhurst, L. I., New York, July 25.
ROBERT KEMPTON HARVEY, Kearney, N. J., to Miss Lydia Elizabeth Mesquita of Brooklyn, August 22.
WILLIAM JOSEPH DOYLE, Wilkes-Barre, Pa., to Miss Catherine Murray of Ashlev, September 3.
ROGER M. MINKEL, Svecia City, Iowa, to Miss Dorothy Dusk of Iowa City in Fort Dodge, September 8.
STEPHEN J. DONOVAN, Detroit, to Miss Rachel Alice Greaves of Ann Arbor, Mich., September 7.
JOHN DUTTON STEELE JR. to Dr. Betsy Spragles Owen, both of Ann Arbor, Mich., July 2.
LAWRENCE T. MINISH JR., Frankfort, Ky., to Miss Virginia Duncan of Greenville, June 13.
PAUL L. BOISVERT, Geneva, N. Y., to Miss Martha M. Hancock of St. Louis, September 19.
MAX LEOPOLD BRODNY, Boston, to Miss Jeannette Steinberg of Brookline, Mass., August 23.
ALEXANDER W. BLUMBERG to Miss Ruth Tietbolli, both of Williamsport, Pa., August 22.
GEORGE WIDENER KNADLER to Miss Caroline F. Feuchter, both of Philadelphia, recently.
FRANK MOORE McDONALD to Miss Ellene Sage Elderkin, both of Akron, Ohio, June 20.
FREDERIC G. PERRY, Plymouth, Ind., to Miss Sarah Ellen Gilworth of Warsaw, June 6.
ROY T. AGOSTINI, Old Forge, Pa., to Miss Mary Ann Adonizio of Pittston, June 25.
STERLING J. RITCHIEY to Miss Josephine Johnson, both of Colfax, Iowa, September 21.
A. BURTON SMITH, Wyoming, Pa., to Miss Ida M. Parrish of Kingston, August 12.
VINCENT T. LATIBURY JR., to Miss Faith C. Cony, both of Augusta, Maine, July 3.
NATHANIEL COPULSKY to Miss Edith Goldstein, both of Brooklyn, October 10.
JULIUS C. GOLDBERGER, New Orleans, to Miss Frances Renfeldt of Omaha, June 9.
HENRY TURKEL, Cleveland, to Miss Dorothy Goldberg of Detroit, recently.
ROY W. KEY to Miss Golda McLane, both of Sherman, Texas, June 20.
GRACE O. DONN to Mr. Dante Pierce, both of Des Moines, September 10.
DANIEL MYERS to Miss Nina Denny, both of Portland, Ore., July 4.

Deaths

John Winters Brannan, New York, Harvard University Medical School, Boston, 1878, member of the Medical Society of the State of New York and the Association of American Physicians, member and past president of the American Clinical and Climatological Association, consulting physician to the Bellevue Hospital, hospitals of the health department, Italian Hospital and Hospital for Ruptured and Crippled, president of the board of trustees of the Bellevue and Allied hospitals from 1902 to 1922 and also consulting physician, trustee of the New York Infirmary for Women and Children aged 83, died August 30, in the New York Polyclinic Medical School and Hospital, of heart disease and arteriosclerosis

Frederick Smith Baird, Bay City, Mich., McGill University Faculty of Medicine, Montreal, Que., Canada, 1913 member of the Michigan State Medical Society and at one time counselor of the tenth district past president and secretary of the Bay Arenac-Gladwin-Iosco Counties Medical Society served during the World War, on the staff of the Mercy Hospital, aged 48, died, August 2, of coronary thrombosis and myocarditis

Edwin Clinton Anderson, Chattanooga, Tenn. Eclectic Medical Institute, Cincinnati 1880, Chattanooga Medical College, 1897, member of the Tennessee State Medical Association, past president of the East Tennessee Medical Association for nine years held the chair of professor of pathology at the Chattanooga Medical College, aged 78, for many years on the staff of the Erlanger Hospital, where he died August 14

Clarence Woldemar Wille * Lakewood Ohio University of Pennsylvania Department of Medicine Philadelphia, 1897, entered the U S Public Health Service and for ten years was assistant surgeon in various federal hospitals formerly chief of the U S Marine Hospital, Cleveland, on the staff of the Lakewood City Hospital and consultant in surgery to the Veterans Administration, aged 62, died suddenly, July 1

William Joseph Birkofer * Gothenburg, Neb., State University of Iowa College of Medicine Iowa City 1897 member of the House of Delegates of the American Medical Association in 1910 formerly mayor of Gothenburg at one time vice president of the Nebraska State Medical Association and secretary of the Dawson County Medical Society aged 64, died, August 15, of diabetes mellitus and gangrene

Richard Goodwin Wadsworth * Boston Harvard University Medical School, Boston 1900 member of the New England Obstetrical and Gynecological Society fellow of the American College of Surgeons, for many years a member of the staff of the Free Hospital for Women, Brookline secretary-treasurer of the Boston Medical Library, aged 62, died, July 4, at his summer home in Wareham, of thrombosis

Willie Needham Blount, Laurel, Miss. Louisville (Ky.) Medical College, 1894 member of the Mississippi State Medical Association, served during the World War on the staff of the Laurel General Hospital, chief surgeon of the Gulf Mobile and Northern Railroad Company aged 63 died August 27, in the Touro Infirmary at New Orleans

William Henry Burmeister * Chicago University of Michigan Department of Medicine, Ann Arbor 1907 served during the World War, formerly assistant professor of pathology at the University of Illinois College of Medicine, on the staff of St Joseph's Hospital, aged 54, died August 11, at his summer home in McHenry

H Max Mehlig, Bellingham, Wash. Central College of Physicians and Surgeons, Indianapolis 1897 member of the Washington State Medical Association and the Associated Anesthetists of the United States and Canada for many years county coroner secretary of the staff of St Joseph's Hospital aged 62 died July 18

Curtis Boyd Munger * Medical Director Captain U S Navy Newport, R I Cooper Medical College San Francisco 1903 fellow of the American College of Surgeons entered the navy in 1905 aged 57 commanding officer of the United States Naval Hospital, where he died October 3 of cerebral hemorrhage

Robert Fritchey Roth, Westmont N J Hahnemann Medical College and Hospital of Philadelphia 1927 member of the Medical Society of New Jersey aged 33 died July 29 in the West New Jersey Homeopathic Hospital Camden of chronic appendicitis partial intestinal obstruction and incisional hernia

Frederic Elmer Jenkins, Lake Como Fla. Bellevue Hospital Medical College, New York, 1885 at various times served in the medical corps of the national guard and reserve corps of the U S Army, served during the World War, aged 73, died, July 1, of bronchiectasis and nephritis

Frank Butler Evans, Sandpoint, Idaho Northwestern University Medical School, Chicago 1904, formerly member of the state legislature of Nebraska and the senate of Idaho county physician and member of the school board, aged 55, died, July 22, in Portland, Ore., of heart disease

Meriwether Lewis Anderson, Richmond, Va., Medical College of Virginia, Richmond 1900, member of the Medical Society of Virginia, at one time demonstrator of obstetrics at his alma mater, served during the World War, aged 63, died, August 4 in St Luke's Hospital

Frederick William Hamlin, Rochester, N Y., New York Homeopathic Medical College and Hospital, 1888, at one time professor of obstetrics at his alma mater, formerly on the staff of the Flower Hospital, New York, aged 74, died, July 19 of chronic interstitial nephritis

William Henry Barr * Philadelphia Jefferson Medical College of Philadelphia, 1906 fellow of the American College of Surgeons formerly chief surgeon of the Ashland (Pa.) State Hospital, aged 56, died, August 15, in Ocean City N J, of coronary sclerosis

Richard M Boyd * Aberdeen, Miss., Memphis (Tenn.) Hospital Medical College, 1902 served during the World War on the staff of the Aberdeen Hospital aged 60 died, August 23, in the George Washington Hospital, Washington, D C, of cerebral hemorrhage

John R Baldwin, Greenville Miss (licensed in Mississippi in 1904), member of the Mississippi State Medical Association, formerly city and county physician, aged 55, died, August 5, in the King's Daughters' Hospital, of chronic nephritis and myocarditis

Fred Lyle Patterson, Coraopolis Pa., Jefferson Medical College of Philadelphia, 1907 member of the Medical Society of the State of Pennsylvania aged 54 died, July 9, in the Ohio Valley General Hospital, McKees Rocks, of chronic endocarditis

Samuel Ayres * Kansas City, Mo., University of Louisville (Ky.) Medical Department, 1883 chief surgeon of the Kansas City Southern Railway, on the staff of St Mary's Hospital aged 78, died, August 7, in Rochester, Minn., of pneumonia

John Gerald Byrne, Seattle, Northwestern University Medical School, Chicago, 1894, member of the Washington State Medical Association served during the Spanish-American and World wars, aged 65, died August 28, in the Providence Hospital

Melvin G Yocum, Mentone, Ind. Eclectic Medical Institute, Cincinnati 1890 member of the Indiana State Medical Association, past president of the Kosciusko County Medical Society, aged 70, died, July 7, of arteriosclerosis and diabetes mellitus

James Livingstone Tower, Albany, N Y Queen's University Faculty of Medicine, Kingston, Ont. Canada, 1913 member of the American Psychiatric Association aged 45 died, July 10, of hypertensive heart disease and cerebral edema

Arch Edward Baldwin, Seattle M B University of Minnesota Medical School, Minneapolis, 1924 member of the Washington State Medical Association aged 42 died, August 8, in the Providence Hospital of Addison's disease

Henry Braunlich * Davenport Iowa University of the City of New York Medical Department, 1883, aged 76, formerly on the staff of the Mercy Hospital where he died August 10, of uremia and hypertrophied prostate

Truss Malcolm Brister * Bogalusa, La., Memphis (Tenn.) Hospital Medical College 1907 served during the World War aged 54 on the staff of the Elizabeth Sullivan Memorial Hospital, where he died August 22

Charles A Blair, Morenci Mich. Michigan College of Medicine and Surgery, Detroit 1892 member of the Michigan State Medical Society aged 77 died, August 4, in Hollywood, Calif. of carcinoma of the abdominal viscera

John Reynolds Patton, Boston University of Vermont College of Medicine Burlington 1897, connected with the Veterans Administration aged 60 died July 28 in the New England Baptist Hospital of lobar pneumonia

Elmer E Ash * Goshen, Ind. Kentucky School of Medicine Louisville 1885 past president of the Elkhart County Medical Society aged 73 died August 16 of carcinoma of the sigmoid and diabetes mellitus

George Edgar Williams, Valdeese, N. C. State University of Iowa College of Medicine Iowa City, 1897, served during the World War, aged 62, died, July 29, in Washington, D. C., following an operation for carcinoma.

Arthur Henry Boyden @ Worcester, Mass. Tufts College Medical School, Boston, 1909 fellow of the American College of Surgeons, on the staff of the Worcester City Hospital, aged 56, died, August 23.

Octavius Manlius Spencer, Chicago, Vanderbilt University School of Medicine, Nashville Tenn., 1915, formerly a surgeon in the U. S. Public Health Service, aged 43, died, July 13, of heart disease.

Theodore Davis Adlerman, Brooklyn, Eclectic Medical College of the City of New York, 1892, on the staff of the Cumberland Hospital, aged 66, died, August 15 in Honolulu, Hawaii, of myocarditis.

Helen Genevieve Colby Bond, Concordia, Kan., Kansas City (Mo.) Hahnemann Medical College 1904 member of the Kansas Medical Society, aged 64, died, August 23, of carcinoma of the breast.

Perry Grant Ingersoll, Dunlap, Iowa State University of Iowa College of Homeopathic Medicine, Iowa City, 1905, aged 52, died, July 10, in Omaha, Neb., of paralytic ileus and diabetes mellitus.

Julius S. Newland, San Diego, Calif., Eclectic Medical Institute Cincinnati, 1892, aged 91, died, July 2, in the San Diego County Hospital, of chronic myocarditis and cerebral hemorrhage.

Henry W. Vanderhoof, Colorado Springs, Colo. Bennett College of Eclectic Medicine and Surgery, Chicago, 1874 Chicago Medical College, 1885, aged 86, died, July 21, of pneumonia.

Guy Collins Anderson, Eads, Tenn., Memphis Hospital Medical College 1902, served during the World War, aged 56 died, August 21, in the Veterans Administration Facility, Memphis.

Alpheus Eli Adams, Newburgh, N. Y. College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1879 aged 79, died, July 16, of carcinoma of the prostate.

William A. Burkhalter, Greenwood Miss. Tulane University of Louisiana Medical Department New Orleans, 1889, aged 70, died, August 30, of bronchopneumonia and bronchectasis.

Abraham Burack, Brockton Mass., Tufts College Medical School, Boston 1912 member of the Massachusetts Medical Society, aged 46, died, August 23, at the Beth Israel Hospital.

Horace Van Nort, St. Louis, St. Louis Medical College, 1883, formerly a druggist, aged 80 died, July 11, in the St. Louis City Sanitarium, of heat prostration and arteriosclerosis.

Howard Jerome Goodrich, Delhi N. Y. College of Physicians and Surgeons Medical Department of Columbia College New York, 1894 aged 66, died July 7, of paralysis agitans.

John E. Anderson @ Neshanic Station N. J. College of Physicians and Surgeons, Baltimore, 1884 aged 74, died August 15, of arteriosclerosis and Buerger's disease.

Alonzo Wells Daniel, Nashville Tenn., Vanderbilt University School of Medicine Nashville 1936, aged 24, died suddenly, August 14, of a self-inflicted bullet wound.

J. J. O'Neill, Oshkosh Wis. Northwestern University Medical School Chicago, 1895, aged 65 died July 31 in the Mercy Hospital, of adenocarcinoma of the prostate.

Mary Parker Hopkins Brandrup, Mankato Minn. University of Minnesota Medical School Minneapolis, 1901 aged 65, died August 23, of carcinoma of the sigmoid.

Thomas Nathaniel Willis, Louisville Ky. Hospital College of Medicine Louisville, 1878, aged 81 died July 16, in Floyd Knobs Ind., of myocarditis and nephritis.

Salvatore Auriemma Weehawken, N. J. Regia Università di Napoli Facoltà di Medicina e Chirurgia Ital., 1908, aged 56 died August 14 of arteriosclerosis.

Albert T. Baker, Rettil Wash. State University of Iowa College of Medicine Iowa City 1877 Civil War veteran, aged 89 died July 10 of chronic nephritis.

Samuel Lancaster Pottinger, Louisville, Ky. University of Louisville Medical Department, 1894, aged 66 was found dead in bed July 15 of heat exhaustion.

Henry R. McMullan, Roane Texas (registered by Texas State Board of Medical Examiners under the Act of 1907) aged 62 died in July of myocarditis.

James Fuller Miller, Pocatello, Idaho, Tennessee Medical College, Knoxville, 1901, served during the World War aged 59, died, July 18, of arteriosclerosis.

William Henry Baugh, Shoshone Idaho, Missouri Medical College, St. Louis, 1891, aged 72, died, August 4 of diabetes mellitus and arteriosclerosis.

Jerome E. McLaughlin, Winchester, Idaho, University of Minnesota Medical School, Minneapolis, 1906, aged 60 died, July 20 of cerebral hemorrhage.

Edwin Everett Dougherty @ Los Angeles, Indiana University School of Medicine, Indianapolis, 1910, aged 60, died, July 17, of chronic myocarditis.

Wilson Jesse Woodruff, Wapello, Iowa, College of Physicians and Surgeons, Keokuk, Iowa, 1885, aged 77, died July 22, of carcinoma of the kidney.

Walter Barnett Wallace, Detroit, Detroit College of Medicine, 1895, aged 68, died suddenly, July 20, in St. Luke's Hospital, of cerebral hemorrhage.

Shigemitsu Itami, Philadelphia Medical Faculty of the Osaka Imperial University, Osaka, Japan, 1897, aged 59 died, July 5, in Marblehead, Mass.

Harrison Bonham Hulsey, Los Angeles Indiana University School of Medicine, Indianapolis, 1912 aged 47 died, July 17, of cyanide poisoning.

Howard Allen, New Egypt, N. J. College of Physicians and Surgeons, Baltimore 1889 aged 70 died August 22, of uremia and diabetes mellitus.

Benjamin F. Whittinghill, Du Bois Ind. (licensed in Indiana in 1897), aged 91, died, July 5, of cardiovascular disease and fracture of the femur.

Adelaide Marklew Underwood, Pierson Fla. Woman's Medical College of Pennsylvania, Philadelphia, 1890, aged 87, died, July 14, of nephritis.

William Alfred Phillips, Paso Robles, Calif., Western Reserve University Medical Department, Cleveland, 1880 aged 75, died, July 2.

Charles Ramage, Long Beach Calif. University of Edinburgh Faculty of Medicine, Scotland, 1887, aged 70 died, July 4, of tuberculosis.

Howard Higgins Hopkins, Fresno Calif. Cooper Medical College, San Francisco, 1904, aged 60, died, July 13 of cerebral hemorrhage.

Nicholas A. J. Urbanski, Buffalo College of Physicians and Surgeons, Baltimore 1910, aged 49, died July 18 of coronary thrombosis.

Albert Mayfield Allen, Whitmire, S. C., Southern Medical College, Atlanta, 1892, aged 69, died August 24 of cardiovascular disease.

Frances E. Clarke Westergren, Boston, Boston University School of Medicine, 1892, aged 74, died July 8 of coronary sclerosis.

James Halliday Williams, Cincinnati, Medical College of Ohio Cincinnati 1900, aged 59, died suddenly July 12 of heart disease.

Hobart B. Steward @ Coolidge Ariz. St. Louis University School of Medicine, 1927, aged 37 died July 3, in Compton, Calif.

Jack Smiley, Salem Va. Medical College of Virginia, Richmond, 1926, aged 34, died, July 3 in a hospital at Roanoke.

Alexander Hotson, Park Hill, Ont. Canada Western University Faculty of Medicine London, 1889 aged 91, died, July 21.

George M. Glasgow, Cassville Pa. Jefferson Medical College of Philadelphia, 1891 aged 70, died, July 24 of aneurysm pectoris.

John Madison Hall, Hazlehurst Ga. Southern Medical College, Atlanta 1895 aged 60 died July 25 of nephritis.

Charles Edward Keeler, Elderton Pa. Baltimore Medical College 1897 aged 67 died July 6 of acute endocarditis.

William Philip Schirring Palatine Ill. Rush Medical College Chicago 1894, aged 64 died suddenly, July 11.

Joseph L. Bell, Berkeley Calif. University of Louisville (Ky.) Medical Department, 1897 aged 66 died July 1.

Alvin Judson Hurt, Chester Va. Chattanooga (Tenn.) Medical College, 1893 aged 72 died July 22.

Helen Weyant, Toledo Ohio (licensed in Ohio in 1914) aged 92 died, July 12.

Bureau of Investigation

BERNER'S TABLETS

A Reducing Nostrum Declared Fraudulent by the United States Postal Authorities

The Postmaster General has declared, on evidence satisfactory to him, the Re-Duso Sales Company Berner Sales, Berner's Tablets, and their officers and agents as such at St. Louis engaged in conducting a scheme for obtaining money through the mails by means of false and fraudulent pretenses, representations and promises. By the authority vested in him, he closed the United States mails to these concerns and parties on July 8, 1936.

Carl Berner started the "Re-Duso" and "Berner's Tablets" business for the alleged treatment of obesity in December 1934 and was the sole owner. Re-Duso and Berner's Tablets were sold through newspaper solicitation, the copy being typical of the patter used by the exploiters of the obese. One of these advertisements reads as follows:

"REDUCE!"

SAFELY—no diet or exercise—no strong laxatives—try this modern method of losing weight without injuring your health—Berner's Tablets, 3450 Texas Grand 9057. We deliver

The overweight person who "fell for" the bait and communicated with Berner received a printed sheet headed "Berner's Tablets," describing the treatment, which read in part:

Berner's Tablets are a small chocolate-coated tablet about the size of an aspirin. They are safe—yet very effective. Berner's Tablets eliminate excess fat by reducing the appetite and giving a very gentle and mild laxative action causing the most natural elimination of excess fat and waste matter accumulated in the system. Berner's Tablets simply offer you an economical way to do what modern doctors do in the treatment of obesity.

No physicians, chemists or pharmacists were connected with the business, and Berner, the promoter, had no medical training, yet the advertising copy as set forth implied that "modern doctors" were in full accord with the Berner obesity fraud.

Post Office officials stated that chemical analysis of the "chocolate-coated tablets" revealed them to consist essentially of boric acid and cascara.

Such a preparation, when used as directed would not reduce the weight of the user unless it did so by irritating and upsetting the normal digestive functions. Obesity is due to various causes, of which overeating and lack of exercise are not inconsequential factors. A person accustomed to overindulgence in food would not experience a sudden strengthening of will power by thrice daily swallowing a combination of boric acid and cascara.

In addition to the boric acid and cascara tablets the promoter also furnished on request another preparation known as the "Little White Tablet," which contained, according to the postal officials, ½ grain of thyroid extract. The Little White Tablet was not a part of Berner's regular treatment but was a special concession to the purchasers of Berner's Tablets.

Prospective purchasers of obesity nostrums would do well to beware of all advertised remedies claiming to be harmless and requiring "no diet or exercise." If a preparation is harmless it is ineffective, and if it is powerful enough to cause reduction of body weight regardless of diet or exercise it must do so at the expense of health. Periodicals that carry obesity advertisements such as those for Berner's Tablets take an unfair advantage of reader confidence.

"THERMALAID"

In THE JOURNAL for October 3 appeared an article relative to "Thermalaid" in which it was pointed out that the *Kiwanis Magazine* was one of the publications in which the advertisement for this product had appeared "during the past few years." The secretary of the Kiwanis International writes to point out that the last time any advertising of this company appeared in *Kiwanis Magazine* was in March 1931 over five years ago. Since that date, *Kiwanis Magazine* has not accepted any advertising of this or similar character. THE JOURNAL regrets to

have given the impression that *Kiwanis Magazine* is now carrying such advertising and wishes to congratulate the publishers on having adopted suitable censorship of medical advertising material.—Ed

PRINTER ASSUMES RESPONSIBILITY FOR ERROR IN KOCH PAMPHLET

A letter received from Mr. Hugh A. Kaumeier of the Sales Department of the American Printing Company, Detroit, states that the illustrations criticized in the article on William F. Koch (THE JOURNAL, Aug. 15, 1936) appeared as they did because of a printer's error for which his company assumes the responsibility. He states furthermore that Dr. Koch did not see a proof of the second run of this folder and left the proofreading to the printer.

Correspondence

INJECTION OF SUPRA-ORBITAL NERVE

To the Editor—Francis C. Grant (THE JOURNAL, September 5, p. 772), in describing the technic for injection of the supra-orbital nerve, states that "the nasal branch is often difficult to block, for it may divide from the main trunk of the supra-orbital well within the bony canal."

Seeing that the supra-orbital nerve does not give off a nasal branch, I presume that the author is referring to the other division of the frontal nerve, the supra-trochlear, which does send a branch to the root of the nose and communicates with the infratrochlear branch of the nasal nerve. The supra-trochlear nerve could be reached (in supra-orbital block) only when the alcohol suffuses or is forced back to the parent stem—the frontal branch of the ophthalmic—which procedure, just as in the case of a too deep injection of the infra-orbital nerve, might damage some of the contents of the orbit, the cavity of which is traversed by both nerves—the frontal with its two branches, and the infra-orbital.

PENN G. SKILLERN, M.D., South Bend, Ind.

HEREDITARY RESISTANCE TO TUBERCULOSIS

To the Editor—In THE JOURNAL, August 15, page 471, Miller and Rappaport have elaborated on the theory of inherited resistance to tuberculosis in a manner difficult to accept. Of course it is well known that in this country the mortality from tuberculosis varies greatly among certain race groups, being high among the colored races, particularly the Negro, and relatively low among Jews and Italians. It is also well known that the mortality is unusually high in isolated race groups, such as South Sea islanders that have come for the first time in contact with tuberculous infection. It would thus appear that those races which have been in contact with civilization and its concomitant tuberculosis over the longest period of time would be more resistant to the disease. The authors, in explaining how this hereditary resistance is brought about, say that the resistance "has thus become progressively increased by the addition of acquired resistance through successive generations." This argument for the inheritance of acquired characteristics is a biologic concept always difficult to accept and the authors themselves admit, would meet with prejudice.

To me, the most plausible concept has been the "survival of the fittest," and this is equally applicable to other diseases as well as to tuberculosis. It is common knowledge that isolated racial groups such as native Africans and Eskimos have in a short time died off in large numbers on first coming into contact with an infectious disease such as measles or tuberculosis. The survivors in these groups, who may be considered from this standpoint the fittest, represent the resistant remnant that lived to transmit to later generations their resis-

tance to the particular infection. The "survival of the fittest" theory may in the same way apply to other diseases such as syphilis, which is today far less virulent than it was during the sixteenth century.

The importance of the hereditary factor in allergy seems least impressive. In large urban populations there are just as many Negro as white children reacting to the tuberculin test, despite the fact that the mortality is from three to five times as great among the Negroes. This would suggest that the allergy is just as prevalent in the less resistant as in the more resistant group. In spite of the many arguments against hereditary resistance to tuberculosis, ample experimental evidence exists that animals such as turtles and rats are very resistant to the human tubercle bacillus. And, as was mentioned, the resistance of race groups to tuberculosis is also well known. The hereditary and constitutional factors contributing to this resistance remain a mystery. Some light is beginning to be shed in this direction by investigations of the relationship of the adrenal cortex and the spleen in the resistance to bacterial and other intoxications.

JULIUS KAUNITZ, M.D., New York.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

HAY FEVER DUE TO RAGWEED SENSITIVITY

To the Editor—I have a patient who, during the second week of August developed for the first time typical seasonal attacks of hay fever and asthma. The attacks of asthma which are more severe at night are relieved only by epinephrine hypodermically, which has to be administered about every three hours in doses of from 0.3 to 0.4 mg. Tests for allergy have resulted in: For pollens: orchard grass 2 plus wormwood 3 plus June grass 2 plus timothy 2 plus red top 2 plus Bermuda 3 plus pigweed 2 plus ragweed (short) 3 plus ragweed (giant) 3 plus goldenrod 1 plus English plantain 1 plus lambs quarters 1 plus marsh elder 1 plus. For epidermals: rabbit 1 plus dog 1 plus. For inhalants: house dust 1 plus pyrethrum 2 plus tobacco 1 plus kapok 1 plus. For foods: pork 1 plus egg white 1 plus minus egg yolk 1 plus beet 1 plus spinach 1 plus barley 1 plus wheat 1 plus minus apple 1 plus pear 1 plus cherry 1 plus hops 1 plus kidney bean 1 plus peanut 1 plus minus string bean 1 plus pike 1 plus tomato 1 plus minus okra 1 plus halibut 1 plus. The history and the physical examinations of the patient who is a young man are essentially negative. The nasal passages and sinuses are normal except for the characteristic hay fever appearance of the nasal mucosa. The routine laboratory tests (urine, blood count, blood Wassermann and blood sugar) do not reveal any abnormal condition. Though the patient is allergic to several pollens the ragweeds (short and giant) evidently represent the main factor at least as far as the present seasonal condition is concerned. In planning a treatment, however, the sensitiveness of the patient to the late spring pollens has to be considered as a potential menace for future manifestations. I realize that in relation to the present season owing to its lateness there is very little to be expected from any desensitization procedure and I am principally concerned with a plan of prevention for the next year. Under this respect your suggestions would be very much appreciated. By considering the severity of the case, are you in favor of a perennial treatment? For how long should that be safely carried on? Would it be advisable (1) to start with a ragweed mixture and then shift to a spring and fall mixture? (2) to begin with a mixture of the several pollens and then shift to a mixture of the ragweeds? (3) to start with a mixture of the several pollens and to shift next spring to a ragweed mixture? The doubt in my mind is that treatment with a mixture of the several pollens to which the patient is sensitive would not result in the patient's getting enough of the ragweed extracts to be desensitized against the ragweed pollens responsible for the present clinical syndrome. Of course the allergy of the patient to the epidermals and foods is also to be taken into account especially during the season for the purpose of eliminating all the possible contributing or aggravating elements. Please omit name.

M.D. Ohio

ANSWER.—The main point in this case is that the patient's asthma and hay fever are almost certainly due to the pollens of short and giant ragweeds. Ragweeds pollinate in the Cleveland vicinity from about August 10 or 15 to approximately the end of September. As the season is over there is no reason for

further treatment this year, but for next year a definite plan of injections should be carried out. These may be started as late as May 1 but it would probably be better to begin about April 1.

Injections may be given about twice a week for a total of from twenty-five to thirty injections. The mixed ragweed extract should be purchased in bulk so that the dosages may be adjusted to suit the sensitivity of the patient. The strength of the injections should be increased from 35 to 50 per cent each time, if possible, until the hay fever season has started, and then reduced slightly, at the end of the season the top dose should be repeated every two weeks (perennial method of treatment) and gradually increased before the next season.

Regarding the other pollens (especially grasses) that gave positive skin tests, it is advisable to disregard them entirely until and unless symptoms develop during the grass hay fever season (about May 25 to the end of July), treatment for positive skin tests should never be given unless clinical symptoms occur. The patient has a "potential" grass hay fever. "Potential" cases should be watched, not treated. The foods that gave positive tests should be avoided during the ragweed season and contact with animals should also be restricted at this time.

The question as to how long perennial treatment is necessary cannot be answered. It will depend on the patient. One who has only hay fever may take injections for three or four years, perhaps, and then stop for a year or more if symptoms are absent or slight, but if asthma also is present the injections should not be stopped so soon. The patient should be tested each year for ragweed pollens, when and if the skin tests become negative for these, the sensitivity is presumably much lessened or perhaps gone entirely.

HAGEDORN-JENSEN METHOD FOR DETERMINING BLOOD SUGAR

To the Editor—Please describe the method of blood sugar determination by the Hagedorn-Jensen method.

T. K. LEWIS, M.D., Birmingham, Ala.

ANSWER.—The Hagedorn-Jensen method of blood sugar determination requires only 0.1 cc. of blood from the finger or lobe of the ear. A protein-free filtrate is obtained by using a colloidal solution of zinc hydroxide. The clear filtrate is treated with potassium ferricyanide, the unconsumed portion of which is titrated back with sodium thiosulfate. The reaction is

The ferricyanide is precipitated in the form of a zinc compound. All reagents must be free of iron.

For getting the filtrate: 1. Zinc sulfate 0.45 per cent solution to be made each week. Prepare a stock 45 per cent solution by adding 45 Gm. of sulfate to enough distilled water to make 100 cc. of solution. Add 1 cc. of this solution to about 75 cc. of distilled water in a 100 cc. volumetric flask, then dilute to 100 cc. 2. Tenth normal sodium hydroxide solution. Dilute 10 cc. of normal sodium hydroxide to 100 cc. with distilled water. This solution must be made each week.

For sugar determination: 1. Potassium ferricyanide solution. Dissolve 1.65 Gm. of potassium ferricyanide (recrystallized) and 10.6 Gm. of anhydrous sodium carbonate in about 800 cc. of distilled water in a 1000 cc. volumetric flask, dilute to 1000 cc. with distilled water. Keep in a brown bottle. 2. Zinc sulfate solution. Dissolve 10 Gm. of zinc sulfate and 50 Gm. of sodium chloride in enough distilled water to make a total of 160 cc. 3. Potassium iodide solution. Dissolve 12.5 Gm. of potassium iodide in about 75 cc. of distilled water in a 100 cc. volumetric flask and dilute to 100 cc. with distilled water. Keep in a brown bottle. To use solutions 2 and 3 add 40 cc. of solution 2 to 10 cc. of solution 3. Make this mixture at least once a week. 4. Acetic acid solution. 3 per cent. Add 3 cc. of glacial acetic acid to about 75 cc. of distilled water and dilute to 100 cc. in a volumetric flask. 5. Starch solution. 1 per cent. Add 1 Gm. of soluble starch to 5 cc. of distilled water and heat slightly. Dilute to 100 cc. with distilled water. 6. Two hundredth normal solution of sodium thiosulfate. This may be made by adding 5 cc. of tenth normal sodium thiosulfate to enough distilled water to make 100 cc. or by dissolving 0.7 Gm. of sodium thiosulfate in 500 cc. of distilled water. 7. To make standardizing solution of potassium iodide. Place 0.3567 Gm. of potassium iodide in a 2000 cc. volumetric flask, dissolve in a few cubic centimeters of distilled water and dilute to 2000 cc. This is used for the titration of the two-hundredth normal sodium thiosulfate. Every new titration must be titrated and the titration repeated at least once a week.

To titrate the thiosulfate solution: Mix 2 cc. of potassium iodide solution with 2 cc. of 3 per cent acetic acid (4) and 2 cc. of starch solution (5) and 2 drops of solution 2 and 3 and 2 drops of starch solution (5). Titrate with solution 6 until all traces of blue have disappeared. Divide the number of cubic centimeters of solution 6 used to obtain the titer of the solution. Example: Assume 2.04 cc. of solution 6 was used divided by 2.04 equals 0.98 the titer.

The following apparatus is needed:

One automatic 2 cc. pipet mounted on the neck bottle.
One 0.1 cc. pipet.

Ooe 2 cc volumetric pipet.
One 3 cc. volumetric pipet.
One automatic microburet, 2 cc. graduated in 0.02 cc mounted on a bottle

Test tubes, 15 by 150 mm.
Test tubes 30 by 90 mm
Copper racks for test tubes for immersion in water bath
Glass funnel 4 cm in diameter

Technic of test Place in a test tube 15 by 150 mm 1 cc of tenth normal sodium hydroxide solution and 5 cc of 0.45 per cent solution of zinc sulfate Add 0.1 cc of blood from the finger or lobe of the ear Rinse the blood pipet twice with the fluid in the test tube. Immerse the test tube in boiling water for three minutes

Prepare a test tube 30 by 90 mm with a 4 cm funnel in which is placed a layer of moistened fat free absorbent cotton Filter the coagulum in the first test tube through the cotton The filtrate is clear Rinse the first test tube with 3 cc of distilled water and filter Rinse a second time with 3 cc of water and add to the filtrate Allow all the solution to drip through Add to the filtrate 2 cc. of solution 1 (potassium ferri cyanoide) Measure accurately Place in a bath of boiling water for fifteen minutes Allow to cool Add 3 cc of a mixture of solutions 2 and 3 and 2 cc of solution 4 (3 per cent acetic acid) and 2 drops of solution 5 (starch) Titrate against two-hundredth normal sodium thio-sulfate (solution 6) At the same time carry out a blank test without the addition of blood Determine the number of cubic centimeters of sodium thiosulfate used in the actual test as well as in the blank titration Multiply this by the titer of the solution From the table given below ascertain the actual sugar value Subtract the figure of the blank test from that of the actual test The difference represents the milligrams of sugar in 100 cc of blood

Table for Determining Blood Sugar

INCREASING HEMOGLOBIN

To the Editor—Is it true that a 25 per cent solution of iron ammonium citrate half a drachm (2 Gm) after meals will increase the hemoglobin quicker than other iron tonics? Can you cite any proofs? I have been told that other iron combinations are converted in the gastrointestinal tract into insoluble compounds and that only a minute part of each dose is absorbed. Please omit name
MD New York.

ANSWER—There is abundant experimental foundation for the use of large doses of iron in anemia Whipple and Robscheit-Robbins (*Am J M Sc* 191 11 [Jan] 1936) showed by experiments on standard anemic dogs that a tenfold increase in the dose of iron will almost double the output of hemoglobin Such doubling would cut in half the time required for cure They also find that iron salts are used with equal facility by the dog to produce hemoglobin when given by mouth in the ferrous ferric or reduced state The determining factor is the amount of the iron metal

Schulten (*München med Wchnschr* 77 355 [Feb 28] 1930) found that the poor regeneration in some cases of posthemorrhagic anemia could with regularity be changed to rapid cure by giving iron in sufficiently large doses e g 6 Gm or more in twenty four hours In chlorosis the author finds doses up to 10 Gm of reduced iron necessary to secure good effects

Buresh (*Deutsche med Wchnschr* 59 882 [June 9] 1933) reported several cases of severe anemia following gastric hemorrhage in which large doses (reduced iron from 3 to 6 Gm daily) produced a definitely accelerated blood regeneration as compared with small doses, e g, in the form of Bland's pills (three twice a day)

Bloedorn (*Minnesota Med* 1 5 [Jan] 1936) concluded from a review of the literature and from his own experience that the optimal daily dose of iron, as metallic iron will fall between 1 and 1.5 Gm. daily

According to Bethell Goldhamer Isaacs and Sturgis (*The Journal*, Sept 15 1934 p 797) Iron in a soluble salt is apparently more efficiently utilized than the same quantity as ferrum reductum but the latter will produce equally good

results if given in adequate dosage and possesses the advantages of small bulk and comparative freedom from irritative effects on the alimentary tract In our experience 4 Gm of ferric ammonium citrate, representing about 0.8 Gm of iron, or 1.5 Gm of ferrum reductum, is an optimum amount for daily administration, and in these dosages the two forms of iron are quite comparable in their effects"

REACTIONS TO TUBERCULIN TEST

To the Editor—A woman aged 28 had always been in perfect health until about eight months ago when she was given an intracutaneous tuberculin test on the left arm Her brother at that time had a positive pulmonary tuberculosis Her tuberculin test reacted about two plus Several sputum examinations showed no tubercle bacillus She did have an afternoon temperature of 99.4 F for three weeks There was no loss of weight or night sweats There was no cough X-ray examination showed a small area of increased density in the left apex about one half inch in diameter which appeared to be heavily calcified About one week after the tuberculin test she developed a constant pain in the left arm that radiated into the hand and axilla Since then it has extended into the left side and left breast The pain seems to be in the muscles and not in the joints The pain became throbbing in character at times There was no noticeable enlargement of the lymph glands in the left axilla Various forms of heat as infra red diathermy and the hot water bottle have been applied Massage with liniment and alcohol have been given She has been given calcium lactate salicylates and A B D capsules All this treatment does not seem to give much relief Her tonsils are out her teeth have been roentgenographed and are normal and the sinuses are clear She has no indigestion no symptoms of kidney trouble and no leukorrhea She states that within the last week the same aching has started in the opposite arm Could this condition be an irritation of the lymphatics caused by the tuberculin test? If so what treatment would you recommend? What is the prognosis?

VERY W RITTER MD Seattle.

ANSWER—The number of tuberculin tests administered in the United States in the past few years is well in the millions Apparently there is no record of any after-effect resulting in the symptoms described in this communication by any of the observers from the time of Mantoux to the present Pirquet described delayed reactions from his test, but they were no different than the usual reactions except in point of time of their appearance Recently it has been observed occasionally that children or young adults who have the tuberculin test administered with no apparent reaction at the usual time of interpretation but who in the course of a few weeks develop some febrile condition, such as scarlet fever, may have definite redness appear round the site of the administration of the tuberculin This phenomenon has not been adequately explained Indeed, it is usually thought that the exanthematous diseases, pregnancy and a few other conditions actually depress allergy but not enough observations have been recorded to convince one that this is always true

In the case cited, the reaction to the tuberculin test was mild No lymphangitis was reported, and there was no visible enlargement of the lymph nodes in the axilla The lymphatic channels from the arm drain into the axillary lymph nodes There is no drainage toward the hand or the breast The pain of which the patient complained in the left arm that radiated into the hand, axilla, side and breast did not make its appearance until one week after the test was administered Moreover, aching has recently appeared in the right arm The progressiveness of the symptoms, together with the fact that such large numbers of tuberculin tests have been administered without the recording of any such complication, leads one to conclude that the development of pain was a coincidence and that its cause must be sought elsewhere.

NON SPORE FORMING ANAEROBES

To the Editor—Kindly list the non spore forming anaerobes Please omit name
MD Chicago

ANSWER—A list of non spore forming anaerobes would consist of scores of long cumbersome scientific names Therefore this question could be answered to the best advantage by referring to a standard manual on bacteriology Determinative Bacteriology by Bergey, contains a list of all bacteria both pathogenic and nonpathogenic Under the various families it is relatively easy to note the anaerobic species

In the family Nitrobacteriaceae, on page 41, species 2, *Thio bacillus denitrificans* is anaerobic

In the family Coccaceae page 47 five species of anaerobic streptococci are noted On page 97 in the family Coccaceae are noted eight species of anaerobic micrococci (species 38 to 46)

In the family Bacteriaceae, page 406 are listed nineteen species of Bacteroides.

In the family Actinomycetaceae page 495, is listed one species of Leptotrichia as anaerobic. It is also well known that several species of Actinomycetaceae prefer small quantities of oxygen for growth.

In the family Mycobacteriaceae page 557, are listed four anaerobic species of fusiform bacilli.

In the family Spirochaetaceae page 619, the spirochetes, of which there are several, all grow best at a low oxygen tension. In this family, on page 624, under genus Borrelia, are listed fifteen species most of which have been grown only under strictly anaerobic conditions. In the same family, under genus Treponema, page 627 (in which is included the syphilis organism), seven species are listed, all of which are strictly anaerobic.

It is to be noted of course, that many varieties of bacteria, especially among Spirillaceae and streptococci will grow better under partially anaerobic conditions especially for a time, after isolation from the body.

LIFE EXPECTANCY AND ENDOCRINOLOGY OF ALLERGY

To the Editor—1 What is the average life span of clinically allergic persons i. e. does the age of death among allergic individuals differ materially from that of the normal person? 2 Are there any figures available as to the relative frequency of hypertension nephritis diabetes cancer and other chronic diseases among allergic persons as compared to the normal person? 3 Is there any theory now accepted as to why many allergic women lose their sensitivity after the menopause? Please omit name.

— Tennessee

ANSWER.—1 The expectancy of allergic patients does not differ from nonallergic individuals except in those with asthma. In these, the life expectancy is affected primarily because of the occurrence of pulmonary infections especially pneumonia, and because of myocardial damage (Dublin, L. I. and Marks H. N. Mortality of Risks with Asthma. Published by the Association of Life Insurance Medical Directors of America, Metropolitan Life Insurance Company, 1923).

2 Hypertension is unusual in all allergic conditions while diabetes may be considered almost a rarity in association with allergy.

Regarding the incidence of other chronic diseases among allergic (asthmatic) patients, Bray (Recent Advances in Allergy Philadelphia, P. Blakiston's Son and Co., Inc., 1934 pp 131-140) gives the following analysis of the literature.

Tuberculosis. Only one asthmatic patient in a hundred gives any positive evidence of active tuberculosis. Only one patient with active tuberculosis in two hundred suffers from true asthma.

Rheumatism. Acute in about 26 per cent of asthmatic patients chronic in 08 per cent of asthmatic patients.

Syphilis. Less common in asthmatic than in nonasthmatic persons.

Heart disease. Not common in allergy.

Nephritis. 06 per cent in asthma.

3 Endocrine disturbances are believed to play a part in allergic symptoms. While rarely if ever of primary importance, their action is to "prepare the soil." Endocrine changes however, may produce opposite effects. They may either predispose to or lessen the tendency for attacks of asthma. Thus the menopause or pregnancy may in some patients mark the beginning or an increased severity of allergic symptoms, while in others it may coincide with the termination or temporary subsidence of allergic symptoms. What these endocrine changes are and how their influence is exerted is not known.

USE OF TETANUS TOXOID

To the Editor—Some time ago it occurred to me that the administration of tetanus toxoid would considerably diminish the necessity for the use of horse serum in sensitive patients. It seems to me that this procedure would be especially valuable in horse-dander sensitive patients as according to a statement in the book, Asthma and Hay Fever Theory and Practice by Coca Walzer and Thommen every patient sensitive to horse dander is sensitive to horse serum. I would greatly appreciate your opinion of this procedure in these patients. Is tetanus toxoid available commercially and if so where can it be obtained and what is the dosage?

VICTOR L. CONEX M.D. Buffalo

ANSWER.—Rarely tetanus toxoid may give rise to urticaria and systemic reactions. Experience indicates that such an allergic response may be expected in a much smaller percentage after toxoid injections than after injections of antitetanus serum. Tetanus toxoid is available commercially and can be obtained through the drug trade (see report of Council on Pharmacy and Chemistry on Tetanus Toxoid Alum Precipitated THE JOURNAL, May 16 1936 p 1735). It should be noted that

tetanus toxoid is used for lasting preventive immunization against tetanus. As a rule two subcutaneous injections of 1 cc. each are given from six weeks to two or three months apart an additional third dose is given only at the time of the injury. In the preventive treatment of wounded persons, tetanus toxoid is to be used only if the patient has received two injections of toxoid at least a month previous to the injury, in other cases tetanus antitoxin should be given. There is a growing opinion in favor of active immunization against tetanus of persons whose work subjects them especially to the danger of tetanus infection.

SELECTION OF ELECTROCARDIOGRAPH

To the Editor—I shall appreciate your advice regarding the type of electrocardiograph to get for a cardiac clinic. The dispensary cardiac clinic of which I have charge is considering obtaining an electrocardiograph for use in the study of its cardiac patients. Economy is an important matter to the dispensary. Therefore the question is whether a small apparatus such as the Cardiette put out by the Sargent Company would be satisfactory. The cardiac clinic treated 167 patients in 1935 there being 393 treatments. This year there is an increase in attendance and it is felt that an electrocardiograph will serve as a stimulus toward a greater interest in cardiology.

M.D. Connecticut

ANSWER.—In choosing an electrocardiograph the following points are of importance accuracy, reliability, durability, ease of operation service (adjustments, repairs, replacement of parts) and cost. While the lower priced instruments are attractive in cost it would seem that for daily service in a cardiac clinic one of the higher priced machines, with presumably more rugged and durable materials, would be preferable. Most cardiologists feel that greater accuracy is had from the "string" type of electrocardiograph. If the cost of the more expensive machines is prohibitive, the smaller instruments have proved quite satisfactory. Replacement of defective or broken parts and service is of great importance and should be given careful consideration. The choice of an electrocardiograph is much like that of an automobile, their manufacture has become so standardized that the purchaser is assured that he receives what he pays for—no more and no less. One does not expect the performance of a Ford to parallel that of a Lincoln.

OPHTHALMOSCOPIC SIGNS OF DEATH

To the Editor—I read in a newspaper item that a definite diagnosis of death can be made by observing with the ophthalmoscope the broken columns of blood in the retinal vessels. Does it apply to the arteries or veins or both and what is their appearance compared to normal?

WYATT BARNES M.D. Decatur Ala.

ANSWER.—The only definite ophthalmoscopic sign of death is the change in the color of the fundus from the normal red to a yellowish. This occurs as nearly coincidental with death as can be detected. In some instances the arteries practically disappear, whereas in others they maintain a full nearly normal appearance. The interrupted blood column makes its appearance only in the veins and is probably due to intravascular coagulation of the blood. A rather complete discussion of this subject is given in the American Encyclopedia of Ophthalmology, volume V, page 3784.

PROSTATITIS DUE TO TRICHOMONAS

To the Editor—I have a patient with frequency and burning of urination and nocturia. Examination of the urine is negative. The secret expressed from the prostate contains many pus cells and a few Trichomonas vaginalis organisms. The patient's wife is under treatment for Trichomonas vaginalis infestation. I should like to know whether prostatitis caused by Trichomonas vaginalis has been reported and the kind of treatment advised. Please omit name.

M.D. Wyoming

ANSWER.—Prostatitis due to Trichomonas vaginalis has been reported by L. G. Stuhler (Proc Staff Meet Mayo Clin 8:221 [April 12] 1933) and by A. C. Drummond with a review of the literature (Am J Surg 31:98 [Jan] 1936).

About 0.3 per cent of patients with prostatitis will be found to have Trichomonas vaginalis in the prostatic secretion. In any stubborn or rapidly recurrent Trichomonas infection in the female this complication should be suspected and the prostatic secretion of the husband should be examined.

Usually treatment by means of prostatic massage two or three times weekly accompanied by irrigations of the bladder with warm 1:8000 potassium permanganate solution results in a prompt disappearance of the parasites from the prostatic secretion. If this is not the case one or two intravenous injections of 0.3 Gm of nearsphenamine at five day intervals should be given.

EFFECTS OF CONGO RED AS HEMOSTATIC

To the Editor—Recently congo red was administered intravenously in a case of persistent profuse bleeding bronchiectasis and the bleeding stopped spectacularly. Of course, the cessation of the hemoptysis might have been purely incidental but I have seen similar results in cases of persistent bleeding peptic ulcer and there are reports in the literature of a similar nature. The congo red was used as a 1 per cent aqueous solution and two injections of 10 cc. each were given twenty four hours apart. Would you please give me the current medical opinion regarding the value of intravenous congo red as a hemostatic in cases of persistent bleeding from the gastro-intestinal and pulmonary organs and the rationale? Please omit name and address.

INTERN New York.

ANSWER.—Wodekind in 1930 observed that congo red had a hemostatic effect in pulmonary hemorrhage when injected intravenously. Becker in 1930 confirmed these observations. Deinhardt in 1931 and Rossak in 1933, as well as Nikolajew and Gurewitsch in 1935, reported favorable results from its use most especially in bleeding from inflammatory gynecologic processes. It was found ineffective by the last named authors in cases of extra uterine pregnancy or hormonal hemorrhages. Graves and Kickham have found it of value in hemorrhages of the urinary tract, provided the patient still possesses a relatively normal coagulation mechanism. It is of no value in actual blood disease. As to the rationale, one may say that a transitory (twenty four hours) shortening of coagulation time has been noted accompanied by an increase in blood platelets. It is also imagined that compression of capillaries may result from the deposit of the dye in the reticulo-endothelial system in which it is promptly stored after its injection into the blood.

BLACK EYE AS SIGN OF INSTANTANEOUS DEATH

To the Editor—Some time ago I was called to the scene of an auto mobile accident. When I arrived a young man had died. The victim had what is commonly known as a black eye. The question arose in my mind as to whether he was killed instantly or not. Was I correct in assuming that if he was killed instantly there would be no ecchymosis of the eyelids as there would be no pressure to force the fluid into the tissues?

C L BOURDEAU MD Missoula Mont.

ANSWER.—If the young man had been killed instantaneously there would have been no time for discoloration of the eyelids by extravasation of blood into the tissues to take place. The question might be raised whether the "black eye" existed before the fatal injury.

VISSCHER BOWMAN TEST FOR PREGNANCY

To the Editor—I have been taking a series of pregnancy tests using the Viisscher Bowman pregnancy test method. I have been taking the patients at random and have observed frequently that both male and female patients whose urine presents sufficient sugar to reduce Fehling's solution frequently give a positive test. In your opinion do you believe it ultimately a test for a form of metabolic sugar or has it any real value as a pregnancy test?

JOHN F LOEHLE MD Lebanon Pa

ANSWER.—This test is a complicated chemical reaction employing several ingredients, and the final result is not a clearly defined one. A number of different reducing substances may interfere with the test. Consequently its value as a test for the diagnosis of pregnancy is uncertain and therefore unreliable, while so complicated a test cannot reasonably be expected to replace simpler established ones for sugar.

The original article describing it appeared in the *Deutsche medizinische Wochenschrift* 60 1823 (Nov) 1934, abstract references are to be found in *THE JOURNAL*, Feb 2 1935 page 431, and Feb 8, 1936, page 504 and also in the *Journal of Laboratory and Clinical Medicine* 21 986 (June) 1936. The abstract of a subsequent article by C Dolf is to be found in the *British Medical Journal* 1 38 (Feb 29) 1936.

ASH FROM CREMATED HUMAN BODY

To the Editor—How much ash is left after a human body is cremated? I mean the ash of an average adult. If possible give me the weight of the ash in grams. I cannot find this information in the literature. If you cannot help me will you please put me in touch with the people of a big crematory so that I may obtain some literature on cremation.

THOMAS G GAERSTE, MD Curaçao D W I

ANSWER.—The ash of the average cremated adult weighs about 2300 Gm., the weight varying with the size of the bones. Literature on cremation may be obtained from the International Bureau of Cremation at Helsingborg Sweden the Cremation Society of England at London the Cremation Society of America at Portland Ore. or the California Crematorium at Oakland, Calif.

USE OF NITROUS OXIDE GAS IN FOOD PRESERVATION

To the Editor—I am experimenting with the processing of a food by means of nitrous oxide gas which seems to accomplish the purpose better than any other agent I have found. Can you advise me whether there is any known effect on the human system by taking nitrous oxide gas internally? The amount of gas normally consumed in this product would be that occupying the space of a liquid measure of 1½ ounces. I realize that there may be some questions raised on the part of health authorities and I am anxious to get all the reliable data that I can so as to determine whether to pursue the experiment further or not.

S D LEVINGS Chicago

ANSWER.—As far as we know, there is no information in the literature on the use of nitrous oxide for the preservation of meat on a commercial basis. In the curing of certain meats nitrites are used and it is said that gaseous oxides of nitrogen have been tried as substitutes without particular success. There is little information to show that taking nitrous oxide gas internally would be either harmful or harmless. The question of the use of nitrous oxide in the processing of meats awaits adequate experimental investigation before any food product so treated is promulgated to the public. In the absence of adequate data the use of foods so treated might well be viewed with caution.

TESTS OF KIDNEY FUNCTION

To the Editor—I have a patient who is 42 years of age and who excretes no phenolsulfonphthalein. First I gave it intramuscularly and then intravenously. The patient gives a history of low kidney function about thirteen years ago but does not know the exact percentage. There is no clinical evidence of such a test. I would appreciate any information you may have.

LOUIS L SHERMAN MD Oakland Calif

ANSWER.—In Queries and Minor Notes in *THE JOURNAL*, August 22, page 606, "Tests for Urea and Renal Function," are described some tests that can be done in this case. The common cause for lack of excretion of phenolsulfonphthalein with adequate renal function is retention in the urinary tract, either the bladder or the kidney pelvis. A blood urea and excretory urogram should clear up the diagnosis in this case.

ELLIOTT TREATMENT IN GONORRHEA IN WOMEN

To the Editor—I have been led to believe that the early treatment of gonorrhea in women with the Elliott machine is apt to cause a wide dissemination of the infection through the lymphatics. Has clinical experience shown this to be true? Please omit name.

M D Texas

ANSWER.—In the experience of most gynecologists, Elliott treatments are contraindicated during the acute stage of the disease. Treatment increases the discomfort and may add to the severity of the infection.

Council on Medical Education and Hospitals

ADDITIONAL HOSPITALS APPROVED

The Council on Medical Education and Hospitals of the American Medical Association has given its approval to the following hospitals since the publication of the last previous list in *THE JOURNAL*, Aug 29, 1936.

Hospitals Approved for Intern Training

Meadowbrook Hospital Hempstead N Y
Queens General Hospital Jamaica N Y

Hospitals Approved for Residencies in Specialties

St Vincent's Hospital Birmingham Ala Surgery
Olive View Sanatorium Olive View Calif Tuberculosis
Riverside Hospital Jacksonville Fla Mixed
Kansas City General Hospital Kansas City Mo Communicable Disease
Cooper Hospital Camden N J Surgery
New Rochelle Hospital New Rochelle, N Y Radiology

Hospitals Approved for Additional Residencies

Denver General Hospital Denver Tuberculosis
Henry Ford Hospital Detroit Pathology and Pediatrics
Eloise Hospital Eloise Mich Malignant Diseases
University of Nebraska Hospital Omaha Pathology
Bellerue Hospital New York City Neuropsychiatry

Book Notices

The Diseases of the Endocrine Glands By Hermann Zondek M.D. Director of the Medical Division Bikur Cholim Hospital Jerusalem Third edition translated by Carl Prausnitz M.D. M.R.C.S. L.R.C.P. Honorary Research Fellow Victoria University of Manchester Cloth Price \$11 Pp 482 with 168 illustrations. Baltimore William Wood & Company 1935

This volume is now in its third edition, based on the last German edition, which appeared in 1926. However, it takes account of recent advances and presents particularly Zondek's point of view in relationship to the significance of the endocrine system. Its author is widely known as a leader in research in this field in Germany who subsequently was obliged to leave Germany and settled in Manchester, going finally to Jerusalem where he is now in practice. The present edition was translated by Carl Prausnitz, also a former German physician, who also more recently has been established in Great Britain. The Zondek volume begins with a historical introduction and discusses the relationship between the glands and their physiology and chemistry. It discusses also the vitamins and the relationship of the glandular system to the endocrine system. Next it is concerned with methods for the examination of patients and with organotherapy. The second half of the book deals with specific conditions such as goiter, cretinism, obesity, gigantism and dwarfism and the other extraordinary conditions that result in the human body when the glands fail or go astray in their functions. The book is supplemented by an excellent bibliography and numerous well chosen illustrations. It is provided also with a most competent index.

Kurzgefasstes Lehrbuch der Psychiatrie Von Dr. Johannes Lange o. Professor der Psychiatrie in Breslau. Second edition. Paper. Price 7.20 marks. Pp 260 with 4 illustrations. Leipzig Georg Thieme 1936

This compend of psychiatry is the second improved edition to be published. It consists of six chapters, on (1) general psychiatry, (2) varieties of disease, (3) treatment, (4) examination, history, diagnosis and important factors to be remembered in psychiatric disorders, (5) appendix and (6) bibliography. The first chapter includes general symptomatology, causes and discussions of the various psychoses. The second chapter includes the varieties of the psychoses beginning with congenital and abiotrophic entities, traumatic psychoses, dementia paralytica, cerebral syphilis and psychoses epidemic encephalitis, psychoses of the aged, Huntington's chorea, other psychoses associated with encephalitis, meningitis, multiple sclerosis, chorea minor, paralysis agitans, athetosis and brain tumors, psychic disturbances due to acute infections and disturbances of the internal organs, alcoholism, drug addiction, psychoses from other poisons, genuine epilepsy, schizophrenias, manic-depressive psychoses, psychopathic personality and abnormal mental reactions. In the third chapter on treatment, Lange discusses preventive measures, marriage psychotherapy, Freudian and Adlerian concepts, suicides, compulsion, sedatives and the interruption of pregnancy. The fourth chapter consists of a discussion regarding examination history and diagnosis in mental disease. The fifth chapter includes Binet-Simon and Sommer mental tests as well as a general examination regarding school knowledge, practical knowledge, questions of ethics, ability to comprehend judgment and facilities for imagination. The bibliography consists of twenty references. This book is recommended to neuropsychiatrists.

A Textbook of Psychiatry By Arthur P. Noyes M.D. Superintendent State Hospital for Mental Diseases Howard Rhode Island. Second edition. Fabrikoid. Price \$2.50 Pp 329. New York Macmillan Company 1936

The second edition of this excellent textbook for nurses is highly satisfactory. The comment can be made that it is probably as valuable for beginning psychiatrists and students in psychiatry as for nurses. While in detail it is not as complete as this author's textbook on Modern Clinical Psychiatry, the descriptions of disease entities are relatively complete nevertheless and so well written that the conditions can be easily understood even by the nurse who is not specially psychiatrically trained. The discussion of psychiatric nursing management is rather general in the case of each entity. Unfortunately, in no place in the book is much space devoted to details of the special and important forms of therapy usually

carried out by nurses, such as recreational therapy, occupational therapy and hydrotherapy, but there is a chapter on psychiatric nursing in which there is a brief general discussion of these forms of treatment. There is some general discussion at the end of the volume covering mental hygiene, mental deficiency and the psychoneuroses which should be of some cultural interest to nurses but probably will be ignored by most of them. The psychoneuroses, however, are not stressed thus emphasizing the hospital rather than the clinical side of psychiatry. All in all the book continues to be the same satisfactory psychiatric contribution as was its first edition, and it stands well up in the list of works that can be used for teaching nurses the difficult subject of psychiatric nursing.

The Extra Ocular Muscles. A Clinical Study of Normal and Abnormal Ocular Motility By Luther C. Peter M.D. Sc.D. Professor of Diseases of the Eye in the Graduate School of Medicine of the University of Pennsylvania. Second edition. Cloth. Price \$4.50. Pp 351 with 141 illustrations. Philadelphia Lea & Febiger 1936

In 1920 there appeared in these pages a review of the first edition of Peter's *Muscles* and now after sixteen years a second edition has been published. The text is somewhat the same, albeit elaborated, which makes the new book fifty-seven pages more than the old. In the first part, devoted to anatomy and physiology, there is considerable more about instruments for the measurement of binocular vision and fusion and their use but the anatomy is the same. Almost nothing new has been added to the chapter on heterophoria, nor has the material been rewritten. In esotropia the author has committed himself to the belief that the amblyopia present is the result of disuse and consequently is a symptom and not the cause of the squint. Fortunately he has stated this as his belief for certainly it is not the universal opinion. Nor will his statements as to the results procured in the endeavor to develop vision in such amblyopias find universal credence. The O'Connor cinch operation is given much more space and in the hands of the author seems to have yielded satisfactory results. Also the entire chapter on surgery is enlarged and made much more useful. The final chapter, on nystagmus, is unchanged, even to the complete omission of the name of Ohm of Bottrop. The original review said: 'The text is excellent and practical, the illustrations good and really illustrative, and the bookmaking and binding satisfactory. This is a book that every ophthalmic student and practicing ophthalmologist can read with profit and pleasure.'

Les syndromes neuro-hématiques Par Henri Roger, professeur de clinique des maladies nerveuses à la Faculté de médecine de Marseille et Jean Olmer, médecin des hôpitaux de Marseille. Paper. Price 32 francs. Pp 230. Paris Masson & Cie 1936

This monograph is concerned with the neurologic manifestations of diseases of the blood-forming organs. The first chapter deals with the neuro-anemic syndromes. This phase of the subject receives detailed discussion. The authors discuss their frequency, the work that has been done on the subject, and the theoretical and practical problems they present. After the discussion of the historical development of the subject and etiologic aspects, they consider the clinical and therapeutic applications. The diverse nature of nervous symptoms is pointed out and the authors classify them into medullary (medullo-anemic syndromes), encephalic (encephalo-anemic or psycho-anemic syndromes) and neuritic (poly-neuro-anemic syndromes). All forms of anemia are considered from simple hypochromic anemia to pernicious anemia. The pathologic anatomy, pathogenesis and therapy are finally discussed. The second part deals with neurologic disturbances when the red blood cells are above normal (neuropolythemic syndrome). The third chapter deals with neuroleukemic syndromes. In this group the pathogenesis is not always uniform and may result from hemorrhage or true leukemic infiltration. Under the neurohemorrhagic syndromes, hemophilia and purpuras are included and nervous accidents following blood loss in general are discussed. In the discussion of Hodgkin's disease the authors bring out the fact that there has been an increasing incidence of neurologic symptoms in this disorder within recent years. The various sites infiltrated by malignant lympho-granulomas are discussed. Finally, after considering the diseases of the blood that react on the central and peripheral nervous system, the authors devote the last chapter of the book to cases in which the modification of the blood or even diseases

of the blood-forming organs are in consequence of alteration of the nervous system (hematoneurosyndromes). Much of the material in this chapter deals with the modification of the red and white cell series by disturbances of the sympathetic and parasympathetic nervous system under experimental conditions. The authors raise the question as to the possibility of a central regulation of the blood formula. The monograph is an important collection of data that should interest the neurologist and the hematologist. The literature on the various subjects is well covered and at the end of each chapter is a well selected bibliography.

Die Ursprünge des Verbrechens Dargestellt am Lebenslauf von Zwillingen. Von Dr. Friedrich Stumpf. Boards. Price 5.80 marks. Pp. 176 with 3 illustrations. Leipzig: Georg Thieme, 1936.

The author continues the investigations originated by Johannes Lange on Crime as Destiny, *Studies on Criminal Twins*, Leipzig, 1929. Stumpf presents his own results of a study of thirty-seven sets of twins, in whom at least one member of the pair had been guilty of some criminal act. Of the male pairs, fifteen were identical or one-egg twins, seventeen pairs were not. Of the female pairs, three were identical, two were not. In the earlier part of the volume a detailed history of each pair of twins investigated is presented. The author attempts to analyze each group on the basis of a number of specific factors, and the results are clearly presented in tabulated form. Since the author is studying criminality in twins the first factor considered is whether or not both members of a pair were guilty of crimes. If both committed offenses, the correlation is indicated as positive. The second factor considered is whether each one of the twins committed only one crime or was a multiple offender. Stumpf also records whether the crimes were similar or dissimilar in nature. In the fourth place, he considers the environment and mode of life of each of the twins. The fifth factor is a consideration of the abnormal character of the individuals. In psychopathic twins, agreement of the latter factor indicates concordance of the abnormalities. A study of the tables reveals that the identical twins show far greater agreement in criminality than the nonidentical, which is not surprising to any one who believes that the tendency to crime is hereditary as identical twins tend to show greater fundamental similarity. The author's results indicate a preponderance of the hereditary factor in the origin of crime, with which conclusion some sociologists might be inclined to disagree. The difficulty of obtaining a sufficient number of cases of this particular kind is obvious. Nevertheless, the results in this and previous studies are significant. It would be desirable for the purpose of drawing more definite conclusions that a study be made of crime in identical twins reared apart. Adequate information of this type is the most difficult of all to obtain. Studies of twins appear to offer a logical and promising field for a better understanding of the age old question whether nature or nurture is the greatest influence in the destiny of man's life. Stumpf's contribution while limited in scope, should stimulate further investigation along this line.

Collected Writings Alfred F. Hess. In two volumes. Cloth. Price \$15 per set. Pp. 719, 734 with 127 illustrations. Springfield, Illinois: Charles C. Thomas, 1936.

The collected writings of Alfred Fabian Hess (1875-1933) contain the most important papers published during his lifetime. Mrs. Hess has written a short foreword. A biographic memoir written by Abraham Flexner is an appropriate introduction to this important collection of papers. As an investigator and contributor to the progress of pediatrics, Hess had no peer in America. Abraham Flexner quotes Dr. Edwards A. Park, who said that "Hess was the best example of what can be accomplished in science by the ability to think alone and unaided." Park continues: "Hess was the foremost investigator among pediatricians in this country. There was no one else who could possibly be compared with him." His medical papers cover a wide range of subjects, most of which show originality and painstaking work. His first papers dealt with pathologic and clinical subjects, particularly tuberculosis in infants, enlargement of the lymph nodes, tuberculosis of the tonsils, primary tuberculosis of the mesentery glands, the incidence of tubercle bacilli in New York City milk, and other papers on this subject. His contributions on infantile scurvy introduced some of our modern conceptions of this disease. He found that boiling milk

and vegetables destroyed the antiscorbutic factor, though he demonstrated that canned vegetables retain their vitamin C content. He also showed that scurvy may exist in latent form. His contributions to our knowledge of this disease added materially in a more complete understanding of its nature and etiologic aspects. One of his late papers on this subject dealt with the urinary excretion of the vitamin C factor. Hess next turned his attention to a study of rickets. These investigations were epoch making in character. After the profession was becoming skeptical about the potency of cod liver oil, it remained for Hess to show that it had specific curative properties. He discovered that vitamin D in food substances could be produced by irradiation, and also that it was possible to irradiate milk. Other investigations and papers deal with the isolation of the D substance in the sterile fraction of the food. He wrote on the spectrographic method for the study of vitamin D and also described a method for biologic assay of vitamin D in the blood and excreta. In his later papers he became interested in the relationship of foods to dentition and also on radiographic studies of calcification of the teeth from birth to adolescence and the relation of rickets to dental caries in the deciduous and permanent teeth. These collected writings of Alfred Fabian Hess commemorate the life work of one who had a genius for scientific investigation and who showed an unflinching industry and rare intellectual gifts. These volumes will have a permanent value in the story of the progress and development of American medicine.

Lexikon der kosmetischen Praxis. Bearbeitet von In und ausländischen Fachleuten aus Wissenschaft und Praxis. Schriftleitung: R. Volk und F. Winter. Paper. Price 75 marks. Pp. 705 with illustrations. Vienna: Julius Springer, 1936.

A condensed review scarcely does justice to work of this magnitude. The masterly presentation of the entire field of cosmetics as well as the discussion of related subjects on plastic surgery, dermatology, pharmacology and pharmacy in lexicographic style makes information readily available. Hygiene, vitamins, allergies, cosmetic surgery and cosmetic preparations are presented in the light of recent contributions. The clear, precise and concise language may be easily interpreted by a professional man with the aid of a small scientific dictionary. Technical details are given with ample references to the latest literature. The numerous illustrations are excellent. Though compiled by experts in each field, the unity of the work is undisturbed. The book will be a valuable addition to those interested in the fields covered. Compilers, editors and publisher are to be thanked for giving such a timely work to the specialists in each subject. The book may be recommended because of its relative completeness.

Animal Micrology. Practical Exercises in Zoological Micro Technique. By Michael F. Guyer. Professor of Zoology in the University of Wisconsin. With a chapter on Drawing by Elizabeth A. (Smith) Reese. Fourth edition. Cloth \$2.50. Pp. 331 with 76 illustrations. Chicago: University of Chicago Press, 1936.

For thirty years Professor Guyer's handbook of microscopic technique has been used by students as an aid in the intricacies of the preparation of animal tissues by fixation, sectioning and differential staining for the microscopic study of their cellular structure. This edition has been rewritten entirely so as to incorporate recent improvements, among which is the dioxan or diethylene oxide method of embedding tissues in paraffin. This avoids the hardening effects of absolute alcohol and clearing reagents shortens the time of preparation and preserves normal structure. Recently tertiary butyl alcohol was found to have similar desirable qualities. The book presents only the well proved standard methods but covers the entire range of microscopic technique in animal micrology, with chapters on blood, bacteria, embryologic and cytologic techniques, reconstruction, drawing the microscope, and standard reagents. There is also an extended tabular view of methods for the preparation of animal tissues and organs and directions for the preparation of material for zoological laboratory courses. The author might have emphasized in the preparation of smears of stools for human intestinal Protozoa the value of fixation by hot (60 C.) Schaudinn's fluid with the addition of glacial acetic acid (4 per cent) and the rapid method of staining with the use of warm (30 C.) iron-alum and hematoxylin. The use of Wolff's pencils in the preparation of pencil drawings for histology illustrations might also be added in the next edition.

A Treatise on Materia Medica and Therapeutics Including Pharmacy Dispensing Pharmacology and Administration of Drugs By the late Rakshidas Ghosh. Fourteenth edition. By Birendra Nath Ghosh. F.R.F.P. & S. Professor of Pharmacology. Carmichael Medical College Calcutta. Cloth. Price Re 7 As 8 12s 6d. Pp 724 with 13 illustrations. Calcutta Hillton & Co 1936

There has been a progressive "modernization" in successive editions of this book until this edition looks much like an English or American book on the same subject, and it has been brought down to date also in its contents. It conforms to the British Pharmacopoeia (1932) and to the British Pharmaceutical Codex and in addition it lists the Indian indigenous drugs in a special section of about ten pages devoted merely to some important and commonly used drugs. Such selection makes this chapter all the more interesting, as it may well be assumed that some of these at least may also be worthy of attention outside of India. The author attempts to make his book a work on pharmacology as applied to therapeutics and he regrets that "the teaching of pharmacology is not as an applied subject but as a separate subject detached from therapeutics." A result of such teaching is that "while a student, or for that matter a junior practitioner, may possess a knowledge of modern pharmacology, he is incapable of writing a prescription free from incompatibles and based on rational principles, with the result that he has recourse to the use of set prescriptions or proprietary remedies of questionable value." To all this one may say "Amen."

College Biology By Walter H. Wellhouse. Professor of Biology. Iowa State College and George O. Hendrickson. Assistant Professor of Zoology. Iowa State College. Cloth. Price \$3. Pp 381 with 166 illustrations. New York F. S. Crofts & Co 1936

This is the sort of textbook that perpetuates misinformation under the guise of a readable style and altruistic motives. The preface states that emphasis is placed on the biologic bases underlying human behavior and on the interests of general students rather than on the preparation of future biologists. Much of the material contained is stated to be original. Some of it certainly is. The book is inaccurate and often misleading. A few instances will suffice to illustrate the uncritical writing. Plasmodium is stated to form spores in red blood cells, Noctiluca to inhabit tropical seas and to give them the color of tomato soup, a trypanosome to cause a deadly sleeping sickness in South Africa, free oxygen present in digesting food to be utilized by the tapeworm in respiration, man to obtain Trichinella worms by eating "measly" pork and little hookworms in the soil to hook onto human skin and dig their way into the blood stream. Many of the illustrations are well known veterans long in service or wretchedly inadequate new ones, and all are poorly executed. Publishers might profit by having manuscripts critically read before investing in printing them. High schools, junior colleges and state colleges should have textbooks as critically written in matters of scientific accuracy as colleges and universities.

Die Chirurgie der Schädelbasisfrakturen auf Grund 25jähriger Erfahrungen Von Dr. Otto Voss. o. ö. Professor und Direktor der Lehr. Ohren Hals Nasenheilkunde an der Johann Wolfgang Goethe Universität Frankfurt a. M. Paper. Price 24 marks. Pp 182 with 93 illustrations. Leipzig Johann Ambrosius Barth 1936

Voss considers the surgical management of basal skull fractures from a point of vantage acquired through twenty-five years experience. His discussion is based on a study of 122 selected cases of basal skull fractures of which seventy-seven were treated by operation and forty-five by conservative management with a total mortality of 20.5 per cent for the 122 selected cases. General remarks on etiology and pathology are followed by statistical consideration and a detailed pathologic study of special types of basal fractures. Symptoms and signs, especially those associated with involvement of the petrous portion of the temporal bone are correlated with the roentgenologic and operative observations. Under treatment the author discusses indications and contraindications for operation, technic and route of approach, and tabulates the types of operations performed. Case reports and consideration of individual cases give the reader a clear concept of the author's views in diagnosis and treatment. The book is well illustrated with reproductions of excellent photographs of gross pathologic specimens and of films and with numerous colored drawings of histologic

preparations. An extensive bibliography is included. Since the author's material is for the most part a selection of complicated cases with traumatic involvement of the auditory and vestibular apparatus, the facial nerve and the nasal accessory sinuses, or with infection of the ear and meninges, the book will be of more interest to the specialist in head injuries and to the otorhinologist than to the general practitioner.

The Relationship of Eye Muscles to Semilunar Canal Currents in Rotationally Induced Nystagmus By John Favill. A.B. M.D. F.A.C.P. Clinical Professor of Neurology. University of Chicago. Cloth. Pp 46 with 7 illustrations. Privately printed. Chicago 1936

This little work contains results of research over a considerable period of years and embodies a number of papers previously published in various journals and in one book on neurology. After an introduction in which the original work of Ewald is discussed and the views of Ruttin, Lemere and Quix are given the author discusses the assignment of eye muscles to canal currents. The recognized types of nystagmus induced by rotation are presented in a table. Furthermore there is a table showing the theoretically possible types of nystagmus produced by rotation. The author states that the "total number of possible currents or combinations of currents in one labyrinth is twenty-six. Fourteen current pictures account for the known types of induced nystagmus. Twenty-six current pictures remain. Calculations were made as to how to produce these by rotation and what eye movements would result. Experiments with one normal man show the results as predicted." There is a fairly comprehensive bibliography appended, and seven tables are included. This little brochure should prove interesting to all who concern themselves with tests of the vestibular mechanism.

Dermatologie und Chirurgie Darstellung der Grenzgebiete für die Praxis Von Wilhelm Richter. Direktor der Universitäts-Hautklinik Greifswald. Mit Geleitworten von Prof. Dr. A. Bier und Prof. Dr. K. Zieler. Paper. Price 34 marks. Pp 477 with 356 illustrations. Leipzig Leopold Voss 1936

This volume is devoted to the borderlines of dermatology and surgery, written by a dermatologist who served as a consultant at the surgical clinic of Professor Bier. The material is considered in eleven subdivisions and covers more than 250 diseases, many of which are not usually found in textbooks of dermatology. Thus one finds sections on various types of muscle, bone and joint diseases, oral lesions, the surgical complications of syphilis and tuberculosis an unusually complete presentation of tumors of the skin, a detailed description of the different types of cutaneous gangrene and some of the surgical forms of venereal diseases. No attempt is made to present surgical technic or to duplicate the field usually included in books on minor surgery. Emphasis is placed on localization, symptomatology and histopathology as aids to diagnosis and on etiology and pathogenesis as aids to treatment. The large number of black and white and histologic illustrations are well selected and unusually clear. At the end of the book is a bibliography which seems rather incomplete and only rarely gives credit to American authors for their contributions to modern dermatology. In spite of this omission this book can be highly recommended for its vivid portrayal of the borderline field of two important medical specialties.

Why Keep Them Alive? By Paul de Kruif. In collaboration with Ithea de Kruif. Cloth. Price \$3. Pp 293. New York. Harcourt Brace & Company 1936

Most of the writings of Paul de Kruif which appear in this book have been published previously in the *Country Gentleman* or in the *Ladies Home Journal*. Paul de Kruif has established his ability to dramatize medical discoveries and medical work. In this book he is concerned with malnutrition and disease as they affect children, observing the results of malnutrition and disease on the growing child and cogitating as to the failure of our civilization to meet this problem. Dr de Kruif becomes well nigh frantic in his emotional response and conveys his fanaticism to the reader by the manner of his expression. As is unfortunately typical of his other writings in the field of medicine he is far too willing to accept research as established discoveries and is usually too ready to recommend acceptance as routine of a method or technic which is still in an experimental stage. He is likely to assign far too much credit to one

individual for the development of a method or a technic when the work of that individual may not even warrant a share of the credit or priority. Nevertheless, the general effect of his works is good, and they are, moreover, sufficiently popular to command for him a wide audience. 'Why Keep Them Alive?' is more dramatic and moving than some of his previous contributions, yet it cannot compare in interest or authenticity with his world-known contribution on "Microbe Hunters."

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Medical Practice Acts Corporate Practice of Medicine Illegal in Illinois—The United Medical Service, Inc., a corporation organized for profit operated a clinic in Chicago rendering an advertised fixed-fee low-cost medical service through licensed physicians employed and paid by the corporation. The state by its attorney general petitioned for leave to file an information in the nature of a quo warranto to require the corporation to show by what warrant it engaged in the practice of medicine. The trial court held that the corporation could not legally practice medicine in Illinois and rendered a judgment against it. From this judgment the corporation appealed to the Supreme Court of Illinois.

The corporation contended among other things that the ownership of a clinic with offices where the treatment of disease is engaged in solely by licensed physicians employed by the corporation does not constitute the practice of medicine by the corporation. It argued that the fact that the contract of payment for the medical services to be rendered is made between the corporation and the patient does not change the professional relationship between the patient and the physicians who treat him in the corporation's offices. With this contention the Supreme Court could not agree, citing a former decision by the court in *Dr Allison Dentist v Allison* 360 Ill 638, 196 N E 799 wherein it was said after pointing out that the practice of a profession is subject to licensing and regulation and is not subject to commercialization or exploitation.

To practice a profession requires something more than the financial ability to hire competent persons to do the actual work. It can be done only by a duly qualified human being and to qualify something more than mere knowledge or skill is essential. No corporation can qualify.

From the stipulated facts the court said the United Medical Service Inc., had been engaged in the pursuit of activities which under the medical practice act it could not pursue without a license. The medical practice act evinces the manifest intent on the part of the legislature that only individuals may obtain a license to practice medicine. No corporation can meet the requirements of the act. The fact that the certificate of incorporation of the United Medical Service states that one of the corporate objects is the prevention and treatment of disease for profit does not legalize the practice of medicine by the corporation. When a corporation for profit is formed under the general act relating to incorporation the laws of the state determine what powers may be lawfully exercised not the statement appearing in the certificate of incorporation.

A corporate franchise the court said proceeds from the sovereign power and the people have the right at all times to inquire into the title by which such a franchise is claimed or exercised and to have a judgment of ouster if the franchise was improperly granted. In the present case the only relief sought and obtained was the ouster of the corporation from the assumption and usurpation of a franchise charged to have been improperly granted to it. Quo warranto was therefore the proper remedy. The fact that the medical practice act subjects violators to a possible fine or imprisonment does not preclude the use of quo warranto. From the express language of the act in the opinion of the court it is apparent that the penalties prescribed are directed primarily against individuals practicing medicine without a license. The punishment by

incarceration is not applicable to corporations. The maximum fine of \$500 that may be imposed, if it applies both to corporations and to individuals, hardly affords an adequate remedy to prevent recurrences of the unlawful exercise of a power improperly conferred on corporations such as the United Medical Service. There was, therefore, no adequate remedy provided in the medical practice act that could be invoked in the present case.

If the medical practice act be construed to prohibit corporations from practicing medicine by employing licensed physicians to that end, the United Medical Service contended, the act constitutes an unreasonable exercise of the police power by the state. The police power of the state and the Supreme Court includes the power to enact comprehensive detailed and rigid regulations for the practice of medicine surgery and dentistry. There is no right to practice medicine which is not subordinate to the police power. To sustain its contention, the United Medical Service relied on *Liggett v Baldridge* 27 U S 105, 49 S Ct 57 73 L Ed 204, wherein the United States Supreme Court held invalid a Pennsylvania statute providing that every pharmacy or drug store should be owned only by a licensed pharmacist and that no corporation association or copartnership should own a pharmacy unless all the members or partners were licensed pharmacists. The United States Supreme Court held that mere stock ownership in a corporation owning and operating a drug store could have no real or substantial relation to the public health and that the law was an unreasonable and unnecessary restriction on private business. It does not follow, however said the Supreme Court of Illinois, that because a person may have a constitutional property right to operate a drug store he has a like absolute right to engage in the practice of a profession such as medicine dentistry or law. Neither a natural person nor an intangible entity can complain if unable to fulfil the requirements reasonably prerequisite to obtaining a license to engage in a particular profession. The holding in the *Liggett* case continued the court, does not conflict with the well established rule that the state may deny to corporations the right to practice professions and insist on the personal obligations of individual practitioners.

The judgment of the superior court against the United Medical Service, Inc. was therefore affirmed.—*People by Kerner Atty Gen v United Medical Service Inc (Ill)* 200 N E 15.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1926 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

Urea in Healing of Chronic Purulent Wounds—Robinson points out that, in an investigation of the means by which the healing effects of surgical maggots are produced in suppurating wounds of long standing, it was recently discovered that the purine derivative allantoin occurs in maggot excretions and stimulates healing in purulent wounds. Further study has shown that this is not the only substance with therapeutic properties present in maggot excretions. Urea, the still simpler and well known product of protein metabolism, has been found to produce similar healing effects. Interest was aroused in the possibility that urea might have healing characteristics through the picture presented by the structural chemical formula of allantoin. On hydrolysis, the side chain easily forms urea. The conception that allantoin is therapeutically active partly through its side chain led to the present investigation. Urea has been found to stimulate healing in chronic purulent wounds. The effects obtained are a cleansing of the wound by the removal of necrotic material and pyogenic bacteria present and a promotion of the growth of granulation tissue. Like allantoin, urea occurs in maggot excretions and its presence serves as a further elucidation of the remarkable efficiency of surgical maggots in healing chronic suppurating wounds. This healing action of urea probably accounts in part for the custom prevalent for centuries in Europe, Asia and Africa and also practiced in America of using urine to promote the cleansing and healing of wounds. Urea, which is manufactured in enormous quantities for use as a soil fertilizer, is available for therapeutic use without any connection with animal excretions. It can be made from the three simple gases nitrogen, hydrogen and carbon dioxide and is a pure white crystalline substance. In wound treatment a 2 per cent solution in water has been used on

saturated gauze dressings applied directly to the wound. The solution is bland, odorless and nontoxic. The treatment is inexpensive and easily given. Urea is present in the cells of all the tissues of the body, it rapidly permeates the membranes of the cells and its concentration in these rises and falls readily with that of the blood and lymph. In view of the remarkable cleansing and healing properties of urea in chronic purulent wounds it appears that the general conception of this material as only a waste product has tended to obscure its therapeutic character.

Lumbar Puncture in Head Injuries—Based on a study of the anatomy and physiology of the brain and on clinical experiences in a series of more than 500 cases of head injuries with study of necropsy material, together with a review of the literature on the subject, Shatara makes the following deductions: 1. The withdrawal of cerebrospinal fluid by lumbar puncture as a diagnostic procedure should be performed in every case of head injury after the patient has reacted from shock. The pressure should be recorded and the fluid collected in three tubes of about 5 cc. in each. If the fluid is uniformly bloody in the three tubes, if the supernatant fluid is xanthochromic after centrifuging and if the pressure is over 10-12 mm. of mercury, a diagnosis of intracranial injury with probable brain laceration or contusion and hemorrhage can be made. If the fluid is clear but under increased pressure and if there is other corroborating evidence a diagnosis of traumatic cerebral edema can be made. If the fluid is clear and the pressure is normal, one is justified in ruling out an intracranial injury even in the presence of a fractured skull. 2. Lumbar puncture is a useful therapeutic procedure in cases of traumatic edema. The pressure should be reduced by half the excess above normal and the procedure repeated about every six to twelve hours until the pressure is normal. 3. When the fluid is bloody and under increased pressure no ill effects have been noted from repeated punctures, if the pressure is not reduced suddenly.

Cervicitis—Roblee points out that cervicitis is a condition of structural change in the cervix. It is produced by the gonococcus or by nonspecific pyogenic organisms which have gained a foothold because of trauma to the cervix. The erosion of the cervix is columnar epithelium extension replacing the squamous epithelium. The healed erosion of cervicitis is the squamous epithelium growing back over the columnar extension. This causes the racemose gland to become permanently blocked with a resulting hypertrophy of the entire cervix, and producing the picture of chronic cystic cervicitis. Whatever erosion exists at this stage depends on the completion of regrowth of squamous epithelium. If the columnar epithelium is piled up so that the squamous epithelium cannot replace it a papillary erosion with ectropion formation exists. The author emphasizes that the treatment for such a condition must be one of removal of this structural change. To patch it up so to speak means inviting trouble in later years. If the squamous epithelium has lost out in the erosion struggle and grown abnormally, the entire cystic diseased gland bearing area must be destroyed and removed so that a single layer of squamous epithelium can line the newly constructed cervix and its canal. The Sturmdorff operation is designed for this end and accomplishes it effectively. It became the problem to apply this principle to the ambulatory patient. For the past five years various surgical diathermy procedures have been applied to ambulatory cases of chronic cervicitis in the outpatient department of the Washington University School of Medicine. These cases have been followed by its social service at three months for the first year after treatment and every four to six months thereafter. In this manner it has been determined how lasting a result has been obtained by the various

methods employed. The patients are selected from the general gynecologic clinic and referred to the cervicitis clinic. Here the chronicity is determined by the Schiller iodine stain and colposcopy and an attempt is made to rule out a definite malignant condition. Biopsies for study are taken, and the treatment is begun. No anesthetic is used in ambulatory cases. Sodium amytal or some other suitable barbiturate with scopolamine or small doses of morphine and scopolamine are used in cases that are hospitalized for twenty-four hours or longer. It has been felt that the knife probing depth removal has given more lasting results than the wire loop conization that cuts through the cystic area and improves the condition by drainage rather than actually removing all the cystic area by destruction. It appears that there is less tendency to immediate hemorrhage with the knife coagulation method as compared with conization, as no packing is ever used after the former procedure. For this reason the author has adhered to the knife coagulating method for ambulatory cases and favors a large wire loop removal for hospital cases for which the Sturmdorff operation has not been elected. The author employed surgical diathermy in the past five years in 350 cases of cervicitis. Of all cases treated, 86.61 per cent had an uneventful postoperative course and good result. Good end results were obtained in 94 per cent of all cases treated.

Ethylene Glycol and Magnesium Sulfate Paste in Treatment of Inflammatory Processes.—Hinton shows that, in preparing an ethylene glycol-magnesium sulfate paste it is necessary to use about 60 per cent of magnesium sulfate and 40 per cent of ethylene glycol by volume. The exact proportion varies with the different preparations of magnesium sulfate. The ethylene glycol should be brought to a boil and the magnesium sulfate slowly added to the glycol preparation and thoroughly stirred until the solution becomes adherent to the stirring rod. Then it is transferred to an electrical mixer and kept in constant motion for from twenty to twenty-five minutes. A chemical change takes place when the two ingredients are mixed which is manifested by an elevation of temperature. The thick paste should be allowed to stand for ten days before it is used. The preparation should be stirred daily for five minutes during this period. The paste is of a semisolid consistency and can be applied thickly over the affected area and covered by a dressing. It is usually necessary to change the paste every eight hours in cases of severe cellulitis. In cases of localized infection such as a furuncle it can be applied and the area left uncovered. The paste should be put on at frequent intervals. The object in using this preparation is to have a medicament with hypertonic properties so that continuous osmosis will take place in the inflammatory area and by this means the infection will be localized and the edema relieved and as a result the pain greatly diminished if not entirely overcome. During the two year period that the preparation described has been used more than a hundred inflammatory conditions have been observed which have ranged from

simple furuncles to severe cellulitis with lymphangitis and even to furuncles of the upper lip and around the nares. The results have been most astounding in the severe type of cellulitis. Fewer severe infections the preparation has proved equally effective, and it has a definite field of application in the treatment of ordinary furunculosis or low grade infection. There are three reasons for using the ethylene glycol and magnesium sulfate paste: 1. It acts more rapidly than wet compresses of magnesium sulfate or other ointments. 2. It is more uniformly successful in arresting or localizing infections than other methods of treatment. 3. It acts continuously and therefore saves nursing care.

Surgical Treatment of Hypertrophy of Breast.—Fomon emphasizes that in each particular instance the surgeon must critically study the indication to determine whether operative intervention is justified, he must be especially cautious in view of the fact that spontaneous regression is possible. The desirability of the reconstruction cannot be left entirely to the whim of the patient, despite the minor character of the operative procedure. Before describing the operation, the author gives a brief description of the anatomy of the breast and then mentions the several varieties of idiopathic hypertrophy. Then he gives a detailed description of the technic of the operation. He shows a diagram by which the location of the new areola can be determined. Then he takes up the approach to the breast, its delivery, reduction, molding and fixation, the transplantation of the areola, the removal of the redundant skin and the dressing. The author concludes that, although the operation borders on being a major one, experience shows that it is well borne. Recovery is rapid, and the relief is great. Serious complications are rare, provided a sufficiently wide medial pedicle is left intact. The patient may sit up in bed on the third day. Every other stitch is removed on the fifth day, and by the eighth day all have been removed.

Neurologic Syndromes Produced by Arsenic and Lead.—In order to illustrate the relation of arsenic and lead to neurologic disease Cornwall describes clinical observations on six cases. One patient developed locomotor difficulties following consumption of bootleg whisky. Another patient developed ataxia and weakness in all extremities. A third patient developed severe headaches as a result of ingesting wine that was found to contain large amounts of arsenic. The wife of this patient who had consumed wine from the same source developed locomotor difficulty, mental confusion and slurring of speech. A fifth case represents a myelodysplasia due to intoxication by arsenic or lead or both derived from home brewed beer. The last case described is another example of headache as the most prominent symptom. Individual tolerance to the metals is subject to wide variation. Pathologic damage usually results from the retention of the metals in the tissues. Their presence in the blood indicates that they have been released from the

tissues and are in a mobile state. The urinary content indicates merely the amount that is being eliminated at the particular time the specimen is collected. Absence of metals from the urine may mean nothing unless the patient is receiving eliminative therapy at the time the specimen is collected. The quantities in both the blood and the urine may be high at a time when the clinical symptoms are regressing or even after they have been completely relieved. Except in dermatologic conditions it is speculative as to how much significance, if any, can be attached to the quantities found in the hair or the skin. Both tissues may be functioning merely as storage reservoirs where the metals reside in an inert state. When clinical symptoms are present, which may be attributable to metallic retention, mobilization and excretion are usually followed by clinical improvement. The author believes that this is always true in the case of arsenic. When the carbon dioxide content of the blood reaches 70 volumes per cent a refixation of arsenic in the tissues may result and produce an accentuation of symptoms. When this occurs however the urinary excretion is diminished. The situation is somewhat different with lead, and too rapid mobilization may accentuate the initial symptoms or produce additional ones such as gastro enteritis. In such cases immobilization of the metal is indicated and this may be accomplished by the administration of calcium in the diet, by mouth or intravenously. Diarrhea and colic are the commonest acute symptoms due to lead and they can usually be promptly relieved by the intravenous administration of calcium chloride or calcium gluconate. Tincture of belladonna by mouth is also of value. Whereas elimination of lead is thought to be accomplished best by acidification with ammonium chloride or phosphoric acid and a low calcium diet thereby creating a negative calcium balance similar results may be obtained though probably less effectively by the administration of alkalis. Viosterol parathyroid extract and potassium iodide also induce its elimination. In the cases recited sodium thiosulfate was effective in promoting the excretion of both arsenic and lead. In order to assure the best result the sodium thiosulfate should be freshly prepared by dissolving 1 Gm of the crystalline substance in 10 cc of sterile freshly distilled water.

Progressive Muscular Dystrophy—Zabriskie and his associates point out that in a selected group of patients suffering from primary muscular dystrophy who were studied to determine the effect of aminoacetic acid on the metabolism and its therapeutic value Harris called attention to the striking deformity of the mandible in two of the members of the group who happened to be brothers. Further investigation revealed other peculiarities in the clinical picture and it became apparent before long that five patients in the group presented a combination of three distinctive clinical signs which the authors had never encountered together before. The triad referred to consists of (1) contractures appearing early in the course of the illness and involving the larger joints (2) a pseudohypertrophy of the anterior tibial muscle group with great loss in motor power, (3) a deformity of the mandible which exhibits a very wide angle, a malocclusion of the front teeth and a wide spacing of the lower front teeth. The authors describe the histories of these patients and reproduce photographs showing the deformity of the mandible. They also discuss the metabolic data and the x-ray studies.

Simple Treatment for Psoriasis—Krafka observed that in the South psoriasis often clears up to some extent during exposure to the summer sun. This led him to the hypothesis that it might be cured with viosterol. A trial test was made of the hypothesis. A patient with a case of ten years' standing continuous duration was put on a routine treatment of viosterol two gelatin capsules containing 3 minims (0.2 cc) each of halibut liver oil with viosterol daily. Within sixty days from the beginning of the test, the skin of this patient was entirely clear. The author describes two other cases of psoriasis in which he obtained favorable results with viosterol medication. He admits that observations in only three cases do not permit definite evaluation. He says that if the treatment were at all hazardous or difficult he would not presume to lay it before the profession but that in view of the simplicity of the method he thinks it should be put to a trial.

New Microreaction for Serodiagnosis of Syphilis—Casili presents a simple adaptation of the Kahn antigen for slide agglutination. The antigen is prepared and titrated exactly according to the instructions given by Kahn. After the antigen salt mixture precipitate has been standing for half an hour although ten minutes will be sufficient the mixture is centrifugated at high speed for approximately ten minutes. This last step constitutes the first modification. The clear supernatant alcoholic salt solution is carefully decanted off. A clean piece of soft white cloth is inserted into the tube down to but not touching the mush at the bottom, so as to absorb as much as possible of the alcoholic salt solution.

remaining. This mush is a yellowish white, iodized oil, cholesterolized mixture, and it is this substance which is used in the test. This separation of the antigen mush from the alcoholic salt solution constitutes the second and really significant modification. Now there is placed on three clean slides, previously labeled known positive, known negative and unknown, 0.1 cc. of the inactivated serum corresponding to the label. A smaller amount of inactivated serum can be used with equally good results. One loopful of antigen mush is then added to each of the serums and with the same loop emulsified until no visible particles remain. A thin platinum wire loop 0.5 mm. in diameter is used and is sterilized in the flame and allowed to cool before each loopful is taken. This procedure may be continued for as many unknown serums as desired, but the author feels that five unknown serums is the maximum number advisable. Clumping almost immediately follows emulsification in the positive serums; the negative ones remain milky and homogeneous. For weaker positive serums a minute may elapse before clumping is observed. The results are read with the naked eye and are best observed with reflected light from below. The observation should not exceed five minutes and clumping is facilitated by occasional gentle tilting of the slide back and forth. Reading should be made as strongly positive, weakly positive and negative, although with added experience more quantitative readings are not, as a rule, difficult.

Influence of Breast and Artificial Feeding on Infantile Eczema.—Grulee and Sanford point out that although infantile eczema has received much attention in recent years the effect of diet on these infants, once so stressed, has been largely lost sight of recently. For this reason the authors studied 20,061 babies. An infant was considered suffering from infantile eczema if there were any lesions on the face or body at the time of examination. This does not include 'cradle cap'. None of these infants received any treatment except the discontinuance of soap and water to the skin and the use of olive oil only for cleansing purposes. None of the feedings were changed in any way. In the artificially fed infants 1½ ounces of boiled cow's milk and one-tenth ounce of cane sugar per pound of body weight were used. In all infants cod liver oil, orange juice, cereals and vegetables were added to the diet. The authors found that the general incidence of infantile eczema is lowest in the breast fed infants. In the partially breast-fed it is twice as frequent as in the breast-fed infants, and in the artificially fed infants seven times as great. In the monthly incidence both those infants entirely breast fed and those partially breast fed show an increase to the sixth month and then a rapid decrease through the ninth month. The artificially fed infants continue to show an increase until the eighth month and only a slight decline in the ninth month. In the seasonal incidence all groups are increased in the winter and spring and decreased in the summer and autumn.

Capillary Resistance Test and Its Relation to Vitamins C and D.—Weld says that among the various manifestations of scurvy the hemorrhagic tendency has been suggested as that most useful for detecting latent or subclinical cases. The hemorrhages are due to an increased permeability of capillaries and several workers have suggested the use of the capillary resistance test to diagnose latent scurvy. The author

mentions a number of these tests and he hoped that some such method might be useful in detecting early or mild cases of vitamin C deficiency and hence be of service in determining the optimal vitamin C content of the diet. He first applied Dalldorf's technic, in which the lowest degree of suction necessary to produce any petechiae, in a cup 1 cm. in diameter applied to the skin of the outer aspect of the upper arm for one minute, determines the threshold, to a group of normal individuals. This consisted of members of the laboratory staff and convalescent patients in the hospital. The ages of the children ranged from 4 to 14 years, the infants being under 2 years of age. All were receiving adequate amounts of vitamin C in the diet. In the cases of the infants the skin of the abdomen was used instead of that of the upper arm, though in several instances the arms were tested as well with similar results. The author obtained a great variation in responses. He observed that young children tend to have a higher resistance than older children or adults. No improvement in the capillary resistance following administration of tomato juice was observed in a group of eighty adults. These were in an institution, their diet was well controlled and it was one low in vitamin C. Several children suffering from scurvy or known to have had no source of vitamin C for weeks were found to have normal resistances. In ten of eleven subjects viosterol in moderate doses or irradiation with an ultraviolet lamp promptly raised the capillary resistance. From these observations the author concludes that the capillary resistance determination is not a useful means of determining the state of nutrition with regard to vitamin C. Vitamin D is a more effective agent than vitamin C in increasing the capillary resistances.

Craniocervical Movement and Muscle Strength.—Weiss grow shows that manipulations of the head and neck in the diagnosis and treatment of disorders of the upper respiratory tract all call for a better understanding not only of the reflex mechanisms but also of movement and muscle strength.

craniocervical neuromuscular apparatus. Except for the cephalogyrus paralysis that occurs as part of the syndromes of Schmidt and Jackson and the occasional references to the nuchal musculature in the elicitation of the tonic neck reflexes, little attention has been paid by the neurologist to the cephalocervical region. The craniocervical movements and muscle strength are particularly affected in lesions that involve the supranuclear motor representations of the lower cranial nerves. When the head of the patient opposes the examiner's hand in the anterior aspect, the patient's chin rotates toward the hemiplegic side and contralateral to the lesion. Head movements that occur in irritative and destructive lesions of the brain should be explained on the basis of the function of the craniocervical system. A case with a Nothnagel syndrome is presented to show the effects of an extrapyramidal lesion on the function of the craniocervical structures. The disturbances in movement and muscle strength of the craniocervical apparatus are furthermore illustrated in multiple vascular lesions of the pons and medulla and compared with the reactions obtained in encephalitic involvements of these regions. Different reactions were obtained in cervical spinal diseases depending on the columns affected. Thus in disease of the anterior horn associated with a case of syringomyelia a different response was elicited from that noted in a case of multiple sclerosis. In a case of multiple sclerosis a clockwise and counterclockwise unilateral head clonus the first one to be presented in the literature, was observed. Lesions of the peripheral cervical nerves produce a much more circumferential and diffuse muscle weakness than that resulting from the localized intracranial unilateral lesions. They also differ distinctly from the effects on selective nuchal muscle groups as encountered in encephalitis. Cases of torticollis myositis or cervical osteoarthritis can be differentiated from the craniocervical disturbances of the preceding groups by palpation, local tenderness and other observations.

Passive Vascular Exercises in Obliterative Vascular Disease—After presenting a classification of the peripheral vascular diseases Board gives his attention to the primary organic diseases of the arteries the primary vasomotor disturbances being disregarded. He points out that the symptoms are due to lessened blood supply to the tissues of the affected extremity. Subjective coldness is often a prominent symptom of organic arterial disease. The objective signs are of greater importance than the patient's symptoms in arriving at a diagnosis. They are absence or decrease in pulse lowering of surface temperature and color changes in the affected extremities with ulceration and gangrene in the late stages. As a rule the foregoing signs can be elicited by palpation and inspection. The oscillogram thermocouple and roentgen rays are

helpful. The principal objective in the treatment is the reestablishment of an adequate collateral circulation and the relief of pain. While operations on the sympathetic nervous system have been helpful, when vasospasm predominates they have been disappointing in the obliterative diseases. It is true that often vasospasm plays a part in organic disease, but relieving the spasm does not affect the obliterative changes in the vessel walls. It is not logical to subject a patient to a formidable operation, such as ganglionectomy, to relieve a minor part of the cause of his circulatory failure. The older conservative treatments of improving collateral circulation by physical methods and active exercises have been beneficial but the improvement has been of short duration. Startling advances in the conservative treatment of obliterative vascular disease have been made since the report of Herrmann and Reid in 1933 on the results obtained by the use of passive vascular exercise. The apparatus consists of a motor driven pump and a glass chamber into which the extremity is placed. The glass boot is fitted snugly about the thigh or arm by a soft rubber cuff and the boot is connected with the pump by means of a rubber tube. The machine runs automatically and is capable of producing any strength of negative and positive environmental pressure at any selected rate of alternation. Usually 80 mm of mercury negative and 20 mm of mercury positive pressure have been found the most beneficial, and the rate of alternation is one complete cycle in about fifteen seconds. The treatment varies in frequency and length but on the average is from two to five hours daily. Approximately sixty to 100 hours is necessary to develop an adequate collateral circulation in patients with obliteration of major or secondary arteries. The most striking results have been obtained following the ligation of a large artery or its occlusion by emboli or thrombosis. Pain is usually relieved in a few hours treatment and in the majority of cases amputation has been avoided. Frozen feet have responded promptly if intensive treatment is instituted before complete obliteration of the arterioles has taken place. In arteriosclerosis with or without diabetes, passive vascular exercise has been an efficient means of overcoming the ischemia of the extremity. Pain is relieved and trophic ulcers usually heal rapidly. Threatened gangrene may be aborted and small areas of dry gangrene may be made to demarcate with minimum loss of tissue. However, the author emphasizes that passive vascular exercise is not a cure all and that the older conservative methods of treatment that have proved to be of value should not be neglected.

Treatment of Lymphogranuloma Inguinale—On the basis of the etiology and the pathology of lymphogranuloma inguinale von Haam analyzes the various methods of treatment. He thinks that surgical removal of the bulk of infected glands, which constitute dangerous foci for the further spread of the disease can be recommended. The curative effects of partial adenectomy is demonstrated by study of a series of cases so treated. The hopelessness of any type of therapy in the chronic forms of the disease esthiomene and inflammatory stricture of the rectum are emphasized and explained on the basis of the character of the pathologic lesions encountered in these conditions.

Paralysis Due to Posture—Clayton presents cases of nerve paralysis, which are apparently due to pressure during the maintenance of some posture. He describes cases of paralysis of the anterior tibial, the axillary, the ulnar and the radial nerves. An effort was made to discover to what extent minor cases of pressure paralysis occur that do not last a sufficient time to require treatment. Inquiries from hospital outpatients showed that the foot may 'go dead' on crossing the knees and that the hand or occasionally the whole arm may be 'dead' on waking in the morning. This 'deadness' clears up quickly on movement. In many cases it occurs only occasionally. The author thinks that some of these cases can be explained as perineuritis with added pressure. A few may be due to pressure only. It seems likely that in the others fatigue, cold and damp weather, or a septic focus may have been the predisposing cause.

Changes in Blood Pressure on Descent into Mines—It was O'Sullivan's object to discover whether recurrent changes in blood pressure, caused by descent into mines, play any part in the etiology of miners' nystagmus. Twenty-five healthy miners were examined before and after descent and a rise of systolic pressure was found in all of them (about 20 mm of mercury in two, 15 mm in four, 10 mm in eight, and 5 mm in eleven). In fourteen there was also a rise in pulse pressure. An hour after the descent the systolic pressure was still raised in five of the men, and slight transient oscillations of the eyeballs could be observed in all of these especially when they stooped. In four of these five cases of latent nystagmus the systolic pressure had risen more than 10 mm. Similar observations were made on twenty-five men suffering from miners' nystagmus and in this group the rise in systolic pressure after descent was more conspicuous (19 mm of mercury in one, 15 mm in eight, and 10 mm in the other sixteen). An hour afterward as many as fifteen still had raised systolic pressures. All twenty-five showed a rise of pulse pressure on descent. These results suggest that men who have nystagmus are also relatively susceptible to changes in blood pressure on descent. Though by no means conclusive they accord with the theory that repeated rises in pressure caused by descent into mines play a part in the etiology of miners' nystagmus.

Human Psittacosis in Australia. F. M. Burnet and J. Macnamara —p 84

Disturbances of Circulatory System Due to Pneumonia—Gartrell discusses the toxic effects on the circulatory system of such diseases as pneumonia, influenza, typhoid and typhus fevers and hyperthyroidism. The prime factor is the toxin, which may poison both the heart itself and the peripheral

vascular field, the latter effect being probably the more important. Even in the absence of myocardial damage, serious injury may be inflicted on the capillaries and arterioles. The mechanical factors in the causation of failure of the heart include capillary stasis in the diseased lung tissue, interference with respiration, fever, cough and emotional disturbance. Important as these factors may be, the normal heart has sufficient reserve to cope with the extra strain, but if the myocardium is damaged by the toxin or hampered by pre-existent cardiovascular disease, the mechanical factor may be the last straw precipitating cardiac failure. Peripheral failure is a condition akin to shock in which the walls of the small peripheral vessels are so damaged by the toxin that they lose their tone and dilate, with the result that the venous return to the heart becomes inadequate for the maintenance of the circulation. In the majority of patients the damage is not so severe. If venous congestion occurs or if the right side of the heart dilates, venesection to the extent of not less than 12 ounces (350 cc.) is indicated. If there is much anoxemia, oxygen should be given continuously day and night, at the rate of 2 liters per minute, for in some cases anoxemia is a factor in precipitating cardiac failure. The routine administration of digitalis is advocated by some and deprecated by others. The physician must remember that peripheral failure is more common than myocardial failure. Therefore it is in only a limited number of cases that there is any scope for its beneficial action. In the remainder it is tantamount to adding yet another poison to a system already beset by toxins. Rest, obtained by adequate doses of morphine if necessary, is an essential part of treatment. In pneumonia even apart from peripheral failure, the skin capillaries contain a great deal of blood. It is easy to see why hydrotherapy meets with some measure of success in cases of peripheral failure because it reduces the temperature and at the same time constricts the terminal vessels, so helping the peripheral circulation. Camphor appears to withdraw blood from the skin but its tendency to dilate the heart does not enhance its popularity. Alcohol is distinctly contraindicated. Epinephrine is of great value, for it not only causes constriction of the small arterioles but also increases the force of the heart's contraction and dilates the coronary vessels. However, when the toxic damage to the walls is sufficiently severe, even epinephrine fails. Solution of posterior pituitary may be given in addition to epinephrine in doses of 1 cc. subcutaneously every twelve hours, because its action is more prolonged. Unfortunately it tends to dilate the heart and to constrict the coronary vessels. Therefore it must be ascertained that the myocardium is practically unimpaired before throwing on it the extra strain. Strychnine is of value chiefly during convalescence.

Treatment of Diphtheritic Paralysis—Consideration of the mechanism of diphtheritic paralysis led Dodel and Foucher to ask whether the neurotoxic toxin fixed by the cellular lipoids could not be displaced by another neurotoxin with strong affinity for the nervous lipoids. For these theoretical reasons they investigated the possibility of displacing the combination of the diphtheritic toxin with the nervous system lipoids by means of chloroform administered orally. This therapy they attempted by administering from 30 to 60 cc of saturated chloroform water diluted in syrup. The method was applied in eleven cases of diphtheritic paralysis. The results were good and though spontaneous recovery may occur following such paralysis, the authors point out that in five of their cases the paralysis were of serious nature. Two of their patients died of pulmonary complications existing at the time the treatment was instituted. In one case, however, the preventive administration of chloroform water did not prevent the appearance of paralysis. Although the therapeutic value of the procedure is still somewhat uncertain, the authors believe that they have proved that the ingestion of chloroform water is without danger.

Treatment of Ozena by Acetylcholine. Z Chérédjian and T Sciclounoff —p 1290

Treatment of Ozena by Acetylcholine—Chérédjian and Sciclounoff review various theories on the cause of ozena. The theory that they support is the so called endocrine-sympathetic and sympathetic-parasympathetic theory. Many investigators have attempted to develop a rational therapy based on this theory of causation, but few have attempted treatment with acetylcholine. The vasodilating action of this choline derivative is more intense at the skin level weaker at the splanchnic and kidney level, and absent at the level of the lungs. In the cases reported by these observers the acetylcholine was absolutely pure. It was given usually by hypodermic injections and rarely intravenously. The injections were absolutely painless and the single physiologic effect observed was that of dilatation of the retinal artery. Of the three men treated by this means one recovered one improved and one failed to improve. Of the six women treated four recovered and two improved. The authors conclude that this is a promising method of treatment and they suggest that the failures may be due to a hypocalcemia and that the artificial production of hypercalcemia in these patients might facilitate or reinforce the action of the acetylcholine.

Cholesterol Esters and Total Cholesterol in Liver Disease—In comparing the relations of cholesterol esters to total cholesterol Laroche and Grigaut use the method previously described by Grigaut in determining the quantity of cholesterol esters. The colorimetric method of Liebermann was used for determining the total cholesterol in the blood serum. Investigation of these ratios in patients with various diseases convinced the authors that the diminution in the amount of cholesterol esters and the lowering of the cholesterol ester-total cholesterol ratio is an index of hepatic insufficiency. In the cirrhotoses the quotient is normal but it is well known that biologic tests usually fail to identify parenchymatous lesions. The cases in which the quotient was especially lower were those of subjects affected with secondary hepatic jaundice or severe terminal

icterus. The change in the quotient in xanthomatous subjects previously treated by irradiation of the liver furnished a powerful argument in favor of the hepatic site of esterification. Finally, experimentally in the dog, phosphorus intoxication appears to produce a moderate lowering of the quotient. These clinical therapeutic and experimental facts agree and demonstrate the hepatic site of the formation of cholesterol esters.

Kidney Disturbances in Hypertrophy of Prostate—Saegesser shows that the determination of operability is especially difficult in cases which stand at the threshold of operability. He discusses the test methods that have been recommended: the determination of the urea content of the blood, the dilution and concentration tests, the quantity of urine that is excreted in twenty-four hours, cryoscopy, refractometry and determination of the alkali reserve and of the sodium and the chloride content of the serum. Following a discussion of the pathologic-anatomic aspects and of the functional disturbances of the kidney of patients with hypertrophy of the prostate, the author gives a summarizing evaluation of the various methods of examination. He says that the urea values of the blood are found to be normal in a large percentage of cases with disordered renal function. An operation should never be done merely on the basis of a normal urea content. He states that a favorable outcome of the dilution and concentration test makes it probable that the patient will survive the operation, but the ultimate prognosis is not necessarily favorable. The determination of the quantity of urine excreted in twenty-four hours is of value only if considered together with the results of other examinations. The refractometric examination of the blood serum frequently discloses normal values. The determination of the alkali reserve of the blood revealed no parallelism with the other functional tests and the author thinks that this test has no particular value for the prognosis. The sodium content of the blood showed in many cases a relative reduction and the chloride content a relative or absolute increase. Although these changes are to a certain extent characteristic for hypertrophy of the prostate, more observations are required in order to determine whether they are helpful in the estimation of operability.

Gynecologic Significance of Essential Thrombopenic Purpura—After discussing the symptomatology of essential thrombopenic purpura Guggisberg gives his attention to the behavior of the genital organs in thrombopenia, pointing out that hemorrhage of the mucous membranes is one of the main symptoms of thrombopenia. The mucous membranes chiefly affected by the hemorrhage of thrombopenia are those of the nose and of the genitalia. The menstrual flow is usually increased in thrombopenia and it is frequently combined with severe nasal hemorrhage. The author discusses the relations between thrombopenia and the process of propagation, that is, the significance of thrombopenia in pregnancy, delivery and the puerperium. Some observations indicate that in certain cases pregnancy may be an etiologic factor in the development of thrombopenia. However no definite proof has yet been furnished as to whether there really is a pregnancy thrombopenia. In discussing the influence of pregnancy in an existing thrombopenia, the author says that it may be exacerbated or improved. Birth and the afterbirth period may be entirely normal in thrombopenia. However there are also cases in which the hemorrhages after birth may threaten the life of the woman. During the puerperium, disturbances are frequent, even when the afterbirth period has been normal. The treatment of thrombopenia should be chiefly a general one, particularly during pregnancy. Especial attention should be given to the prevention of anemia.

*Alterations of Neuroglia in Cerebral Astrocytoma Histologic Study of Brain Case. G Agostini —p 19

Differential Glycemia in Arterial and Venous Capillaries in Manic Depressive Psychosis with Abolished Psychomotor Functions A. Ansani —p 33

Alterations of Neuroglia in Cerebral Astrocytoma — Agostini says that the histologic study of the brain in cases of cerebral tumor shows that there is a more or less intense but diffuse gliosis involving the brain even at distant areas from the location of the tumor. The areas around the tumor are involved more intensely by the glial reaction than those at a distance. The gliosis may involve both the white and the gray matter. It is probable that several pathogenic factors, such as predisposition of the individual, local conditions like cerebral compression by the tumor and irritation, and the action of toxic substances originating both from the tumor and from products of local cellular destruction, are involved in the development of the glial reaction. The author's statement is based on the review of the literature and on the histologic study of the brain in a case of cerebral astrocytoma located at the pons and medulla oblongata.

*Behavior of Obstacle Phenomenon in Thallium Acetate Depilation for Ringworm in Children A. Nicastro —p 1152

Obstacle Phenomenon in Thallium Acetate Depilation. —Nicastro tested the obstacle phenomenon in the urine of a group of children during the process of depilation by thallium acetate in the treatment of ringworm. The figures showing positive results of the test began increasing from the fourth day of administration of the drug, reached the highest point on the eighteenth day, remained stationary until the twenty-eighth day, and then slowly diminished and became normal within the thirty-fifth and fortieth days. The author states that thallium acetate induces intense functional and anatomic alterations in the body. It has a selective action on organs of ectodermal origin, especially the nervous system. It causes a biochemical disequilibrium with elimination of a great amount of nitrogenous substances through the urine by which the obstacle phenomenon takes place. Falling of the hair is due to inhibition of the hair follicles by the local toxic action and neurotrophic effects of the drug. The highest figures of the curve in the obstacle phenomenon coincide with the days of falling of the hair and with the persistence of alopecia. Regrowing of hair coincides with a diminution of the figures and later on with the disappearance of the obstacle phenomenon in the urine.

*Mechanism of Death in Addison's Disease (Functional Uremia) C. Jimenez Diaz and M. Arredondo Verdu —p 707

Urochrome Present Status of Knowledge E. Ortiz de Landázuri and A. Vergara Olivas —p 729

Hospital Scarlet Fever in Madrid F. T. Valdivieso —p 767

Cause of Death in Addison's Disease —Jimenez Diaz and Arredondo Verdu state that death of patients suffering from Addison's disease is caused by true uremia and acidosis. The latter originates in renal insufficiency that is due to disturbances of the energy metabolism of the kidney resulting from the lack of production of adrenal substances. The functional insufficiency inhibits the production of ammonia by the kidney and results in an increased production of acids with consequent disturbances of the ionic and water metabolism whereupon there is increased elimination of sodium, the sodium-potassium balance of the blood is upset and there occur increased destruction of proteins and increased production of toxic nitrogen bodies (urea and the similar bodies) which cannot be eliminated because of the functional renal insufficiency. As a result acidotic uremia potaemia progressive cachexia and final coma take place. The picture of the mechanism of determination of death in Addison's disease is of importance

because it shows the mechanism of production of death in renal insufficiency in diseases other than Addison's and points out the role of renal insufficiency of adrenal origin in the development of acidosis and of functional uremia.

*Relation Between Cholesterol and Glutathione in Blood in Pulmonary Tuberculosis J. Viale and J. B. Ticinese —p 2032

Cholesterol and Glutathione in Blood in Chronic Pulmonary Tuberculosis —Viale and Ticinese determined the amount of cholesterol and glutathione in the blood of twenty-five patients suffering from chronic pulmonary tuberculosis. They conclude that the amount of glutathione diminishes in direct proportion to the seriousness of the disease and parallels that of cholesterol. The two substances increase or diminish in equal quantities. Glutathionemia, in chronic pulmonary tuberculosis, is an index of the same prognostic value as cholesterolemia. The establishment of an index of the glutathione and cholesterol in the blood, which has been advised by Bethoux for evaluating the potential evolution of the disease and the resistance of the patients, is unnecessary and of no practical value. The determination of the amount of glutathione in the blood is an index of sufficient prognostic value.

*Colitis and Tuberculous Bacillemia J. Villardell —p 571

Colitis and Tuberculous Bacillemia. —Villardell found positive tuberculous bacillemia in four patients out of a group of seventy-five who were suffering from cryptogenic colitis. The clinical picture of the patients suffering from tuberculous bacillemia can be included in the types of diarrhetic colitis and colitis associated with constipation. Patients of the first type give a history of intestinal dyspeptic and nutritional disturbances from childhood. Those of the second type suffer from slight nutritional disturbances and persistent febricula. The roentgen examination of the colon in both forms of colitis shows segmental and total hypermotility of the organ but no signs of organic lesions. The author believes that cryptogenic colitis is a form of latent tuberculosis characterized by the clinical development of colic reactions. Diet is of primary importance in modifying the bacterial flora and the motor intestinal reactions. The author obtained satisfactory results from heliotherapy and small doses of sanocrysin (a double thiosulfate of sodium and gold). The general condition of the patients improved and in some cases the tubercle bacilli disappeared from the blood cultures. He calls attention to the importance of further work in this field for possible detection of a tuberculous etiology of cryptogenic colitis and also for early treatment of the disease.

Erythro sedimentation in Surgical Tuberculosis —Shtitel determined the sedimentation rate of the erythrocytes in thirty patients suffering from surgical tuberculosis in different locations. He concludes that the test is not specific and has a relative diagnostic value. The erythro sedimentation is slightly accelerated in the early evolution of the disease. In patients

in the incipient stage and in those suffering from tuberculosis in evolution, the erythro sedimentation increases after a subcutaneous injection of a small amount of a 1:10,000 tuberculin solution. It does not accelerate, however, when injected in patients clinically cured or in those suffering from osteochondritis. Low sedimentation speed indicates the existence of inactive lesions or of active lesions on the way to recovery. The curve of the sedimentation speed with maintained figures showing no tendency to decrease indicates the existence of lesions in evolution which do not improve by the treatment. In cases of this nature the prognosis is serious and a change of climate is indicated. The presence of an ascending curve of the erythro sedimentation generally indicates the development of an abscess.

Pharmacologic Action of Bee Venom—Starkenstein and Weden cite the results of other investigators who found that the action of bee venom following its intravenous injection is similar to that of the saponins or the sapotoxins. A number of investigators, including the authors, have determined that the action of saponin is largely due to disturbances in the distribution of cholesterol which in turn change the permeability of the cellular walls of different organs and cause changes in the distribution of exogenic and endogenic substances. It has been proved that the action of many narcotics is modified by disturbances in the cholesterol economy of the organism. For instance, following the parenteral administration of cholesterol suspensions the action of many narcotics can be intensified. The reciprocal action of saponin and cholesterol is demonstrated most strikingly in case of their simultaneous administration. The possibility of determining saponin action indirectly by its influence on narcosis provides a method for the detection of the saponin-like character of other substances. In view of the similarity of the actions of saponin and bee venom the authors decided to investigate whether bee venom has the same effect on narcosis as has saponin. Their experiments demonstrate clearly that, in this respect too, bee venom behaves like saponin. However, it has not been definitely determined as yet to what extent this action of bee venom is dependent on disturbances in the distribution of cholesterol.

Protein Fractions of Cerebrospinal Fluid During Childhood—In the cerebrospinal fluids of fifty eight healthy and 122 children with acute and chronic diseases of the central nervous system, Ujsághy studied the total protein content as well as the fractions of albumin, total globulin, pseudoglobulin, euglobulin and fibrinogen. The total protein content was determined by means of the step photometer, the fractions with the aid of the nephelometer following precipitation with ammonium sulfate. In premature children he observed a considerable increase in the total protein and in the globulin content with comparatively greater increase of the euglobulins and fibrinogen. In these premature children the standard values are reached only about the sixth month that is much later than in the maturely born infants in whom they are reached at about the third month. These normal values are for the total protein

between 18 and 26 mg per hundred cubic centimeters (average 21 mg), for albumin between 13 and 21 mg per hundred cubic centimeters (average 17 mg) and for globulin between 4 and 66 mg per hundred cubic centimeters (average 53 mg). The albumins amount to about three fourths the globulins to one fourth, of the total proteins. Euglobulins and fibrinogen are absent from the normal cerebrospinal fluid after the sixth month. The globulin albumin quotient remains always below 0.5. In children with diseases of the nervous system the author found that in suppurating meningitides there was a greater and in tuberculous meningitides a milder increase in the protein values, at first with a relative and absolute increase in the albumins, later with a relative increase in globulins. The fibrinogen appears in almost every case in measurable quantities, but as a rule in large ones. In encephalitides, the author found that in sporadic and in morbillous encephalitis the total protein content may reach higher values and occasionally there are also greater euglobulin and fibrinogen values. In influenzal encephalitis the total protein values are often subnormal, occasionally with a relative increase in globulin. In postencephalitic conditions, subnormal values are more frequent and the euglobulin and fibrinogen values may still be increased months after the encephalitis. In children with cerebral tumors the total protein as well as the fractions usually show subnormal values. In epilepsy the values vary within the normal limits immediately after the attacks the globulins may be relatively increased. In chorea minor the values do not exceed the norm. In syphilitic nurslings the protein values are usually within normal limits but there may be an increase in euglobulin and fibrinogen. In cases in which meningitis and syphilis concur, the changes that are characteristic for syphilis are displaced by the albumin increase that occurs in meningitis, only the relatively higher euglobulin and fibrinogen values indicate syphilitic origin. In juvenile tabetic dementia paralytica there is an absolute increase in globulin. Hypernormal total protein values as well as increases in euglobulin and fibrinogen occur also in Little's disease. Subnormal values occur in idiocy and imbecility.

Measles and Tuberculosis—In the course of an epidemic of measles, Svasits studied the action of measles on latent and active tuberculous processes in the lungs by means of clinical roentgenologic and laboratory methods. Of seventy children who had a positive tuberculin reaction, seven presented symptoms indicating activity. These were mostly young children. Thus it seems that an intercurrent attack of measles is particularly dangerous for young children who have an active tuberculosis. The author emphasizes that during an epidemic of measles all children with a positive tuberculin reaction should be protected regardless of whether the process is active or not. Protection is especially important in the case of small children. In case of an active process the protection should be complete (at least from 3 to 6 cc of measles convalescent serum), in case of inactive tuberculosis and outside of clinics, it is sufficient to mitigate the measles by the administration of from 20 to 30 cc of serum from adults or of 30 to 50 cc of blood

Irradiation in Dupuytren's Contracture—Following a review of the theories that have been advanced regarding the pathogenesis of Dupuytren's contracture, Feurstein evaluates surgical treatment, conservative measures (hot baths, massage, wearing of splints at night) and injections. When he himself developed a Dupuytren's contracture he decided to try ray therapy. A review of the literature convinced him that the opinions about the value of roentgen and radium therapy dif-

ferred and that the reports about radium therapy were few. Since in earlier years his hands had been rather excessively exposed to x-rays, he decided to resort to radium in his own case. He divided the Y shaped area of hardening in his hand into two fields and applied a radium container with 50 mg of radium, brass filtration and a wrapping of gutta-percha and gauze twice for forty-eight minutes (40 mg element hours each time). After eighteen days he repeated the treatment with half this dose and after another month he again applied the first dose. Later he repeated the first total dose at longer intervals three times, once distributing the dose to three fields. The result of this treatment was highly satisfactory. The pains subsided after two sessions and the slight contracture also disappeared. The characteristic fibrous pads in the hand became smaller. Later the first signs of Dupuytren's contracture developed also on the other hand. Radium treatment again proved effective. The good results he had obtained on himself induced the author to try radium in eight other cases of Dupuytren's contracture. He reports the histories of three of them and concludes that radium treatment is especially advisable for the early stages, because, if applied at this time, it not only arrests the further progress of the disorder but also counteracts the symptoms, even though it may not effect a complete restitution. However, after the contracture has reached considerable degrees, the patient should be treated surgically.

Roentgenotherapy of Mammary Carcinoma—In continuing his studies on the simultaneous radium and roentgen therapy of mammary carcinoma and on the basis of results reported by Keynes and Wester Melchart decided to try exclusive roentgenotherapy in the form of the near irradiation. He worked with an apparatus for surface therapy, with tensions of from 50 to 100 kilovolts, with a focus-skin distance of from 5 to 8 cm, with from 1 to 3 mm of aluminum filtration and with fields having a diameter of from 6 to 8 cm. The doses varied between 3,500 and 10,000 surface roentgens. With this treatment the primary tumor could always be made to disappear. When metastases developed, they could be counteracted either with this method or by means of contact therapy. However, prophylactic barrier irradiations did not prevent further metastases. The method failed also in the treatment of the metastases of the supraclavicular glands. Moreover, the method involves the danger of necrosis in patients who have been previously irradiated. The author thinks that so far the combination of preliminary irradiation surgery and after-irradiations must be regarded as the best method for the treatment of mammary carcinoma.

*Pylephlebitis as Complication of Appendicitis. A. T. Lidzky.—p. 240
Urethral Injuries. A. I. Vasiliev.—p. 251

Operative Treatment of Diseases of Biliary Tracts—Klarfeld reports 170 cholecystectomies, twenty-six cholecystectomies combined with choledochotomy, four cholecystogastrotomies, one cholecystojejunostomy and one hepaticoduodenostomy. There were sixteen fatalities in a total of 207 operative cases, a rate of 7.7 per cent. Internal biliary fistulas were observed in six cases, two between the gallbladder and the stomach, one cholecystocolic, one cholecystoduodenal, one between the choledochus and the duodenum and one between the choledochus and the stomach. The cause of death was peritonitis in four, hemorrhage in three, cardiac failure in three, pneumonia in two, cancer metastases in two, subdiaphragmatic abscess in one and ulcerative esophagitis in one. There was not a single fatality in 105 cases of cholecystectomy in which the peritoneal cavity was closed without drainage. The author states that closure without a drain is followed by a smoother postoperative course, obviates painful dressings, prevents postoperative hernia and shortens the period of hospitalization. It is however

contraindicated in the presence of obstruction of the common duct, insufficient peritonization of the stump of the cystic duct or of the gallbladder bed, doubtful hemostasis, injury to the biliary tracts or soiling of the wound with gallbladder contents. Hydrops or edema of the gallbladder does not constitute a contraindication to closure without a drain. Operation in the acute stage is more hazardous than in the interval. He advocates early operation. The death rate in neglected cases on patients past the age of 40 amounted to 18 per cent in his series, whereas the early operation had a mortality of 2.2 per cent. The operation of cholecystotomy is seldom indicated. The common duct need not be opened in every case of cholecystectomy. This is indicated only in the presence of a cholangitis with or without stones.

Pylephlebitis of Appendiceal Origin—The review of literature suggests, according to Lidzky, that the incidence of pylephlebitis or mesenteric pyemia, as a complication of appendicitis, is on the decrease. He believes that this is due to the more universal application of the principle of early operation in acute appendicitis. One or more chills, rise in temperature, icteric discoloration of the skin and of the sclerotics, enlargement of the liver and a blood picture characteristic of a severe acute suppurative process suggest the diagnosis. The early diagnosis, however, is difficult and even liver puncture as proposed by Nössen, Martens and other authors may in the presence of multiple small liver abscesses give negative results. There exist few indications for ligation of the ileocecal veins at the time of appendectomy. A secondary operation proposed by Wilms and having for its aim ligation of the ileocecal veins in order to arrest the spread of infection into the superior mesenteric vein, the portal vein and the liver has given encouraging results. To be effective it must not be delayed until the development of a characteristic clinical picture. The prognosis in the presence of this complication is grave, the mortality ranging with various authors from 80 to 100 per cent. The best prophylaxis is the early operation of acute appendicitis. This indication becomes even more stringent in the presence of a chill in an acute case of appendicitis.

Peripheral Paralysis of Facialis Following Acute Otitis. H. Björk.—p. 622

Muscles of the Gintal Region in Primates. A. Riska.—p. 631

Eye Symptoms in Thyrotoxicosis—In two of the reported cases of edema of the temples in thyrotoxicosis the condition appeared and disappeared during active thyrotoxicosis together with the classic symptoms of the disorder and in the third case the edema occurred parallel with exophthalmos in a patient with postoperative myxedema and disappeared on medication with thyroid substance simultaneously with recession of exophthalmos and myxedema. Wahlberg is inclined to ascribe the edema of the temples like exophthalmos and edema of the eyelids in thyrotoxicosis, to humoral action of the adenohypophyseal principle by way of the sympathetic nervous system or directly on the local tissues. He says that, since edema of the eyelids and temple is seen only in certain cases and often asymmetrically, there must be variations in sensitivity to the humoral influence, partly variations in the different cases, partly locally in a given case, and that possibly the characteristic variability otherwise in the picture of thyrotoxicosis may also depend on such variation.

Atypical Leukosis with Multiple, Tumor-like Infiltrate—Von Bonsdorff says that this case, regarded by him as an acute hematopoietic systemic disease related to chloroma, was rapid febrile course and changes in both the white and the red blood picture and with pronounced fibrosis of the spleen in a girl aged 15 was dominated by multiple tumor formation, probably built up of myeloid cells with origin to be sought in an autochthonous heterotopic metaplasia of mesenchymal (reticulo-endothelial) element in the affected organ.

STUDIES IN OVULATION

THE OPERATIVE OBSERVATIONS IN PERIODIC INTERMENSTRUAL PAIN

LAWRENCE R WHARTON, M D

AND

ERLE HENRIKSEN, M D

Assistant Attending Gynecologist and Resident Gynecologist
Respectively the Johns Hopkins Hospital

BALTIMORE

By periodic intermenstrual pain we mean the recurring discomfort which some women feel half-way between their menstrual periods. The peculiar, persisting periodicity of this pain arouses the curiosity of intelligent patients, for, as one woman told us, it is "as regular as clock-work." Many women can foretell to the day the onset of the next menses from the date of this periodic intermenstrual pain. The Germans have called this syndrome *mittelschmerz*.

The cause of this pain has never been determined. At the present time it is variously attributed to uterine contractions, to peristalsis of the tube as it propels the ovum toward the uterus and to ovulation.

We are herewith presenting a study of sixty-one cases of this syndrome. After sketching the historical background of the problem, we shall outline the main features of normal ovulation and see whether periodic intermenstrual pain is in any way associated with ovulation. The fact that thirty of our patients were subjected to laparotomy has given us an unusual opportunity to observe the pathologic changes and to determine the effect of various operative procedures on this syndrome.

It is usually asserted by American gynecologists that Sir William O Priestley³ was the first to describe this condition. Similarly, German writers are apt to ascribe the priority to Fehling.⁴ Without delving too deeply into ancient lore, however, it is quite evident that at least twenty-five years before either of them wrote about this subject the condition was known and its connection with ovulation was suspected.

In 1847 Pouchet casually wrote the following paragraph, which one finds buried in his voluminous book on ovulation and conception in mammals:

At about this time, and occasionally only on the eighth day after the cessation of the menses, many women feel in the region of the pelvis occupied by the tubes a sensation of weight or even of moderately severe pain which lasts one or

two days. These symptoms, which surely indicate some organic function, correspond, not to the expulsion of the ova by the follicles of de Graaf, but to the contractions which the fallopian tubes make to propel the egg toward the uterus.

Among other early writers on this subject Priestley must be mentioned, for he may have been one of the first to attribute the discomfort to ovulation. In the *British Medical Journal* in 1872 he reported four cases with the records of his pelvic examinations.

In 1883 Lawson Tait⁵ said:

A singular condition has been noticed by Dr Priestley, of intermenstrual pain occurring about midway between the periods, which is almost certainly due to an ovarian condition, though it is not clear of what kind. Since reading his paper I have seen several cases, but have been unable to refer them to any category.

The views of these pioneers formed the basis of future discussion, but nothing definite was added for years, although many new theories were enunciated. It must be remembered that in their time ovulation was believed to occur at the height of menstruation and intermenstrual ovulation was thought to be rare. Sporadically during the next twenty-five years cases were reported in Europe and America (Fehling,⁴ Palmer,⁶ Croom,⁷ Marsh,⁸ Addinsell,⁹ Storer¹⁰ and others). The actual data thus assembled are naturally of great interest. Two cases of alternate pain were observed by Storer, in which the intermenstrual discomfort, recurring every month, was felt regularly in alternate sides. Storer's study is comprehensive, as he reports twenty cases of his own, one of the largest individual groups that have ever been assembled. It was only the keenness and independence of their clinical observations that led some of these men to suspect that ovulation might possibly occur occasionally between the menstrual periods.

Another source of confusion lay in the fact that very few of those who suffered from periodic intermenstrual pain were explored surgically, because abdominal operations were rarely performed in those days. Dr Howard A Kelly^{10a} emphasized this in 1908, thereby suggesting a constructive method of approach in studying the problem. He assembled the few cases in which operation had been performed and concluded that the results of treatment had been discouraging—that the condition was not self limited and had been known to recur periodically every month through the whole menstrual

From the Department of Gynecology of the Johns Hopkins Hospital and University.

Owing to lack of space, this article has been abbreviated in *THE JOURNAL*. The complete article appears in the authors' reprints.

life. He pointed out that dilation and curettage of the uterus had been tried in eleven recorded cases without benefit and that bilateral oophorectomy had brought complete relief in four of five reported cases. Similarly uterine suspension had been of little value, although in one case it had been entirely successful. He even went on to indicate that at times very conservative measures had been helpful, such as the use of an intra-uterine pessary when the uterus was sharply anteverted, and that in one instance merely rest in bed had been successful.

Dr. Kelly agreed with Priestley that the discomfort was associated with ovulation, although he remarked that "it was hardly possible that ovulation would take place regularly between two menstrual periods for a number of years, or even through the whole of sexual activity."

Heaney¹¹ then reported three operative cases in 1910, all involving removal of one or both ovaries, and in all the pain was cured. After reviewing the literature, however, he concluded that the discomfort was not due to ovulation but was an abortive attempt at menstruation. In 1916 Welton¹² reported one operative case which was cured by supravaginal hysterectomy and left salpingo-oophorectomy, the patient having a myoma of the uterus and a cystic left ovary. The intermenstrual pain had been located regularly in the region of the left ovary.

This cursory review shows the confusion that existed until well into the twentieth century. As we have pointed out, this was due to two reasons: first, the current opinion that ovulation and menstruation were synchronous, and, second, the lack of opportunity in these cases to study the pelvic organs by means of laparotomy.

THE PHENOMENA ATTENDING OVULATION

The main features of the first difficulty were quickly eliminated when the relation between ovulation and menstruation was better understood. It is probably true that between 1903 and 1930 more was learned about the phenomenon of menstruation than had ever been known before. Between 1903 and 1910 the careful studies of Fraenkel, Meyer and Ruge, Hitschmann and Adler, and Schroeder cast an entirely new light on the whole process, particularly the function of the corpus luteum and the histology of the endometrium. This work suggested very strongly that ovulation occurred about two weeks before the beginning of the menstrual period. The next notable contribution was the work of Corner,¹³ who in 1923 was the first to recover unfertilized ova from the fallopian tubes of primates, although he had previously recovered them repeatedly from the oviducts of the sow. In the monkey (*Macacus rhesus*) he found that the menstrual cycle practically paralleled that of woman, exhibiting the same regularities and irregularities, the usual length being twenty-seven days, and the duration of the menses from four to six days. He determined that ovulation "occurred about twelve or thirteen days before the expected onset of menstruation," basing this conclusion on the actual recovery of the ova from the tubes, the presence of freshly ruptured follicles in the ovary, and the state of the endometrium.

In 1928 Allen, Pratt, Newell and Bland¹⁴ duplicated in women Corner's observations in monkeys by recovering seven unfertilized ova from the fallopian tubes of six women. This was the first time that this feat had been accomplished. They found the ova by washing out the tubes on the twelfth, fifteenth and sixteenth days of the menstrual cycle and in all these cases found freshly ruptured mature graafian follicles or very early ruptured corpora lutea, depending on the age of the ovum. By these clear-cut contributions the time of ovulation was definitely fixed as occurring between the menstrual periods and usually bearing a definite relation to the approaching menses.

If this is so, ovulation in women is analogous to estrus in lower animals. In women, however, ovulation is ordinarily attended by no remarkable signs or phenomena, whereas in lower animals estrus is the period of heat and may be marked by definite stigmas and by the behavior of the female toward the male. The problem of ovulation and its relation to estrus then began to attract attention and, as a consequence, some features were observed which also have helped us to understand the problem which we are considering: periodic intermenstrual pain.

In 1928 Simpson and Evans¹⁵ reported an instance in which faint, microscopic uterine bleeding was observed to occur regularly and periodically in a healthy woman aged 32. It was seen between the fifteenth and the nineteenth day of the menstrual cycle, was constant in its appearance and lasted only a day or two. These observations covered a period of twenty months. This was apparently the first time that this phenomenon had been seen in a human being.

In 1929 Hartman¹⁶ reported the situation as it exists in the monkey. He confirmed and amplified Corner's observations and made several significant additional contributions. These have since been confirmed by observations that have covered many years, for by means of laparotomy, histologic examination, rectal palpation and vaginal smears it is possible to study the menstrual cycle of the macaque with a directness and accuracy impossible in women. Hartman found that 75 per cent of the menstrual cycles in the macaque were accompanied by intermenstrual bleeding such as Evans and Simpson had reported in one woman, and that it occurred at the time of ovulation. He also noted that in more than half of their monkeys ovulation took place on the eleventh and twelfth days, in the rest ranging from the seventh to the eighteenth day of the menstrual cycle.

In 1933 Papanicolaou¹⁷ reported a similar study in women. In a large series of women he found grossly visible bleeding in 93 per cent on the twelfth day and in 43 per cent on the thirteenth day of the menstrual cycle. By microscopic examination of vaginal smear, however, he observed a much higher incidence, 186 per cent bled on the twelfth day, 152 per cent on the thirteenth day and 238 per cent on the fourteenth day.

In 1934 Hain¹⁸ reported a similar observation in a woman aged 40, the study covering twenty-nine men-

strual cycles. In this case the menstrual cycle exhibited the usual variations and the intermenstrual bleeding occurred between the twelfth and the twenty-second day of the cycle, being visible for only one or two days. In the same year Seguy and Simonnet¹⁰ reported an interesting study of the direct signs of ovulation in women. They found that in many women ovulation is accompanied by the appearance of a thick, translucent glairy secretion in the cervix, and they believed this to be the most evident and the commonest external sign of ovulation. They observed that at that time also the titer of estrogenic substance in the urine reached its highest level. On the basis of these data they examined the ovaries of five women on whom they operated at the moment that the titer of the estrogenic substance was highest and the cervical mucus most evident. In four of the five they found ripe graafian follicles. In the fifth the ovary contained only a small, immature follicle. Furthermore, in the three patients with so-called functional sterility they carried out artificial intra-uterine insemination when these signs indicated ovulation, and impregnation resulted.

Thus, over a period of thirty years the problem of ovulation and menstruation was attacked from many angles, and as a result there is now a clearer notion of the nature of these processes, although at the same time many new and unsuspected problems are created. Nevertheless, it became known that ovulation usually occurs in the middle of the menstrual cycle, that it varies widely just as the menstrual cycle does, that it may occur at any time between the seventh and the twenty-second day, and that it usually precedes the approaching menses by a definite number of days. Also it became known that ovulation in women is analogous to estrus in lower mammals and that, even in women, ovulation may be attended by slight bleeding or discharge. It remains to be seen how this information can be applied in the study of the clinical problem of intermenstrual pain and whether this clinical syndrome also can be correlated more definitely with ovulation.

CLINICAL STUDY

In this clinical study we present a series of sixty-one cases of periodic intermenstrual pain, practically all of which have been studied in the last five years. In thirty of these, laparotomy was performed for a variety of reasons. We shall attempt to analyze these cases from several points of view and see whether a routine clinical study such as this will make it possible to reconstruct a clinical picture of ovulation in women such as is known to exist in the macaque. One of the features of this picture, faint bleeding, has been carefully noted in women by Ham, Evans and Simpson and Papanicolaou.

Our observations concerning sterility and the significance of associated pelvic disorders may not be in agreement with opinions often recorded in the literature. The relation that intermenstrual pain may bear to a great variety of pelvic lesions is discussed and the effect of corrective pelvic operations is summarized. These cases were subjected to laparotomy at varying times in the menstrual cycle, and in a good many the condition of the ovaries was noted. Contradictory evidence is recorded and the picture is assembled exactly as we have found it.

Incidence—A thorough survey of the literature reveals few reported cases though, oddly enough all

those who have written on the subject comment on its relative frequency. The basis of its apparent rarity in many clinics is only natural in view of the failure to include it in the anamnesis. This salient point has recently been emphasized in our own work.

This is usually a syndrome of such mildness that it will not be noticed unless the physician deliberately inquires about it. Only the acute and severe cases will impose themselves. Our series illustrates the point rather clearly. Among the many thousands of patients who have visited the gynecologic clinic in the past five years, only thirty-two cases of periodic intermenstrual pain have been found, and half of these were of the severe variety that could not be missed because they simulated abdominal emergencies. In private practice, however, we have seen twenty-nine perfectly typical cases in the same length of time. It is apparently another instance of "he that seeketh, findeth."

Time of Pain—Two features have marked this pain as being of a peculiar nature: the time of its occurrence in the menstrual cycle and its recurring periodicity. These are the characteristics that have always stimulated the curiosity of gynecologists and of intelligent patients.

Of the sixty-one patients, forty-eight gave the exact time at which they felt the pain. The majority occurred between the tenth and the twelfth day, with five cases occurring on the tenth, nine on the eleventh, eighteen on the twelfth, seven on the thirteenth, six on the fourteenth and two on the fifteenth day after the onset of the previous period. One patient placed the onset of the pain seven days after the onset of the cycle. Admitting the notorious inaccuracy of the catamenial calendar, in the majority of the typical cases the pain occurred at a fairly definite period on each occasion. If the pain tends to occur each month, most of the patients can predict with fair accuracy the day of its next appearance and the date of the next menses.

Age of Onset—Ten of our patients traced the onset of intermenstrual pain to the menarche, and in 70 per cent it was present before the patient was 20 years old. In 90 per cent the syndrome developed before the age of 30. It is thus a condition that develops almost always in young women and girls, although one will find exceptions. At the upper extreme, one of our patients developed typical periodic intermenstrual pain at the age of 46.

Character of Pain—The typical mild midmenstrual pain has been described many times, our data concerning this type will be presented later. There is also an equally typical acute variety, the significance of which is often missed. In this acute type the syndrome often resembles ruptured tubal pregnancy or acute appendicitis, and for this reason most of these operations have been performed as surgical emergencies. We shall study this group first and later discuss the more typical and commoner type of mild mittelschmerz.

The Acute Type—We have had twenty-one cases of acute intermenstrual pain. These patients were seen and operated on by various members of our staff, quite a few were in the surgical service. In most of these acute cases the preoperative diagnoses were acute appendicitis or ruptured tubal pregnancy. When a young woman presents herself with acute pain in the right lower quadrant, nausea, a temperature of 101 F and a leukocytosis of 12 000 or more, it would require extreme self confidence to advise anything but explor-

19 Seguy J and Simonnet H. Recherche de signes directs d'ovulation chez la femme. *Gynec et obst* 28: 657-663 (Dec) 1933.

tion of the right lower quadrant Hoyt and Meigs²⁰ have recently presented a study of acute abdominal conditions due to rupture of the graafian follicle and corpus luteum, seen in the surgical service of the Massachusetts General Hospital. They reported a series of fifty-eight cases in which operation had been done as surgical emergencies between 1929 and 1934. The usual pre-operative diagnosis was acute appendicitis, although in seventeen the correct impression was reached before operation, an excellent record. As in our series, the leukocyte count sometimes was very high, reaching 27,000. In many instances this is due to the free blood that escapes from the ruptured graafian follicle. In one of our cases, however, there was a leukocytosis of 22,000 without any intra-abdominal hemorrhage.

The differential diagnosis of this condition is difficult and imposes a grave responsibility on the surgeon. These acute cases are not as regular in their periodicity as the mild type of mittelschmerz, indeed, ovulation may have been perfectly normal before. Thus, Hoyt and Meigs reported that twenty-six of their fifty-eight patients had never had a previous attack of periodic intermenstrual pain, in our series the percentage having former attacks was slightly higher. As a rule, however, in these severe acute cases presenting marked hemorrhage the regular, invariable, periodic pain is not as constant a feature as it is in the milder type.

Then, again, the time of ovulation varies widely, as we have shown, occurring normally between the seventh and the eighteenth day of the menstrual cycle. Consequently, one cannot always eliminate the possibility of acute rupture of the graafian follicle because it does not occur exactly on the twelfth day of the cycle.

Nevertheless, this syndrome presents a clinical picture with definite characteristics which usually differentiate it rather sharply from acute appendicitis. The history is often significant for, as we said, in more than half one will find that there have been former similar attacks and that they have always occurred between menstrual periods, usually in the midmenstrual interval. The character of the former attacks is also significant, in that they have usually been short, with prompt convalescence, resembling dysmenorrhea more than appendiceal colic. Rectal pain, leukorrhea and at times a little vaginal bleeding and bladder symptoms may be present. One of our patients had slight diarrhea, probably due to rectal irritation, just as one may see in a pelvic abscess. In general, the history is usually more suggestive of a gynecologic than of an intestinal disorder.

The gynecologic examination shows that the whole pelvis is tender, although this is usually more marked on one side. There is definitely more pelvic than abdominal tenderness. In some of our cases the pelvis felt just as it would in acute salpingitis. There may be a sense of induration on the affected side, but masses are not ordinarily palpable, and the tenderness usually prevents one from outlining the ovaries. Vaginal washings will often reveal microscopic blood in the uterine secretions when it is not visible grossly. The vaginal bleeding is rarely, if ever, sufficient to attract one's attention unless one deliberately looks for it or inquires about it.

Rupture of the graafian follicle is not usually accompanied by as severe hemorrhage as is ruptured tubal pregnancy, the shock is usually less, there is rarely

any irregularity of menstruation, and the vaginal bleeding is much less than in ruptured tubal gestation.

The experience of Hoyt and Meigs and ourselves has shown that, on the basis of these data, one can often diagnose rupture of the graafian follicle with accuracy. When the diagnosis seems clear, should one operate? Under such circumstances, we have pursued a conservative course, watching the patient carefully until convalescence is complete but being ready to intervene surgically if necessary. When the abdominal hemorrhage is severe, it is undoubtedly best to operate, as the possibility of tubal pregnancy cannot be eliminated. In the milder cases we would certainly prefer to watch the patient and avoid surgery if possible. When there is any doubt about the diagnosis, the abdomen should certainly be explored. If, at operation, one finds a ruptured graafian follicle or corpus luteum instead of acute appendicitis or tubal pregnancy, the ovary should be saved, only the bleeding corpus being excised.

The reason for conservatism either in avoiding operation or in saving the ovary is simply that the syndrome often recurs whether one operates or not and may involve both ovaries. Unless the trouble is always due to one ovary, nothing less than bilateral oophorectomy will cure the obstinate case. The futility of operation is therefore clear, except as a life-saving measure or because of the impossibility of excluding appendicitis or tubal pregnancy.

Only three months ago a woman, aged 28, the mother of one child, was admitted to the Woman's Hospital of Baltimore with the diagnosis of ruptured tubal pregnancy. The patient had only one ovary, the other having been removed five years previously because of a dermoid cyst. The immediate clinical picture, indeed, resembled tubal abortion, the history, however, showed that during the preceding year the patient had had five such attacks, although they had been of less severity. At operation the bleeding was found to be due to a ruptured corpus luteum, which was excised. Since leaving the hospital the patient has had two more attacks, at the exact midmenstrual interval.

Such experiences serve to emphasize the fact that in these cases one is dealing not only with an isolated ruptured corpus luteum but with a recurring dysfunction of the ovary. The corpus luteum which happens to be present when the surgeon operates may be the source of the immediate hemorrhage, but the basic cause of the dysfunction lies deeper and is as much a mystery today as it was to Pouchet^{20a} and Sir William Priestley. Microscopic examination of these corpora lutea has shown no unusual changes whatever. Fortunately, these acute, severe cases with marked hemorrhage do not recur as regularly as do the milder one, in fact, the patient may never have another severe attack.

The Mild Type — Among the forty typical mild cases, twenty-three patients complained of bilateral pain, ten localized the pain to the right side, four complained of left-sided pain, and three stated that the pain was present on both sides but was more severe on the right. Of the twenty-one acute cases, eleven patients localized the pain in the right side, six had pain on the left side, four had bilateral pain, and one of these stated that she experienced bilateral pain every other month. Though there is a marked variance in the severity of the pain, it is usually depicted as being cramp-like and intermittent. Infrequently the patient comments on a tendency of the pain to radiate toward the rectum, in

²⁰ Hoyt, W. F. and Meigs, J. V. Rupture of the Graafian Follicle and Corpus Luteum. Surg. Gynec. & Obst. 62: 114-117 (Jan.) 1936.

the majority the pain is localized in the pelvis. Typically, the onset of the pain is gradual, reaching a peak approximately half-way through the pain period, the subsidence is usually more rapid and, except in those few cases in which the pain persists until the onset of the next period, is followed by complete relief. An occasional patient experiences a sense of pelvic fullness for several days following the disappearance of the pain. A few experience no actual pain but complain of a sense of pelvic discomfort not infrequently associated with a feeling of general malaise. The pain is not constant but varies with each occurrence from a sense of fullness to severe cramps. Many patients say that the discomfort is just like dysmenorrhea, except that it may differ in intensity.

Dysmenorrhea—More than half of our patients had no dysmenorrhea, thirteen had slight pain, six had moderate associated pain, while only five complained of severe cramps.

One patient, a white woman aged 22, single, suffered severe cramp-like pains with her first menses, two years later she noted a gradually increasing pain at the intermenstrual period, as this pain became more severe, the dysmenorrhea became less noticeable. At the present time the dysmenorrhea has practically disappeared while the intermenstrual pain is frequently severe enough to confine her to bed for one day each month. For the past six months there has been a scanty associated bleeding and some nausea but no vomiting.

In general, the menstrual periods of these sixty-one patients exhibited the same characteristics that would be found in any group of normal women.

Sterility—Thirty-three patients were married. Of these, four admitted the use of contraceptive measures, one had uterine myomas with endometriosis, and another had obesity with a definite endocrinopathy, thus making it possible to explain the sterility of six women in this group, leaving twenty-seven who, as far as we know, might have conceived. As a matter of fact, twenty-one of these women had conceived, a total of sixty pregnancies being recorded. Only one patient complained of sterility. Of the twenty-eight unmarried women, one had been pregnant. We do not know whether the presence of intermenstrual pain prevents these women from having intercourse during the period of ovulation, which is supposedly the optimum time for conception. It is quite evident, however, that this syndrome is not characterized by sterility. It is often stated in the literature that these women are apt to be sterile.

Sexual Desire During Period of Ovulation—We have asked a few of these patients whether they noticed any increase in sexual desire during the period of ovulation. Their usual reply has been that they felt so wretched then that their only desire was to be left alone. It would be interesting to know whether women who ovulate normally and painlessly note any increase in sexual desire at that time. Animals of course, apparently have no sexual desire and will not tolerate coitus except during the period of ovulation, while in estrus.

Associated Bleeding, Vaginal Lavage—In our group, twelve had intermenstrual bleeding profuse enough to necessitate protection. An occasional brownish discharge is not infrequent, though usually not profuse enough to warrant a pad. We have recently made vaginal washings in five of our typical cases in which the patient denied intermenstrual bleeding. All five showed microscopic blood. On the second day preceding the appearance of the pain the washings have been

free of red blood cells, on the day of the pain red cells have been demonstrated. The pain in each instance lasted for two days, the red cells disappeared from the washings on the fourth day following the onset of the pain. A leukorrheal discharge, usually scanty, is not infrequent and as a rule is mucoid.

The existence of bleeding in these cases can be determined only by definite questioning or by vaginal lavage. The necessity of making these questions a part of the regular gynecologic history is shown by our records. Of the twenty-nine patients seen in private practice twenty-two were found to have an unusual discharge during the period of intermenstrual pain, and we found that nine noticed slight recurring bleeding at that time. Among the thirty-two hospital patients, however, associated intermenstrual spotting was noted in only three cases. This is a comment only on the accuracy of gynecologic histories.

It is our opinion that routine vaginal washings in these cases would have shown that spotting occurs far more frequently than the patients' histories indicate. At least, that has been our experience. Further observations on this subject are needed. We believe that this is the first time that vaginal washings have been used in the study of patients with periodic intermenstrual pain.

Blood Studies—We know of no extensive study of the blood made during ovulation. Of course, when there is free blood in the pelvis from the rupture of the graafian follicle, the leukocyte count is elevated.

Predisposing Factors—We have made a definite effort to discover any general or local conditions which might have preceded the development of this syndrome in the hope that it might cast some light on its etiology. Unfortunately, we have found no constant or frequent denominator.

The commonest single event that ushered in the periodic pain was the onset of ovarian activity, for ten traced their discomfort to the menarche. Four did not have it till they gave birth to a full term child, one by cesarean section. On the other hand, several patients have noted that their intermenstrual pain had been definitely less severe since they had children. In one instance the discomfort developed after myomectomy. We have found only one or two cases that appeared shortly after marriage and none that were preceded by puerperal infection. We have one instance in which the condition was present in both mother and daughter. In the mother it came on after the birth of the third child and disappeared after the next child was born. In the daughter it began after the birth of the second child, and this young woman hopes that she may have her mother's good fortune in seeing it disappear after her next child is born. In by far the greatest majority, the symptom developed without any determinable cause.

Nor were these women of the psychoneurotic type. A cross section of the entire group represents a fairly normal, accepted, average patient, with no greater tendency toward instability than one would find in any average group. Racial characteristics play no part, as we have found this condition in Jew, Gentile and Negro. Our group also includes representatives of every social and economic level of society.

Conditions Found at Operation—Thirty of our sixty-one patients had laparotomies, twenty-one of the thirty operations were performed during the acute pain, the various operators usually expecting to find acute appendicitis or ruptured tubal pregnancy. In every instance the tubes and appendices were normal. The

operative notes are not explicit in all the early cases, and the condition of the ovaries was not recorded regularly. Nevertheless, in fifteen cases we have some record concerning the state of the pelvis and in eight of these the operator found large graafian follicles or corpora lutea, at times oozing fresh blood from the point of rupture.

These conditions are exactly like those reported by Corner and Hartman in the macaque, and by Allen, Pratt, Newell and Bland in women when they succeeded in recovering ova from the fallopian tubes.

These cases are not to be confused with corpus luteum cysts, endometriosis or chocolate cysts, although this mistake can be made easily. On pathologic examination these cases have had normal mature graafian follicles or very early corpora lutea, depending on the time of the exploration. The clinical histories also indicate the absence of any demonstrable ovarian disease, for the menses have been remarkably free from abnormalities, most of these women have borne full term children and there have been no unusual complications.

In an effort to eliminate the chronic, recurring, interval pain, operations were performed on four women, the preoperative diagnoses being either chronic salpingitis or appendicitis. At operation, these structures proved to be normal. In these cases appendectomy has not affected the course of the pain, occasionally, excision of the corpus luteum has given relief. In one, appendectomy and right oophorectomy was done two years ago. For twelve years this patient had suffered bilateral or alternate pain with every intermenstrual interval. At operation the left ovary was normal and the right presented slight cystic changes. The only effect of the operation was to eliminate the pain from the right half of the pelvis, it now is felt regularly every month in the left ovarian region.

In the preceding twenty-five cases the intermenstrual pain was in itself the only reason for surgical intervention. In the following five the intermenstrual pain was wholly incidental, the laparotomies being performed for altogether different reasons. These five cases include three hysterectomies, one salpingo-oophorectomy for tubal pregnancy and one appendectomy with excision of old graafian follicle cysts. The effect of these operations on the syndrome will further assist in localizing the source of the discomfort. These cases fall into two groups—typical and atypical.

In the typical group are four cases: two hysterectomies, one salpingo-oophorectomy and one appendectomy with excision of old graafian follicle cysts. These are typical in the way in which the intermenstrual pain reacted to the operations. The pain was relieved in the case in which the painful ovary was completely removed, it was entirely unaffected by hysterectomy, appendectomy or excision of old graafian follicle cysts. One of the hysterectomies was done for a large myoma, the other because of extensive childbirth injuries. This, we believe, is the first time that the effect of simple hysterectomy has ever been observed on the course of periodic intermenstrual pain.

The fifth case was atypical in many ways.

A Jewess aged 30 began to menstruate at the age of 13; the menses had always been regular every twenty-eight days lasting from six to seven days with profuse flow. She had conceived normally in 1930. Intermenstrual pain accompanied by spotting began in 1933. She was operated on at the Sinai Hospital in July 1935 because of uterine myomas with profuse menstrual hemorrhages. We performed the hysterectomy deliberately on the second day of the intermenstrual pain and

spotting, nine days after the close of the last menses, expecting to find signs of ovulation. The ovaries, however, showed no evidence whatever of graafian follicles or corpora lutea, in short, there was no sign of ovulation, although the menstrual cycle had been normal and the patient had the menses that accompany ovulation.

The later developments in this case are equally surprising, although they are in harmony with the operative observations.

Since July 1935 she has been completely relieved of intermenstrual pain and spotting. The pathologic diagnosis in this case was uterine myomas, endometrial hyperplasia with polyp and endometrial glands invading the uterine wall.

In 1934 Seguy and Simonnet reported a similar case which, although not as complete as ours, nevertheless is complementary in that the time of ovulation was established by the estimation of estrogenic substance and cervical mucus. We have already referred to their report. It is rather confusing that neither of these cases showed signs of ovulation, although the menses were regular and the patients showed signs which in others had indicated ovulation—rise in estrogenic substance, cervical mucus, intermenstrual pain and spotting.

Periodic Intermenstrual Pain and Pregnancy—We have seen that this pain seems to occur with ovulation. Ovulation ceases during pregnancy as far as we know, this pain should therefore disappear at that time. This has been our experience in this group of cases. The pain stops entirely with the cessation of menstruation after the women conceive and returns when the menstrual cycle again is reestablished.

Further observations on this point are needed. During the puerperium, ovulation often occurs without menstruation, many women conceive after a pregnancy before they resume the menstrual cycle. It would be interesting to find and study a case of mittelschmerz under these conditions.

Presacral Neurectomy and Painful Ovulation—Cotte²¹ of Lyons has observed that, in women with both dysmenorrhea and painful ovulation, presacral neurectomy eliminates the dysmenorrhea but has never affected the periodic intermenstrual pain. This is what one would expect because, as one of us has shown, the innervation of the ovary is quite distinct from the innervation of the uterus.

If mittelschmerz is what we think it is, a painful functional disturbance, then sympathetic denervation of the ovary may be of great benefit in relieving the pain. This operation, however, has never been devised or performed successfully.

Endometrium—We have been able to study the endometrium in six cases of intermenstrual pain. In five it was quite normal and in one it showed hyperplasia with a tendency to invade the uterine wall.

SUMMARY

In sixty-one cases of periodic intermenstrual pain for which the clinical features of the syndrome have been outlined, thirty were subjected to laparotomy.

In nine patients who were operated on while suffering intermenstrual pain there was evidence that ovulation had just occurred—ruptured follicles with varying amounts of free blood in the pelvis.

Removal of one or both ovaries is the only operation that has uniformly eliminated the recurring pain. The

21 Cotte Gaston. Chirurgie du sympathique pelvien en gyn. 4 Paris Masson et Cie 1932 p. 318. Troubles fonctionnels du système génital de la femme ed. 2 Paris Masson et Cie 1931 p. 32.

has been the general experience of former observers. Excision of the acute ruptured follicle or corpus luteum has in some cases brought relief.

Supravaginal hysterectomy in two cases had no effect. In these cases the endometrium was normal.

Curettage, cauterization of the cervix, excision of old graafian follicle cysts and appendectomy have rarely affected the syndrome.

The pain seems to occur only during ovulation. We have never seen it before the menarche or after the menopause. If the ovaries are inspected during the pain, recent ovulation is found.

We have noted two exceptions to this rule. These exceptions merely indicate that further observations are needed.

The syndrome is not always persistent. In some cases it disappeared as unexpectedly as it came, untreated or after measures which would ordinarily afford no relief. We feel, therefore, that at times painful ovulation may be due to some temporary change, perhaps a mechanical, inflammatory or circulatory disturbance, and that it disappears when this situation is corrected. Thus, occasionally the syndrome has disappeared after the birth of a child, after a curettage, after the insertion of a stem pessary or even after rest in bed.

We have found no pathologic basis or explanation of this syndrome, almost invariably the pelvic organs are normal in every particular.

Women who have painful ovulation usually are fertile and bear healthy children. Therefore the syndrome does not interfere with the production of normal ova. It is an inconvenient syndrome but interferes with the patient's health only when the pain is severe or accompanied by profuse hemorrhage from the graafian follicle. We have correlated the syndrome of painful ovulation with the known facts concerning ovulation, and the data indicate that the two are synchronous.

We have presented this study not as a finished product but rather as an introduction to the further investigation of a problem that presents many unexplained features. Normal ovulation should be studied carefully. We have noted some surprising facts in even the short series that we present.

Ordinarily, ovulation proceeds so quietly and smoothly that the clinician rarely thinks of it. We feel that every gynecologic history should include specific questions concerning ovulation. As practicing gynecologists, we can say that attention to the features that accompany ovulation has enabled us to clear up several puzzling gynecologic situations and avoid erroneous diagnoses and useless exploratory operations.

1201 North Calvert Street

ABSTRACT OF DISCUSSION

DR. J. P. GREENHILL, Chicago. The occurrence of intermenstrual pain is more common than is generally believed. All who follow the suggestion of specifically questioning every female patient about this type of pain will encounter some cases. Furthermore in most cases in which the diagnosis is made with reasonable certainty, conservatism should be followed, because the only certain way to eliminate intermenstrual pain appears to be removal of one or both ovaries. This is a radical and fortunately rarely necessary procedure especially when it is considered that practically all of these women are young. In twenty cases Cotte transplanted the ovaries into the omentum and relieved all but one of the patients of their intermenstrual pain. The conditions found at operation point definitely to disturbances in the process of ovulation as the cause of this type of pain. When a bimanual examination is made

during an attack of pain, the ovary on the involved side is always tender. Eberhart explored the uterine cavity with a sound in his cases of intermenstrual pain and found unusual tenderness in some. The authors stated that the endometrium in their studies was normal in five out of six cases but they did not tell the exact stage of development of the endometrium. R. Schroeder obtained the endometrium by curettement in five cases of intermenstrual pain during attacks of pain and found that the endometrium showed the first signs of the secretion phase and the end of the proliferative phase. These changes definitely point to ovulation. In many cases of intermenstrual pain there is slight and occasionally moderate bleeding. This condition is therefore similar to the estrous bleeding of animals. Undoubtedly some, if not all, women who have a two weeks cycle of uterine bleeding have an alternation of menstrual bleeding with bleeding due to ovulation. Hence these women ovulate only once and not twice every four weeks. In most cases the pain associated with ovulation is severe for only a short time and it subsides spontaneously. However, there are instances in which disturbances in the follicle and corpus luteum apparatus of the ovary lead to extensive intraperitoneal hemorrhage. These cases resemble rupture of a tubal pregnancy and require a laparotomy. A distinguishing characteristic of most of these serious cases is that the rupture takes place between the twentieth and the twenty-fourth day of the menstrual cycle and not at about the tenth to the fourteenth day as occurs in cases of periodic intermenstrual pain.

DR. J. M. SINGLETON, Kansas City, Mo. I have not had the experience of observing so many cases. It has been my custom to ask "Have you had any intermenstrual bleeding or discharge?" and repeat it at the end of questions on menstrual function. It is strange that in our series at the Kansas City General Hospital and Kansas University more cases of this character have not been observed. With present knowledge of time of ovulation, it would seem that in the majority of cases the pain is ovarian in nature. The case the authors presented in which hysterectomy for fibroids relieved the condition and the authors' vaginal washings and cases of frank bleeding at the time of pain conclusively prove the associated uterine activity. Removal of one ovary would be ideal if curative, but castration is to be reserved for the case in which all conservative measures fail and relief is imperative. In the cases associated with internal bleeding sufficient to constitute surgical emergencies operation must be performed, and differential diagnosis in these cases should benefit by the report of the authors. I have had one case of typical intermenstrual pain under observation for a number of years. Conservative measures such as cervical cauterization for the shrinking of eroded edematous cervixes with their consequent low-grade pelvic inflammatory processes, posture, such as rest, the knee-chest position, garden work on the hands and knees for the relief of pelvic congestion, and suggestive therapy should be tried in the milder cases before resorting to surgery.

DR. CYRUS W. ANDERSON, Denver. In a paper read before the Denver County Medical Society I suggested that the process of ovulation gave rise to definite symptoms. There was a storm of protest from the society and from all over the country. "Surely if ovulation causes symptoms, some one would have noticed it long ago." There are very few women who have pain with ovulation, but at least 80 per cent will have discomfort. This discomfort is very much like that arising from flatus in the intestine. It is high up in the region of the umbilicus where fetal movements are felt in early pregnancy. Many of my patients can tell which ovary is ovulating by differentiating the side on which the discomfort is felt, and I have proved this by surgery. A woman who had been charting her menstruation and ovulation over a period of eighteen months was sent to the hospital for an appendectomy for chronic appendicitis. Just before the operation she said "I have just noticed ovulation on the left side." In removing the appendix we saw the freshly ruptured follicle in the left ovary. I have had patients report what apparently is double ovulation, ovulation first on one side and then on the other. That would account for the occurrence of dissimilar twins. Charting the time of ovulation is the key to the safe period method of contraception. Whether or not one is interested in this field of contraception it will be of value in the treatment of sterility.

I have had several cases of apparently perfectly normal couples who had lived together for two, three and even seven years without a pregnancy. A woman had been married seven years and was anxious to have a baby. She had a very definite intermenstrual pain and had avoided intercourse during that period on account of the pain. It was suggested that the couple have intercourse on the day on which she was having the pain, and within two months she was pregnant.

DR. LAWRENCE R. WHARTON, Baltimore. The remarks of Dr. Greenhill add a great deal to what I have tried to say. It may be worth while in cases of sterility, as Dr. Anderson has said, to pay attention to ovulation. I paid no attention to it until I commenced to work on this syndrome. If our ideas about this condition are correct, if it is a functional disorder in which the ovaries are normal, then of course the ideal treatment would be if possible to cut the nerve supply in some such way as Cotte tried to do and failed. Denervation of the ovaries has never been successful. If it could be done, it would relieve a good many of these women of discomfort, provided it wouldn't do any harm. Not all of the women with intermenstrual pain were operated on during the acute pain. In those in whom the acute pain was present the endometrium was of the type that Dr. Greenhill suggested, and in the others it was of the interval type because we did the operation earlier in the phase. Dr. Singleton brought up the question about the frequency of this syndrome. We don't think ovulatory pain is very common or nearly as common as some authors have stated, but it probably occurs more frequently than was previously thought. Most women have some slight evidence of ovulation that can be detected. This might be of great value in determining whether women are ovulating and whether sterility is due to that one cause.

DIAGNOSTIC ASPECTS OF ROENTGENOLOGICALLY NEGATIVE GASTRIC DISORDERS

GEORGE B. EUSTERMAN, MD
ROCHESTER, MINN.

This subject is significant since gross intrinsic lesions in the upper portion of the digestive tract are in the minority as the cause of chronic recurrent gastric disturbances. Moreover, my thesis permits incidental appraisal of the merits of roentgenologic diagnosis from the standpoint of the clinician.

The circumspcct physician rightly regards a "negative" roentgenologic report as evidence that he is most likely in the presence of a diagnostic problem and he does not assume the commonplace attitude that there is nothing wrong with the patient. It is obviously taken for granted that such a roentgenologically negative report is submitted by a skilful and experienced roentgenologist. When made by any one less capable, a negative diagnosis must be taken with a grain of salt by both the physician and the surgeon, for lesions may too frequently be overlooked when present or diagnosed as present when absent. The causes underlying such errors of omission and commission have been instructively pointed out by the roentgenologists themselves.¹ Notwithstanding such apparently unavoidable errors, however, developments in radiology of the stomach and duodenum in the last quarter of the century have been remarkable, and they have made possible the detection of gross lesions in the stomach and duodenum in what is reputed to be 90 to 95 per cent of cases, even though

the exact pathologic nature of the lesion visualized cannot always be successfully ascertained before microscopic examination.

Thus, in the process of elimination, a negative report is of the greatest diagnostic value and would for practical purposes exclude ulcer of the stomach and duodenum, gastric carcinoma, pyloric and duodenal obstruction and duodenal dilatation from whatever cause. A negative report also would exclude roentgenologically positive forms of gastritis and the majority of the rare forms of gastric and duodenal lesions such as benign granulomatous and lymphomatous tumors, diverticula, the majority of diaphragmatic hernias and the occasional deformities caused by extensive adhesions. In their aggregate such intrinsic lesions are responsible for about a fifth of the cases of chronic gastric disturbances.² In private general practice, I am reliably informed, the percentage may not exceed 10. For present purposes, the conditions just enumerated may be regarded as roentgenologically positive disorders.

In considering roentgenologically negative gastric disorders the classification proposed by Berger³ is simple yet comprehensive. It is substantially as follows: (1) unrecognized roentgenologically positive gastric disorders, (2) roentgenologically negative disorders of the stomach itself, (3) actual or apparent gastric disturbances resulting from disease of abdominal viscera other than the stomach, and (4) actual or apparent gastric disturbances resulting from disease remote from the abdominal organs.

UNRECOGNIZED ROENTGENOLOGICALLY POSITIVE GASTRIC DISORDERS

I have shown numerically how duodenal ulcer is in our experience at the clinic the commonest intrinsic organic cause of chronic recurrent indigestion. Kirklin⁴ has pointed out that without great technical dexterity and attentive study at least a fourth of such lesions would escape roentgenologic detection, and that even under the best of circumstances about 5 per cent escape such detection. The same can be said of gastric ulcers and small carcinomatous ulcers. A fair percentage of ulcers at or just below the anastomosis following gastrojejunostomy may for well known reasons also be impossible of detection. Benign and malignant neoplasms and granulomatous processes which may produce an appreciable filling defect, however, rarely escape detection by the roentgenologist, especially when the examination is coupled with a study of the mucosal relief. Elsewhere I⁵ have pointed out how, by virtue of the high posterior situation of a lesion in the stomach even a malignant process may occasionally be overlooked on initial examination when the clinical evidence of its presence may be very convincing. If gastritis

2 In the experience of Dwyer and Blackford based on a study of 3,000 cases (Dwyer M. F. and Blackford J. M. Interpretation of Gastric Symptoms. A Clinical and Roentgenological Study of 3,000 Cases. *Radiology* 14: 38-44 (Jan.) 1930) gross lesions of the stomach and duodenum were diagnosed in only 15 per cent. In a consecutive series of 15,000 patients with chronic dyspepsia examined at the Mayo Clinic 137 per cent had duodenal deformities and niches which were interpreted as being the result of ulcer. 15 per cent had gastric ulcer and 0.3 per cent had both gastric and duodenal ulcer. These percentages accounting for a total of 15.5. A little more than 2.6 per cent had gastric carcinoma. This makes a total of 18 per cent of patients with organic diseases of the stomach and duodenum.

especially in its primary subacute and chronic forms, is such a prevalent disease as some of our European colleagues would lead us to believe, many such lesions are going to be overlooked on routine roentgenologic examination. Diaphragmatic hernias, especially small paraesophageal (hiatal) hernias, can also easily be overlooked on routine examination. The necessity for subsequent reexamination when any of the foregoing entities come under suspicion cannot be emphasized too strongly.

ROENTGENOLOGICALLY NEGATIVE DISORDERS OF THE STOMACH ITSELF

In this group are included the so-called functional gastric disturbances or gastric neuroses, as well as the so-called habit dyspepsias, dyspeptic disturbances associated with constitutional inadequacy and roentgenologically negative forms of gastritis, and gastric allergy. Of the three types, gastric neuroses are unquestionably the most frequent and intriguing. This entire group constitutes approximately a fourth of the cases coming under our observation in which the major complaint is of "stomach trouble."

A diagnosis of chronic nervous exhaustion or psychoneurosis in cases in which the symptoms are similar to those of visceral dysfunction should naturally be made with considerable reservation. However, the justification for such a diagnosis was recently pointed out by Macy and Allen⁶ in a study based on a series of 235 cases encountered at the clinic. It was found that such a diagnosis, made on an average of six and a half years before final examination of the patient, proved to be accurate in 94 per cent of the cases. Of interest is the fact that the gastro-intestinal tract was a point of origin of the major symptoms in the largest number of cases. One is reminded of the observation of William James that "the abdomen is the sounding board of the emotions."

Without attempting any discussion of the fundamental nature of these neuroses or of the factors apparently operative in the derangement of visceral function as a result of certain emotional tensions and states, or psychoses, I shall merely mention certain features which characterize the symptoms of gastric neuroses and which are useful in their recognition: (1) the disturbances may be of long duration yet complications or progression may be absent and the patient may be in a good nutritional state, (2) the symptoms vary in the region where they appear, are variable in degree and are frequently continuous, (3) there is lack of the sequence so characteristic of the majority of organic lesions, (4) the pain or discomfort, when present, is usually diffuse and is often projected unaccountably, (5) while the patient may complain bitterly of his disturbances or sensations during waking hours, they may be completely absent at night, (6) intermittent digestive disorders are often coincident with, or follow, emotional stress, (7) physical disability is frequently marked and entirely out of proportion to the severity of the complaint, and (8) there is usually present the evidence of other stigmas of a psychoneurotic or hysterical personality.

While I have never entertained any doubt as to the existence of the acute forms of gastritis, I have much more hesitancy about making the diagnosis of chronic gastritis in the absence of roentgenologic or gastroscopic confirmation. In light of recent developments

it behooves one to be more "gastritis conscious." Faber⁷ insisted that antral gastritis may give rise to symptoms indistinguishable from those of ulcer. In fact, Katsch⁸ maintained that gastritis in its various forms may simulate any organic gastric or duodenal disease. It is reasonable to presume, therefore, that many of the roentgenologically negative forms of gastritis are overlooked or misinterpreted. Alimentary allergy as a cause of chronic recurrent gastric disturbance is more frequently regarded as a possibility now than formerly. A personal or family history of asthma, hay fever, angioneurotic edema, urticaria, eczema or other forms of allergic disease makes essential the exclusion of gastric allergy in the absence of any other plausible explanation. In such cases the chief underlying disturbance is spasm of the smooth musculature and this may give rise to pains and associated symptoms simulating those of ulcer or to attacks of vomiting, with or without participation by the intestinal tract.

GASTRIC DISTURBANCES RESULTING FROM DISEASE OF ABDOMINAL VISCERA OTHER THAN THE STOMACH ITSELF

The preponderance of abdominal visceral disease other than of the stomach or duodenum in the causation of recurrent dyspepsia gave rise to the surgeons' bon mot "the stomach is the fire alarm box, the fire is somewhere else." From a third to two fifths of all chronic gastric disorders have their origin in disease of the gallbladder, appendix, pancreas, liver, small bowel, colon or such conditions as epigastric hernia or helminthiasis. As neither time nor space permits detailed discussion of this phase of the subject, my remarks will be limited to a brief consideration of some of the noteworthy features.

Chronic calculous or noncalculous cholecystitis is the most common cause of the distressing chronic, recurring types of dyspepsia affecting adults. We at the clinic see each year 60 per cent more cases of cholecystic disease than of chronic gastric and duodenal ulcer combined. Dwyer and Blackford demonstrated that whereas 15 per cent of their dyspeptic patients harbored organic lesions of the stomach and duodenum, 21.3 per cent had disease of the gallbladder. One should always entertain the suspicion of cholecystic disease in the case of a middle-aged obese patient, especially a woman, who is not obviously neurotic or aerophagic and who has recurrent attacks of epigastric discomfort, gaseous distress, belching, or a sense of fullness. In most cases the dyspepsia is selective in type and the symptoms are more likely to appear soon after meals, although ulcer-like manifestations occur sufficiently often so that many such patients are erroneously treated for ulcer. Cholecystographic examination is indispensable to detection of the disease, especially in cases in which the symptoms are mild and the patients have not experienced the characteristic biliary colic. Of course, in the absence of a typical train of symptoms and signs a normal cholecystographic response argues for conservatism. Occasionally one sees cases wherein the clinical evidence of cholecystic disease is convincing and other lesions have been satisfactorily excluded but in which the cholecystographic appearances are normal. At operation one of two types of pathologic condition is usually revealed: chronic

noncalculous cholecystitis of grade 2 or 3 or a fairly well preserved gallbladder containing small stones

The clinical, surgical and experimental evidence for appendiceal dyspepsia has been presented by Graham and Guthrie,⁹ by Moynihan¹⁰ and by Braithwaite,¹¹ respectively, in a convincing manner, and a host of other competent investigators have made valuable contributions. Notwithstanding this fact, and realizing that in some perplexing or obscure cases of indigestion permanent cure was obtained on removal of a diseased appendix, I am of the opinion that this form of dyspepsia as a disease entity looms less important now than formerly. The needless sacrifice of many normal appendices in the past made essential stricter diagnostic criteria as regards this form of dyspepsia. In the last few decades routine exploration of the upper abdominal organs at the time of removal of the appendix and more careful preoperative roentgenologic study of the stomach and biliary tract disclosed the fact that lesions in the upper part of the abdomen were more frequently associated with disease of the appendix than was heretofore realized. In Dwyer and Blackford's compilation of 3,000 cases a chronically diseased appendix was the cause of gastric symptoms in 5.5 per cent.

Disease of the liver may provoke epigastric pain through enlargement of that organ, or hepatitis and indigestion may result from the associated gastritis, or serious hemorrhage may occur as the result of esophageal varices. One is frequently surprised at the insidious onset of these conditions without obvious cause, and the silent progression of the disease in cases of hepatic cirrhosis, the portal variety in particular. In the absence of icterus and anasarca, the diagnosis can usually be established by careful physical examination, by means of tests of hepatic function, and by roentgenographic examination of the esophagus for evidence of varices without being obliged to resort to abdominal exploration or laparoscopy.

The frequency of pancreatic disease as a cause of epigastric pain or digestive disturbances, or both, is not generally appreciated, largely because of difficulties in diagnosis. Even the acute forms of pancreatitis, with which I am not directly concerned here, are often mistaken for some other acute abdominal condition. Subacute and chronic inflammatory lesions and malignant neoplasms give rise to gastro-intestinal disturbances that often dominate the clinical picture. Subacute and chronic pancreatitis is usually the result of, or associated with, cholecystic disease, duodenal or gastric ulcer, and obesity. In recent years some authorities have stressed the importance of duodenal diverticula situated near the papilla of Vater as a cause of pancreatitis. Von Bergmann and his associate¹² stated on the basis of experimental and clinical observation that the pain in the milder forms of pancreatitis appears at the height of physiologic activity of the organ, which is usually two or three hours after meals. In addition they commented on the frequent left epigastric situation of this pain, with extension to the back, and on the persistence of a half-girdle zone of hyperalgesia, which according to them seemed to be of marked diagnostic significance. Such pain must be dis-

tinguished from that of penetrating or perforating ulcer, from transposed or contralateral pain of cholecystic disease and from the pain of diaphragmatic hernia, renal and colonic lesions, sciatica and lumbago.

In a review of eighty-eight verified cases of primary malignant neoplasms of the pancreas without jaundice, Wilbur and I¹³ discovered that the presenting or predominant symptoms in sixty-four of these cases were purely gastric in nature. Next in order of frequency were pain (chiefly epigastric, with posterior projection), loss of weight, and the presence of a palpable mass in the upper or middle portion of the abdomen.

In an attempt to establish a diagnosis of pancreatic disease after satisfactory routine exclusion of lesions in the stomach, colon and kidneys, many laboratory procedures have been advocated. Comfort¹⁴ has shown that an increased activity of the serum lipase appears to be a very efficient test for pancreatitis, less so for pancreatic carcinoma unless the pancreatic duct is obstructed by the latter. But neoplasms and cysts often produce defects in contiguous organs, such as the duodenum, antrum pylori and colon, as a result of direct invasion or pressure, defects which are recognizable on roentgenologic examinations in an appreciable number of cases. Such objective signs, while themselves easily misinterpreted, are of great diagnostic value when properly correlated with the other symptoms and signs elicited.

Many individuals with intestinal disorders, functional or organic, seek relief for what they earnestly believe to be "stomach trouble." Sometimes there are actual associated gastric lesions, as in cases of chronic gastroenteritis, or reflexly engendered gastric disorders of a spastic nature, as in cases of stenosing lesions of the small bowel, in spastic colitis and in "irritable" colon. In the early stages of carcinoma of the proximal part of the colon and also in some cases of ileocecal tuberculosis, ulcer-like symptoms may be manifested. However, routine inquiry into bowel function, often disclosing the past or present existence of diarrhetic bloody or mucoid movements, of obstipation or of segmented stools, may supply the first clue as to the real nature of the trouble. Such a clue is strengthened when the pain, discomfort or tenderness is at the umbilical level or lower and if it follows the approximate course of the colon.

Epigastric hernia is one of the various causes of pain of parietal origin simulating visceral disease, this has been well described by Moschcowitz.¹⁵ Pemberton and Curry¹⁶ reviewed the symptoms in 296 cases of epigastric hernia in which patients were submitted to operation. Their study, however, indicated that visceral disturbances which could be ascribed solely to the hernia were infrequent and variable in nature, ranging from infrequent ulcer-like manifestations to diffuse abdominal cramps bearing no relation to alimentary or exertion.

Gastric disturbances resulting from Addison's disease, intestinal parasites, tuberculous peritonitis, retroperitoneal adenopathy of an inflammatory or lymphomatous nature, and disease of the lower thoracic vertebrae (arthritis, caries, metastasis), while perhaps of

significance than the entities just considered, always obtrude themselves when least expected. If for example the pigmentation, asthenia or hypotension of suprarenal insufficiency is delayed in appearance or is not a prominent sign, the cause of the anorexia, epigastric pressure, nausea, vomiting and diarrhea may be misinterpreted. As the upper portion of the digestive tract can be infested with *Giardia lamblia*, *Strongyloides stercoralis*, *Ascaris lumbricoides* and hookworm, as a result of which indigestion, abdominal pain, anemia or hemorrhage can occur, parasitism should be excluded, especially if the patient resides in a subtropical or tropical region.

GASTRIC DISTURBANCES RESULTING FROM DISEASE REMOTE FROM THE ABDOMINAL ORGANS

With fairly satisfactory exclusion of the roentgenologically positive, roentgenologically negative, and the extragastric abdominal disorders just discussed, it is not unlikely that some pathologic process in organs remote from the abdominal viscera, or some systemic toxemia is present in larval, latent or not easily recognizable form. Systematic examination for evidence of those diseases which would most likely give rise to indigestion should be made, granted that complete anamnesis, careful physical examination, and routine urinalysis, blood count and flocculation or serologic tests have so far not furnished a clue. Disease of the circulatory, pulmonary, nervous or urinary systems deserves first consideration. Next in order of importance are diseases or dysfunction of the endocrine organs, deficiency diseases (pernicious anemia, pellagra and sprue in particular), toxic states induced by noxious gases, heavy metals and drugs, and inordinate use of tobacco and alcohol. One should be especially mindful of the role that carbon monoxide and lead might be playing in obscure cases and to what extent a patient's occupation or environment might expose him to industrial forms of poisoning. In the aggregate, at the clinic these diseases and intoxications account for from 15 to 20 per cent of cases of chronic digestive disorders.

A few observations concerning this group as a whole might serve a more useful purpose than detailed consideration of each entity. For example, one may speculate why organs as remote from the stomach or duodenum as the gonads, myocardium, lungs or kidneys can give rise to recurring gastric disturbances, so marked at times as to overshadow any symptoms that could be directly attributable to the involved organ itself. The varied factors giving rise to such disturbances, as well as the nature of their morbid physiologic and anatomic effects on the stomach and its continuations, are gradually being better understood. Included among such factors are a common innervation, so that disease of one organ may, for example, reflexly produce spastic and hypersecretory disturbances in the other. Another factor is a circulatory interrelationship, so that the circulatory failure of hypertensive heart disease, for example, may produce passive congestion in the stomach, giving rise to impairment of gastric motility and secretion and even to degenerative changes in the gastric mucous membrane. The gastric disturbances associated with various endocrinopathies, especially disease of the gonads and the adrenal, pituitary and thyroid glands may in large measure be the result of autonomic imbalance owing to the intimate relation of the sympathetic and parasympathetic nervous systems to the endocrine glands and of the former in turn to the digestive organs.

Only on infrequent occasions are gastric disturbances the sole expression of a disorder remote from the stomach, I have seen such instances, however, in cases of active pulmonary tuberculosis, in toxic or uremic states as a result of prostatic hypertrophy, pyelonephrosis or chronic glomerulonephritis, and in cases of pernicious anemia and sprue. A renal stone may occasionally give rise to gastric disturbances closely simulating duodenal ulcer, but it has been my experience that the nature, situation and projection of the pain usually arouse suspicion as to the true site of the trouble. One derives comfort from the fact that the routine systematic physical examination, urinalysis and flocculation test, and if necessary a few other well directed laboratory investigations, will usually disclose the true nature of the underlying cause no matter how irrelevant the subjective complaint may appear to be. The nature and degree of gastric disturbances vary widely because the direct and indirect influences on gastric function of various disorders remote to the stomach are variable.

An increasing number of carefully controlled studies of gastric secretory and motor function and of the condition of the gastric mucous membrane as determined by roentgenologic examination of the mucosal relief, or gastroscopy, disclose a higher incidence of such motor and secretory disturbances and of inflammatory changes in the gastric mucous membrane in disorders remote from the stomach than has heretofore been realized. The symptoms engendered by such disturbances permit of rough classification into the following types: (1) vague, mild or nondescript, characterized by "gas," epigastric fulness, mild anorexia or nausea, (2) those of the nausea and vomiting type, as seen in the painless form of tabetic gastric crises, in migraine, uremia and acute hyperthyroidism, and in some cases of cholecystic disease, (3) the catarrhal gastritis complex, in advanced cases the symptoms and signs being strongly suggestive of gastric cancer, (4) those of the intestinal type, characterized by (a) the "irritable" colon complex or (b) chronic recurrent diarrhea, usually in association with achlorhydria, (5) the hemorrhagic type, in which hematemesis or melena is the predominant or exclusive symptom, as in portal cirrhosis, erosive and ulcerous gastritis, and ulcer in Meckel's diverticulum, (6) ulcer simulating, a not uncommon type, and (7) the pain predominating type, as seen in the painful form of tabetic gastric crisis, in the abdominal form of angina pectoris, in periarthritis nodosa, and in the various sclerotic vascular abdominal conditions, such as are described by Ortner.¹⁷

SUMMARY

The efficiency of modern roentgenologic diagnosis permits classification of diseases of the stomach into roentgenologically positive and roentgenologically negative disorders. The former (ulcer, cancer, and so on) constitute about a fifth of the cases of chronic dyspepsia coming under observation at the clinic, roentgenologically negative disorders which have been classified and described constitute the remainder.

Gastric disturbances reflexly engendered by disease of abdominal viscera other than the stomach itself or its continuations in my opinion exceed in importance the gastric neuroses, because of their nature and extent and the comparative frequency of their occurrence. They constitute from a third to two fifths of all cases. The neuroses constitute about a fourth of the total.

17. Ortner Norbert. *Körperschmerzen und ihre Differentialdiagnostik*. ed. 4. Vienna: Urban and Schwarzenberg, 1931. pp. 45-46, 695.

In from 15 to 20 per cent of cases, gastric disturbances are attributable to disease of organs remote from the stomach, but only on infrequent occasions are such gastric disturbances the sole expression of an extragastric disorder. Complete and systematic anamnesis and physical examination, and a few simple well chosen laboratory studies, will usually disclose the true nature of the underlying cause no matter how irrelevant the subjective complaint may appear to be.

ABSTRACT OF DISCUSSION

DR. EDWARD H. SKINNER, Kansas City, Mo. The radiologist who is expected to be of service to his consulting physician must be more than the individual who sees patients file by him in a routine manner before the fluoroscope. Undoubtedly the radiologist should see his patients not only by means of an x-ray tube but by means of the eyes. The increasing number of emotional disturbances producing gastric symptoms may be due to the progress or decline of civilization. Sometimes it is easy to classify the symptom complex. Shakespeare promoted one grouping when he said "Yon Cassius has a lean and hungry look, He thinks too much." It is easy to agree that Cassius had ptosis, a gastric ectasia and a long, indifferent colon, all without true disease but with many vagaries of function. On looking at the large, fleshy, well fed executive, one realizes that his gastric trouble is not because he thinks too much but because he eats too much and drinks too much. Consequently he burps too much.

Radiologists and clinicians should approach the problem of diagnosis on other than purely medical lines. The recognition of the psychologic aspects are too easily disregarded. The influences of the sympathetic nervous system in promoting functional displays that may turn into pathologic disasters cannot be overlooked. I would much prefer to have a clinician with imagination as well as intelligence. Give me one whose boyhood had Conan Doyle and Mark Twain or even Nick Carter to stimulate his growing brain. I feel confident that he would be able to worm a good clinical history out of a patient better than the doctor whose anemic boyhood found solace in Bunyan's "Pilgrims Progress." All should realize that these emotional disturbances with negative examinations by radiologists require more judgment and more clinical imagination than definite pathologic lesions. The first observation that Cannon brought out by means of the x-rays was that, if one gives a cat food plus anger, one obtains spasm. On the contrary, give an individual food plus pleasure and one creates an appetite. Those who pursue roentgenographic examinations should avoid the exaggeration of the importance of spastic conditions and any implications of stasis that they may think they see by the fluoroscope. Let us not translate these shadows into diagnostic values because we see them once, for they are entirely too ephemeral. The radiologist will meet this problem of diagnosis more successfully in the presence of negative x-ray observations by combining a careful history. The inexperienced possessor of x-ray apparatus exaggerates, confuses and confounds congenital defects, colitis adhesions, kinks, and nonfillings to an alarming degree. These are some of the things which have stimulated Dr. Eusterman to tell us that we must study our patients we must analyze. His analysis of the field of the negative virtues and deficiencies of the roentgen ray has been most illuminating.

DR. NELSON G. RUSSELL, Buffalo. Many of Dr. Eusterman's patients have been culled over by the internist before they have gone to him and most of the simpler problems have been solved and I think that the general practitioner speaks in terms of the greatest good to the greatest number and if he can save ninety-nine he is willing to let the one that went astray be worked up more thoroughly. The problem is often the acute abdominal conditions those which should be operated on immediately and which would lose a good deal of their opportunities by being studied too long. One realizes one's inefficiencies in making a diagnosis in many of the chronic cases and is only too glad to have every aid one can get. The point in making the diagnosis is not so much making it on the condition of the patient as it is on the ability of the man who studies him. Dr. Eusterman brought that out very clearly.

We have all known it before, but we have hesitated to talk too freely. In regard to the neurotic cases, we all have them and get results with them, and a man's message is just as much on the personal side as on that of his morals or methods. Whether he does it with one method of healing or another or, as some do, by making a very thorough examination and saying that everything is all right or admits for the general well being of the patient that the results are all right, the results are about the same. Dr. Eusterman's paper is a contribution on one of the best elements in any problem or any policy. I believe in his enlightened realism, and that is where I should classify his contribution today.

DR. RUDOLPH SCHINDLER, Chicago. Is it practical to use the term "gross lesions" just for carcinoma and ulcer? One sees that a patient has an atrophic gastritis and large mucosal hemorrhages and terrible pains and knows one cannot cure him. Another patient is seen over ten years. He has hypertrophic ulcerative gastritis. He cannot be helped. Are not these gross lesions of the stomach? Are stomach disorders and disturbances in remote organs accidental symptoms or is one the primary and which one? A patient comes with such a marked hypochondria that one declines gastroscopy. He insists and complete atrophy of the mucous membrane is found. What is the connection? Henning has shown that in tuberculosis chronic hypertrophic gastritis is very common. Moutier has observed changes of the gastric mucosa associated with certain dermatoses. It is possible that an allergic factor causes changes of the mucosa of the stomach as well as of the skin, and it is also possible that the stomach which is chronically inflamed allows allergic products to enter the circulating blood. These, in my opinion, are important questions.

PAPILLOMA AND CARCINOMA OF THE BLADDER IN DYE WORKERS

G. H. GEHRMANN, MD

Medical Director E. I. du Pont de Nemours & Company
WILMINGTON, DEL.

Rehn¹ in 1895 detected two cases of papilloma and one of carcinoma of the urinary bladder in employees of the German dye industry. He suggested at this time that these tumors might have been caused by exposure to aniline. Grandhomme,² a factory physician, viewed this theory with much skepticism, pointing out that thousands of workers who had been exposed to similar conditions for many years had not shown evidence of bladder tumors. Later evidence, gathered by Rehn,³ Schedler,⁴ Leichtenstern,⁵ Posner,⁶ Wendel,⁷ Strauss⁸ and Bardenheuer,⁹ substantiated Rehn's earlier contentions and by 1904 dye manufacturers were convinced that there was a relation between occupational exposure and the development of bladder tumors.

Leuenberger¹⁰ in 1912 reported eighteen cases of bladder tumor occurring among dye manufacturers.

Read before the Section on Preventive and Industrial Medicine at the Eighty-Seventh Annual Session of the American Medical Association, Kansas City, Mo., May 13, 1936.

workers at Basel. He also reported at the same time a study of all bladder tumors at the Basel clinic, showing that 50 per cent occurred among dye workers and that the incidence was thirty-three times greater in dye workers than in non-dye workers.

In 1925 the German government passed a law making bladder tumors in the dye manufacturing industry compensable.

The first aniline tumors to be reported in this country were detected in 1931. Prior to 1914 European countries, principally Germany, manufactured about 80 per cent of the entire output of dyes. It was subsequent to 1914 that the dye industry was developed on a large scale in this country. A period of sixteen years elapsed before the first aniline tumors developed to the point of recognition in America. This period closely corresponds to the average time of exposure necessary to produce these tumors.

ETIOLOGY

Prolonged exposure to relatively low concentrations of certain intermediates produced during the manufacture of dyes and classified as aromatic amines (aniline, alpha and beta naphthylamine and benzidine) are known to have caused the development of tumors in certain individuals. These materials have been classified as causative agents because of the incidence of tumors among the workmen engaged in their handling. This evidence is admittedly not conclusive, and it is quite possible that many other materials or combinations of materials may later be included as causative agents.

It is to be understood that, although it is accepted that certain chemical compounds of the nitro and amino group are responsible for the production of papillomas and carcinomas of the urinary bladder, the exact nature of these compounds is by no means clearly understood, neither is the mechanism of development.

Experimental production of bladder tumors has been attempted for many years with predominantly unsuccessful results. Perlmann and Staehler¹⁰ were able to produce tumors in seven rabbits of a group of seventy by administering amino compounds by daily subcutaneous injections. Six of these tumors occurred among forty animals treated with beta naphthylamine and in only one in a group of thirty treated with aniline. This work confirmed the existence of chemical compounds capable of producing tumors of the urinary bladder.

ABSORPTION ROUTES

The carcinogenic compounds already mentioned enter the circulation through three routes: (a) respiratory, (b) cutaneous and (c) gastro-intestinal. It is generally agreed that the most important route of entrance is the respiratory tract, in the form of dust and fumes. Aniline, as has been demonstrated by the incidence of acute poisoning occurring in industry, is readily absorbed through the skin. The skin absorption of solid compounds such as alpha and beta naphthylamine is questionable.

Absorption through the gastro-intestinal tract is probably of the least importance. However, it must be remembered that present knowledge indicates a long period of exposure to low concentrations as an etiologic

factor. Therefore, any gastro-intestinal absorption should be considered as of more or less importance, despite the low solubility of these compounds.

AGE INCIDENCE

Table 1 shows the age distribution in twenty-four cases of carcinoma. These figures do not indicate occurrence at any particular age. The fact that they show a somewhat higher incidence after 30 is due to the insufficient time of exposure prior to that age.

Table 2 shows the exposure in years and the period of incidence of the twenty-four cases shown in table 1.

Table 3 shows the age distribution of thirty-nine cases of papilloma. Here again the age group shows no significant incidence.

Table 4 shows the period of incidence of exposure in the papilloma group by years.

From these tables it is evident that five years is the minimum and twenty-five years the maximum time of exposure for the development of tumors. It should be pointed out, however, that the maximum period of exposure—twenty-five years here shown—represents

TABLE 1—Age Distribution in Twenty-Four Cases of Cancer

the maximum period of exposure in this series of cases and that more cases will develop as time goes on. One peculiarity of these tumors is that they continue to develop even after removal from further exposure. In Germany they have occurred as long as twenty-five years after workers have changed their occupation.

DIAGNOSIS

The classic symptoms of tumors of the urinary bladder are hematuria, frequency, urgency, burning and pain. These symptoms as a group occur in our experience only in those cases which are well advanced. The diagnosis in this series was made by periodic cystoscopic examination and the classification of the tumors by biopsy. Prior to cystoscopic examination, five of the twenty-four carcinomas showed hematuria. Symptoms of frequency, urgency and burning were so inconsistent as to be almost negligible as a diagnostic aid. It has been our experience that cystoscopic examination is the only safe method of early diagnosis of these tumors.

Tumors may be single or multiple, papillary or sessile, infiltrating or noninfiltrating, ulcerating or non-

¹⁰ Perlmann S and Staehler W. Ueber kunstlich erzeugte Geschwulste der Blase. Klin. Wchnschr. 11: 1955 (Nov. 19) 1932. Zur Ätiologie der Blaseschwulste, Ztschr. f. Urol. 27: 195 1933. Experimentelle Erzeugung der Blaseschwulste. Ztschr. f. Urol. 36: 139 1933.

ulcerating, malignant or benign. The incidence of carcinoma in this group of sixty-three cases is thirty-eight. An analysis of 124 German cases by Gay¹¹ indicates that the incidence of carcinoma was twice that of papilloma. This difference may be explained by the difference in methods of detection in Germany and in this country. The sixty-three cases reported here were all detected by routine cystoscopic examinations. The German workmen were not subjected to cystoscopic examination except in those cases which showed gross or microscopic hematuria. Comparison of these two groups gives further evidence that routine cystoscopic examination is the safer method of early detection. All bladder tumors should be regarded as potentially malignant regardless of their histologic structure. There have been cases in this group which cystoscopically appeared as papillomas but on microscopic examination, although predominantly benign, have shown unmistakable evidence of carcinomatous invasion.

Aniline tumors may be located anywhere in the bladder, the most frequent site, however, is the paratrighonal space. Observations indicate a biologic change which possibly affects the entire bladder wall. The appearance of repeated tumors in various locations and multiple tumors would tend to confirm this point of view and disprove the contention that the damage is localized.

PATHOLOGY

The histologic structure of aniline tumors does not differ from tumors of unknown etiology. They occur in all gradations, from the slowly growing villous papilloma, which may remain latent for many years, to the rapidly growing, destructive and anaplastic carcinoma, which produces early and widespread metastasis.

TREATMENT

The treatment of aniline tumor does not differ from the treatment of tumors of unknown etiology. It is to be emphasized, however, that the best results from treatment may be expected with early diagnosis. Benign papillomas are easily destroyed by fulguration, with an excellent prognosis, while carcinomas require much more extensive procedures and the prognosis is not so good.

PREVENTIVE MEASURES

Preventive measures are divided into two groups: (a) plant operative control and (b) medical control. The plant operative measures consist of manufacturing processes that provide complete protection against any exposure from dust or fumes. These carcinogenic materials must be manufactured in a completely closed system, which must be maintained in perfect working condition and operated under most rigid rules. Particular care must also be maintained over the mechanical group whose duty it is to make repairs on this equipment.

Exhaust ventilation designed to remove any dust or fumes that may escape from any of the equipment is essential. The final disposition of exhausted air is extremely important and the ventilation discharge should be sufficiently remote from all operations to prevent contamination in any plant area. Adequate measures of production in Germany have so successfully protected the workers that no new cases have developed in men who have been employed in these factories since the installation of their protective facilities. There

are, however, some tumors still developing in workers who were exposed during the time when the protective measures were not in operation.

MEDICAL CONTROL METHODS

Every applicant for work in areas where he will be exposed to aniline, alpha and beta naphthylamine and benzidine should have a cystoscopic examination in addition to a regular complete physical examination. Any disease of the genito-urinary system is a contra-indication to employment, as is family history of cancer, history of hematuria or venereal disease. No applicant for this type of work should be accepted who is under 21 or over 40 years of age.

Cleanliness is essential in the operation. Beards and mustaches must be removed. Each workman must have a complete suit of working clothes, including head covering. This clothing must be laundered at least once a week and kept in a special locker which is separated from the locker for street clothing. A shower bath, with warm water and soap, should be taken at the end of each shift. These rules apply to all mechanics making repairs in these operations.

All workers should have a complete physical examination and cystoscopic examination once a year. Every three months there should be a complete urinalysis and with the appearance of macroscopic or microscopic blood, cystoscopic examination is indicated.

Any case that has ever shown tumor or localized hemorrhagic areas should be examined cystoscopically every three months. Since removal from further exposure does not lessen the liability to further tumor development, we recommend, in order to keep the number of exposures to a minimum, returning patients with positive signs to their original work after they have been operated on.

PROGNOSIS

The prognosis is good in cases of benign tumor. However, further growths may occur at any time and may be primarily benign or malignant. The prognosis in malignant aniline bladder tumors in general is not favorable. Simon believes that they are biologically different, run a slower course and respond better to therapeutic procedures.

CONCLUSIONS

1. Papilloma and carcinoma of the urinary bladder are caused by long exposure to certain nitro and amino compounds. The average time of exposure necessary to produce tumors is twelve years.

2. Tumors may be single, multiple, benign or malignant. All benign tumors should be considered potentially malignant.

3. Early diagnosis is essential and the periodic cystoscopic examination is the only safe method of detecting these tumors early.

4. Proper methods of plant control and medical supervision will eliminate the incidence of these tumors.

7 West Tenth Street.

ABSTRACT OF DISCUSSION

DR. VICTOR D. WASHBURN, Wilmington, Del. From December 1929 to the present time there have been under treatment sixty-three men who had neoplastic disease of the urinary bladder as a result of their occupation as dye workers. Of this number there have been four deaths from carcinoma of the bladder, a death rate of 6 per cent. There has been one death from carcinoma of the head of the pancreas in a patient whose autopsy the patient was found to have a small neoplasm of the urinary bladder and one accidental death of a man who was

¹¹ Ferguson, R. S., Gehrmann, G. H., Gay, D. M., Anderson, L., and Washburn, V. D. Symposium on Aniline Tumors of the Bladder. *J. Urol.* 31: 121 (Feb.) 1934.

viously had had a tumor of the bladder. There are six men under treatment at present and six men have been under treatment during the last six months. In other words approximately 75 per cent of our patients are alive and free from tumor, 19 per cent are either under treatment or have been recently treated, and 6 per cent are dead. Eliminating the accidental death and the liver carcinoma death and seventeen men whose records were not easily accessible, I can report that twenty-five men when first seen presented no symptoms, subjective or objective and nineteen presented symptoms such as hematuria and urinary frequency. All of the twenty-five men without symptoms are alive, six of them classified as having papilloma, six papillary carcinoma grade 2, two papillary carcinoma grade 3 and eleven did not have a biopsy. Of these twenty-five men, nineteen responded to fulguration through the cystoscope, one ungraded required high voltage x rays, one with a grade 3 growth has received fulguration radon implantation and high voltage roentgen therapy. In one similar case fulguration and open operation were given, in one grade 2 fulguration and high voltage roentgen therapy. It is believed that these results are superior to those usually obtained and for the following reasons: 1. Discovery of the disease in its incipience by routine cystoscopy. 2. Lower age incidence with consequent longer expectancy of life. 3. Treatment predicated on biopsy, classification and grading of each case. 4. Papillomas and carcinoma, grade 2 treated by fulguration.

DR. J. N. BAKER, Montgomery, Ala. I am wondering why chronic exposure to this particular chemical irritation would not cause damage to the renal cells and to the epithelium lining of the pelvis of the kidney and the ureter. I should like the author to explain why the bladder mucosa alone seems to be vulnerable.

DR. W. F. VON OETTINGEN, Wilmington, Del. I may add that in my opinion the reason why these tumors are mostly located in the trigonal region is that the urine carries the toxic material and this comes in close contact with the bladder wall. Whereas in the kidney pelvis and ureter there is a constant flow and in the bladder there is a stationary condition depending on the conditions of the urine such as pH and the concentration of the excreted urine, one may expect precipitation on the bladder walls, especially in the trigonal region. In experiments being carried on at present we have not yet succeeded in producing tumors but we have seen pictures similar to those occasionally seen as the first symptoms in these workers. In the experimental animals (dogs) the first signs are not located in the trigonal region but in the anterior wall, since the animal is walking on four legs and thus the sedimentation of anything dissolved in the urine has a different topographic location.

DR. GEORGE H. GEHRMANN, Wilmington, Del. I am unable to answer the question at this particular moment and so far as I have been able to determine, the investigators in Germany have been unable to answer this question. It is quite possible that Dr. von Oettingen, who is carrying on experimental work on this particular subject at the Haskell Laboratory of Industrial Toxicology, may develop information which will in the future enable us to answer this particular question. Can you add anything to this, Dr. von Oettingen?

The Pelvis at Birth—The pelvis of the child at birth is partly bony and partly cartilaginous. The innominate bone does not exist as such, its place being taken by the ilium, ischium and pubis which are united by a large Y-shaped cartilage, the three bones meeting in the acetabulum. The iliac crests and the acetabula as well as the greater part of the ischiopubic rami are entirely cartilaginous in structure. The cartilaginous portions of the pelvis gradually give place to bone but complete union in the neighborhood of the acetabulum does not occur until about the age of puberty and occasionally even at a later period. Indeed we may say that the innominate bones do not become completely ossified and fully developed until between the twentieth and twenty-fifth years. Each innominate bone is developed from twelve centers of ossification.—Stander H. J. Williams *Obstetrics*, D. Appleton Century Company, New York, 1936, page 18.

FRACTURE OF THE NECK OF THE FEMUR

EVALUATION OF THE VARIOUS METHODS ADVANCED FOR TREATMENT

PAUL B. MAGNUSON, M.D.
CHICAGO

To appreciate the value of methods for the treatment of fractures, it seems reasonable first to have clearly in mind the various types of fracture and the angles at which they occur. In other words, let me define the terms. This should be the first step in any discussion of an argumentative nature. It is impossible to get an accurate knowledge from the literature of the percentages of fractures of the neck of the femur at a given angle or in a given location. I have classified them only in a general way as fractures of the neck of the femur and have subdivided them into fractures occurring near the head, in the middle of the neck and at the base of the neck, which are frequently complicated by fracture involving the trochanter. This is not adequate classification to serve as a guide in the treatment that is applicable to the given type of fracture. Analysis of the situation shows that the neck of the femur is composed of cancellous bone not more than 2 inches long, which bears the weight of the body at a distinct angle to its long axis. Cancellous bone is noted for its ability to disintegrate when exposed to trauma. A particular example of this, with which every one is familiar, is Colles' fracture at the lower end of the radius in elderly persons. In this fracture, which is always produced by indirect violence, the blow is struck more or less in the long axis of the bone, with the force directed slightly toward the extensor surface, and when reduction is attempted it is found that, no matter how perfect the end-to-end apposition may be, the radius is never the same length as it was before the injury, the reason being that the cancellous cells are actually crushed and there is disintegration of a certain amount of bone, so that reestablishment of normal length cannot be regained. In elderly persons these cancellous bone cells are brittle and are easily crushed, with consequent permanent shortening. The amount of shortening depends on the amount of force exerted at the time of the fracture, and the brittleness of the bone.

It is true, however, that the neck of the femur differs somewhat in its cell structure from the lower end of the radius. In the young person the weight bearing lines in the neck of the femur are distinctly reinforced from the upper part of the head, obliquely downward and outward across the neck and into the shaft, almost connecting the upper part of the head with the medial cortical bone in the upper end of the shaft. It will be noticed that in the elderly person who takes comparatively little exercise these lines are frequently almost completely absent. Therefore there is much more similarity between the neck of the femur and other cancellous bone in elderly persons than there is in younger individuals. These lines of increased density in the neck of the femur correspond to a direct weight bearing line between the shaft and the upper part of the head and acetabulum, and it is at this point that the body rests on the head of the femur. The

each other, especially when combined with adduction followed by Leadbetter's² circumduction and internal rotation and extension. Since the proximal fragment is completely uncontrollable, ability to bring the fractured surfaces into complete contact and hold them there depends somewhat on the angle of the fracture and its distance from the head. It is a matter of common knowledge that extracapsular fractures for the

most part heal without difficulty. This had been attributed to adequate circulation, but I believe that one of the important factors in the healing of the fracture is that the proximal fragment is not entirely out of control, owing to the attachment of the capsular ligament around it.

Dickson and Diveley³ state in a personal communication, that in intracapsular fracture they do not advocate open operation or nailing in fresh fractures, because their results have been satisfactory with the Whitman abduction method with Leadbetter modification except in patients of obese type in whom there are definite difficulties in main-

Fig 3—Anteroposterior aspect of various fracture lines diagrammatically shown and the effects of abduction

taining firm fixation by plaster. They report by this method 70 per cent bony union and 14.7 per cent non-union with a mortality of 15.3 per cent, in their general hospital cases whereas in their private cases they had 80 per cent union and 5 per cent mortality. These statistics are much better than those reported from other general hospitals and must be attributed to personal skill and attention to detail by a well controlled service. The average of union for the Whitman method is more nearly from 40 to 50 per cent as indicated by the statistics of other workers.

Tremendous efforts and many methods have been advanced to improve the poor results. Speed⁴ has very aptly called this the unsolved fracture, and I believe it is still unsolved and will always remain so as are other fractures if 100 per cent functional or anatomic results are expected. There are many obstacles to be overcome aside from those mentioned. Heretofore there has been little or no discussion of the angles at which these fractures occur and to what extent external or internal rotation may affect the proximal in its relation to the distal fragment.

At best each fragment of the neck is short. Anteroposterior roentgenograms are inadequate so far as they

concern judging the approximation of the ends of the fragments and in my opinion a great many of the lateral roentgenograms also are inadequate and inaccurate.

Because of the poor shadow that is cast by the cancellous bone of the neck, many irregularities cannot be evaluated by either of these views, nor can the angle of the fracture line be judged accurately. Because of the shortness of the fragments a considerable amount of angulation can occur without being noticed, unless the axis of the fragments is projected by a long line drawn through the middle of each. Rotation of the proximal fragment cannot be detected by x-ray examination. What appears to be the middle of each fragment is frequently not the middle, because of rotation that may occur (figs 3 and 4).

From the sixteen inquiries made, the answers showed general agreement on one point: that accurate reposition of the fragments was necessary to promote union. How may the rotation of the distal fragment affect the proximal fragment at various angles, producing what may seem to be a reduction which would be accurate enough in the shaft of a long bone, but which actually produces bony contact between only a small portion of the fractured surfaces of the neck, leaving the rest of the fractured surfaces exposed to a bath of bloody synovial fluid?

Fig 4—Lateral aspect of various fracture lines diagrammatically shown and the effects of internal and external rotation

The capsule of the hip joint is the only structure surrounding the proximal fragment and it is only the posterior part that can be used as a guide for the position of this fragment. If this part of the capsule is put on the stretch by internal rotation it will act as a bed or soft splint along the posterior surface of the neck. In a transverse fracture if the fragments are end to end it will force them into contact, and

³ Dickson, F. D. and Diveley, R. L. Personal communication to the author.

⁴ Speed, Kellogg. *Surg. Gynec. & Obst.* 60: 341 (Feb.) 1935.

hyperextension of the femur will further increase this contact by tightening the Y ligament. If, however, the capsule is so distended that these fragments cannot be brought end to end and with the edges in apposition, internal rotation and extension will tend to angulate them, and this angulation depends for its direction on the angle of the fracture. If the fracture line runs

Fig 5—Valgus position of head with varus position of neck and shaft. Impaction with resultant good weight bearing line.

from the upper edge of the head downward and outward (3 and 3a, fig 3), emerging on the inferior surface of the neck following more or less the weight bearing line through the neck, the fragments may possibly be brought into reasonable apposition by manipulation of the Whitman-Leadbetter type, but in internal rotation and hyperextension the upper end of the lower fragment will move backward and the tightening of the Y ligament, plus the tightening of the posterior capsule, will push the fragments past each other as it would in any oblique fracture. If the fracture line is at an angle where the rays of an anteroposterior or lateral roentgenogram will not pass through, as I believe is

frequently the case, this displacement could not be discerned in the roentgenogram. If the fracture line runs from the inferior proximal portion of the neck outward and upward, creating the opposite angulation, the same thing could occur (2 and 2a, fig 3). But the tightening of the Y ligament in extension would push the outer end of the upper fragment upward, because the upper end of the lower fragment would impinge against the fractured surface of the proximal fragment, and through that fragment into a varus position. If the fracture occurs at nearly an opposite plane of angulation, that is, running from the front of the head and neck backward and outward, internal rotation of the leg would push the upper end of the lower fragment against the fractured surface of the upper fragment, throwing that into a backward displacement. In this case the lower end of the upper fragment would push into the posterior capsule, leaving a gap between the fragments near the shaft with contact of the fragments near the head. If the angulation of the fracture should be from behind outward and forward, internal rotation would do the opposite thing (3 and 3a, fig 4), in other words, there would be contact between the lower end of the upper fragment near the shaft and a tendency for the upper end of the lower fragment to pull away from the upper fragment posteriorly. If the fracture should be in the middle of the neck, unless the fragments were brought absolutely end to end before internal rotation took place, the tendency would be for the occurrence of posterior angulation (1, 1a, 1b, fig 4) that is the apex of the angle toward the posterior capsule so that the anterior parts of the fractured surfaces would be in contact and there would be a small wedge-shaped gap between the posterior fractured surfaces.

There is one type of intracapsular fracture of the neck of the femur that I have never seen fail to heal. This type occurs in some mysterious way by which the fracture line occurs near the head the head is thrown into a valgus position and the neck and shaft into a varus position, so that there is a direct weight bearing line between the shaft and the upper part of the acetabulum, with a certain amount of impaction existing between the two fragments (fig 5). Patients with this fracture are able to bear weight immediately and walk with comfort, and they need no immobilization or support after the acute soreness of trauma has disappeared. This type of fracture is not common, but it is nevertheless a complete fracture of the neck of the femur at a point where the distal fragment of the neck is long. One would suspect that, if nonunion is due to poverty of circulation in the middle of the neck in these cases there would be rapid atrophy of the neck. Experience has not shown that this occurs. That weight bearing can be allowed early in this type of fracture is well known, and so far as I have been able to learn by personal inquiry no one has ever seen an atrophy of the neck occur.

CHOICE OF A METHOD

These things being true, there are certain essentials which one should be sure of in choosing the method of treatment for a particular fracture.

First, that anatomic reposition of the fragments can be accomplished.

Second, that the method used will maintain the fracture in this position for sufficient time to allow complete union.

Third, that the patient's physical condition, physical characteristics and economic circumstances will allow continuation of the treatment to a favorable conclusion with the least possible disability to joints, muscles and ligaments.

Fig 6—Before reduction

The prognosis will be made on the characteristics of viability in the bone as indicated by x-ray examination and by the patient's previous physical condition; secondly, by the angle of fracture as determined by views at several angles and possible effect on interference with circulation from the capsule and the blood supply; thirdly, by the ability to place the fragments in anatomic reposition and maintain them there until union can take place.

The well leg traction splint as advocated by Anderson⁵ and Jones⁶ has come into considerable popularity in recent years, and certain it is that apparently good reduction can be obtained by proper application of this method. However, it maintains constant traction on the injured leg, and results, so far as I can ascertain from personal inquiry, have not been all that were expected. It is almost impossible to get lateral views at various angles after the apparatus is applied, and therefore one cannot be sure that the fragments are in perfect position. It will certainly hold the fragments in position so far as extension will hold them in position, and enough abduction can be secured to maintain that position, but I question whether some of the failures in union are not due to the fact that it actually holds the fragments somewhat separated and the ends of the fragments are bathed in synovial fluid instead of being held close together. One cannot say at this time, based on any authoritative information, what percentage of bony union occurs under this form of treatment. It has one tremendous advantage over the Whitman method, i. e., that the patient can move around quite freely and the nursing care is greatly simplified, and also that there is practically no risk involved in the treatment.

A number of methods have been advanced for internal fixation of fracture of the neck of the femur. There are advocates of blind nailing and there are advocates of nailing after the joint is opened, with visual reduction of the fracture in perfect anatomic position. I have no doubt that there are men who have had experience and have enough skill to do blind nailing and attain a large percentage of good apposition and good fixation and consequently a large percentage of good functional results, but there is no large volume of statistics available to support this opinion.

The Smith-Petersen three-flange nail is probably more widely used at present than any other method of internal fixation. In 1925 Smith-Petersen⁷ introduced this method, and in a personal communication he says that, of his first twenty-five cases, 75 per cent resulted in bony union, of the next twenty-five, a little more than 70 per cent had bony union with no fatalities from operation and no complications. At first he opened the hip to obtain proof of perfect reduction. Johansson⁸ modified this nail, Wescott⁹ modified the Smith-Petersen technic by using protractors to direct the nail. Wescott⁹ advocates in addition, the necessity of checking by roentgenograms at various angles to determine the alignment and apposition of the fragments, and I believe that this detail is of tremendous importance, but I question whether the rather complicated technic for making these roentgenograms and the measurements that are advised would be available in most institutions. Here again attention must be called to the fact that what works perfectly in the hands of a skilled observer with unusual mechanical ability will not work as a general rule.

Thornton¹⁰ also simplified the Smith-Petersen technic discarding entirely the use of a fracture table. He has reported to Smith-Petersen fifty cases with no failures, but he adds that some of them are too recent to be judged and that he believes there will be some failures,

since no one can hope to have 100 per cent good results in any large series of cases. These men at this time report over 80 per cent of union by the use of the Smith-Petersen nail.

Scuderi and Callahan, with Cubbins,¹¹ have devised a visual reduction method and use a V-shaped stainless steel channel inserted at a definite angle determined by a pin placed against the upper rim of the acetabulum. This method has not yet appeared in print, but I have seen a number of the cases so treated and from personal communication with the authors it appears to me to be a definite step toward an accurate method of reduction and retention.

The bone graft advanced by Albee¹² and others as a means of fixation has not been largely used in fresh fractures. It is probably a means of mechanical support which is nonirritating to the bone, but it is very irritating to perform because of the necessity of securing the fixation apparatus from the patient's own anatomy. Moore¹³ has devised a method of using three stainless steel pins which are much heavier than

Fig 7—Anteroposterior view showing pins in position

Kirschner wires, placed in such a way that they give support from three different directions. One runs from the upper end of the shaft upward, inward and a little backward, the second from a little above this point approaching the posterior surface of the shaft upward, inward and forward, the third, above the others, engaging through the lower part of the neck into the lower part of the head. These pins are driven in until they engage the head in its densest portion beneath the cartilage. The distal ends of the pins are threaded and round nuts are applied, which are screwed in tight against the bone. When they are in place they are given a good solid blow with a hammer, which tends to impact the fractured surfaces, and the distal ends are fastened together with fine wires wound about them to give additional tension (figs 6, 7 and 8). Moore does this under the closed method with local anesthesia, and the results I have seen have been brilliant. He applies no fixation whatever in the way of a splint and allows the patient to be up in a wheel chair the day following operation. He emphasizes the necessity of one pin at least progressing along the weight bearing line of the neck and shaft up into the head and points out that where direct weight bearing lines can

10 Thornton Lawton quoted by Smith Petersen.

be reestablished the healing is more rapid and complete. All these methods eliminate the long immobilization of Whitman and the consequent disability in the joints and the muscular weakness that follows.

Bozsán¹⁴ has advocated drilling without any fixation apparatus and believes that union is promoted by this means, the patient being fixed in Whitman's abduction spica after this procedure. He believes that internal fixation damages the living structure of the neck and head to the point of necrosis.

All the men who use internal fixation of whom I made inquiry have concluded that long immobilization is unnecessary and are impressed with the fact that the disability in the hip, knee and ankle that occurs with the Whitman method is overcome by the use of internal fixation. This, of course, is a great advantage, since the average age of the patient suffering from fracture of the neck of the femur tends to increase the disability in the joints caused by stiffness produced by prolonged immobilization. It is interesting to note that in every

Fig. 8—Lateral view showing pins in position.

case the men doing pioneer work in this field have stated that they believe anatomic reposition necessary and that where good results have not been obtained they have felt many times it was due to the fact that there was not anatomic reposition and firm retention. Even those who advocate the closed method as a routine procedure call attention to the fact that with patients in whom firm immobilization cannot be obtained because of adiposity or for other reasons they resort to internal fixation.

I¹⁵ have advocated during the past few years the open reduction of fresh fractures of the neck of the femur along the line of the operation which Brackett advised in ununited fractures of the femur assuming that there are no contraindications due to physical disability. In this operation the head is hollowed out in the form of a parabola, the trochanter is cut off obliquely from above downward and outward the end of the neck is fitted into the hollowed out head and the trochanter is reattached below its former location. The results in all cases in which this was done have been excellent. There

is of course always three-fourths inch shortening but in every case a perfect functioning hip has been obtained. In no case has there been atrophy of the neck or of the head. The patients are allowed to bear full weight at the end of eight weeks and most of them have walked without crutches and with perfect comfort in ten weeks or less. This method of course involves a major surgical procedure which however does not seem to be shocking. There have been no complications or deaths in fresh fractures. In forty cases of ununited fracture, many of the heads that showed necrosis before the operation were revascularized and are functioning normally, which would indicate that work and close contact of the fragment promotes union. This modification of the Brackett operation has been extremely successful and satisfactory and in selected cases I believe gives the most perfect results in the shortest time of any procedure with which I am familiar. It reestablishes the weight bearing line from the shaft of the femur directly up into the head, brings the shaft and head into close bony contact, allows normal weight bearing, and does not necessitate immobilization of the joints of the hip, knee or ankle.

CONCLUSIONS

While the number of cases is not great enough at this time to make any definite comparison possible certainly there is evidence enough to give one the strong impression that

1 X-ray evidence of reduction in fracture of the neck of the femur can often be very misleading if the roentgenogram is taken only at two angles, therefore roentgenograms at a number of angles should constitute a routine both before and after reduction.

2 If there is any considerable obliquity of the fracture line, visual reduction is preferable with fixation applied while the fracture is in view.

3 There should be a classification of fracture of the surgical neck as to the line and plane of the fracture. In addition to this, a classification of the fracture as to the amount of displacement occurring immediately after the injury in order to determine whether certain lines and planes of fracture interfere with the circulation more than certain other lines and planes of fracture. The amount of displacement would indicate the amount of tearing of the visceral capsule that might be present, thereby indicating whether this factor should be taken into consideration in making a prognosis.

4 The patient's physical condition, age and weight should be considered before any method of treatment is decided on, and, whatever method is used, anatomic reduction should obtain and the method applied that will maintain the fracture in this position while healing.

5 Of the closed methods, Whitman, Leadbetter, Whitman, and well leg traction certainly have their place in the field of treatment of fracture of the neck of the femur, but from present information mechanical fixation with three-flange nails, steel pins or bone grafts offer greater comfort to the patient, greater chance of bony union, easier nursing and less disability following union so far as the joints of the leg are concerned than any of the closed methods.

6 Regardless of what method is used for maintaining position, close bony contact, anatomic apposition and absolute fixation I believe are the three prime factors in securing better results in fractures of the neck of the femur.

ABSTRACT OF DISCUSSION

DR. FRANK D. DICKSON, Kansas City, Mo. What Dr. Magnuson was getting at was that the primary aim in the treatment of fracture of the neck of the femur is a reduction, and whether one uses a cast to hold this reduction or prefers to use some form of nailing or internal fixation device is largely a matter of choice. Which is the better has by no means as yet been determined. The important point is the reduction of the fracture. I was interested in what Dr. Magnuson had to say about too much abduction. I believe that the greatest fault in reduction of fractures of the neck of the femur is too much abduction. Internal rotation is the important maneuver with a moderate amount of abduction. It is true that in transverse fractures of the neck of the femur one must be very careful about the degree of internal rotation. In oblique fractures one can use more. The statistics on fractures of the neck of the femur are in an unsettled state. The figures that are given for fractures of the neck of the femur by the Whitman-Leadbetter method apply to all the cases as they come into the hospital. Most figures on nailing operations apply only to selected cases. There is no group of statistics comparable so far as the closed method of treatment or the internal fixation method of treatment is concerned.

DR. WILLIS C. CAMPBELL, Memphis, Tenn. I have been a strong exponent of the Whitman treatment for many years but I have become convinced, from my observation of the shorter period in which union is secured in some cases at least and of the results that have been obtained in decreasing the time of treatment, that some method of internal fixation is the method of choice at the present time. I do not believe that it makes very much difference whether one uses a nail or two or three pins. The aggregate amount of steel in the wound is approximately the same, it is just a question of choice. The mechanical principles are identical. The statement has been frequently made that the reason for nonunion is the failure to reduce but since it has been possible to prove reductions by two view roentgenograms, it has been found that reduction is accomplished in practically all cases. Dr. Magnuson has stated that exact position of the head cannot be determined by the side view roentgenograms. I cannot agree with him and believe that by two views reduction can be accurately determined. I have employed open operation with open nailing and blind nailing using the Johanson method but with the nails on the market today there is danger of the wire bending; it may even be broken off in the head as a foreign body. In one of my cases there was a curling up of the wire possibly from rotation of the head but fortunately it was possible to extract it. I have heard of one or two cases in which the wire was broken off. Rarely are extractors required for removal of the nail. As a rule there is so much bone atrophy around the nail that if the patient is turned on the side and shaken rather hard the nail will drop out. What effect this atrophic condition may have in the future I do not know but I have seen no ill effects so far. Years ago I made an analysis of twenty-five cases in which I used the impaction of Cotton (which has been previously described) and twenty-five cases in which I used the Whitman reduction without impaction. The results were identical. No harm was done by impaction but no good was accomplished. As to the question of arriving at some method of treatment for fracture of the neck of the femur which can be carried out by the general practitioner as suggested by Dr. Kellogg Speed, there will never be such a method until there is a change in the laws of physiology and nature. The last word has not been said and I think it will not be said for some time if ever.

DR. FRED C. FERCIOT, Lincoln, Neb. A woman aged 69 had a fracture of the neck of the right femur in 1932 which was treated by the Whitman abduction method with results of bony union. Last year she suffered a fracture of the neck of the left femur which was treated by fixation with a flange nail. At the end of nine months the patient walked with a fair gait and she is able to demonstrate a good degree of abduction. A woman aged 82, suffered a fracture of the neck of the left femur and began light weight bearing in less than two months and has been up and about for thirteen months with excellent functional stability and range of motion. I have felt that this method of treatment effects what may be termed

a fixed impaction of the femoral neck on the head thus favoring revascularization of the head and early union. In suitable cases I have found it highly satisfactory.

DR. J. ALBERT KEY, St. Louis. From what Dr. Magnuson said about comparing the neck of the femur with the lower end of the radius one can assume that he considers the neck of the femur cancellous bone. I think he is wrong. The neck of the femur is compact bone, with a very dense cortex on either side, and especially at the lower border. I don't think the angle of the fracture makes any difference, and I don't think anatomic reduction is to be aimed at or important. In fractures of a long bone one is not particularly concerned about anatomic reduction. In fact, it has been my feeling that I got union quicker and better and stronger if the ends of the fragments were a little off center but in good alignment. I feel that impaction is important if it can be held. I have used impaction by Cotton's method and got nonunion with Whitman plasters and this was because I couldn't fix the hip. I can apply a Whitman plaster just as tight as the patient can stand it, but in a couple of weeks I can run my fist down between the anterior superior spine and the plaster. The patients move around in the plaster, and they move around in double spicas. I think that I have put on my last Whitman plaster for a fresh fracture of the neck of the femur. The two-pin method is not the answer. If a man is capable of doing it the Smith-Petersen nail is the best treatment yet devised but it cannot be done consistently by the ordinary man. A man who isn't a good enough surgeon to put in a Smith-Petersen nail can put in two pins. I cannot put in a Smith-Petersen nail by blind nailing, but I run a drill in first to get my direction and then take a roentgenogram. I pull out the drill a three-sixteenths-inch drill, not a wire, use that as a guide to drive my nail, either in the same hole or directed upward or downward or backward or forward, as is indicated, and also as a measure for the length of the nail. That is the way I think more union will be obtained than by any other. But if one cannot do that the next best thing to do is to get the fracture not necessarily anatomically reduced but the head on top of the neck and drive this cortex of the neck into the head and hold it there.

DR. LAURENCE JONES, Kansas City, Mo. This paper has dealt with internal fixation as an approved method for the treatment of intracapsular fractures of the neck of the femur. Sufficient attention has not been devoted to the choice of metals used for producing this. Most of the appliances now in use are made of a plain chrome rustless steel. This is due to the influence of the instrument maker, who prefers it to other varieties, as it is easily machined. Investigation has shown that many steel alloys cause bone necrosis. A sample in vitro test is first to place any metal in Ringer's solution that is about to be used for fixation. For example, Vanadium steel of the standard Lane plate will corrode rapidly and at the end of thirty-six hours will leave a definite deposit at the bottom of the test tube. Similarly the plain chrome rustless steel will corrode not quite as rapidly but very definitely, and when placed in the bone of a dog will lose weight at a rate ranging up to 10 per cent in the first thirty days. For internal fixation the chrome-nickel alloys are the metals of choice. The optimum composition seems to range from 8 to 18 per cent either of chromium or of nickel. Bony trabeculae in contact with these alloys will remain intact, whereas those exposed to plain chrome rustless steel will show definite absorption. Therefore one must be careful not to use a metal that will delay if not completely inhibit bony union.

DR. PAUL B. MAGNUSON, Chicago. It seems to me that more discretion should be given to choosing the method for the patient not of promoting anybody's method because after all, the operator is trying to get a result. I think attention has not been paid to whether the fracture is oblique or transverse. A transverse fracture brought end to end can be impacted and held beautifully. The nearer the head the fracture is, and the more one can set the head up on top of the neck the better it will hold, because a weight-bearing line is transmitted directly up into the head. I have been advocating that in the use of the modified Brackett operation in fresh fractures because the transmission of the weight is directly up into the head but that cannot be done in all of them because the method is not suited to all of them.

THE INCIDENCE OF TRICHINOSIS IN SAN FRANCISCO

JAMES B. McNAUGHT, M.D.
AND
EUGENE V. ANDERSON, M.D.
SAN FRANCISCO

The incidence of trichinosis has been studied in only a few localities in the United States. The material examined was muscle obtained either at autopsy or from the dissecting room. The percentages of positive cases have varied from 3.5 in New Orleans¹ to 27.6 in Boston.² Since there are no data on the incidence of human infestation with this parasite on the West Coast, we have undertaken a study of material available in San Francisco.

In table 1 we have compiled the published reports on the incidence of human trichinosis in the United States listing the localities, the methods used, the number of cases examined and the percentage of positive results obtained at autopsy. Our statistics are added to the bottom of the table for comparison.

Man is an accidental host to *Trichinella spiralis* when he ingests infected meat. Pork is the usual offender, but bear meat has also been reported as a source of infection.³ Gastric juice digests the muscle and wall from about the encysted larvae, which pass into the intestine, where they mature, copulate, and bear their young. The embryos reach the voluntary muscles through the lymphatics and blood stream, encyst, and live there for many years. By finding them in bits of excised muscle,

Fig. 1.—Encysted larvae of *Trichinella spiralis* digested free from muscle (X 65).

one can verify the clinical diagnosis of trichinosis during life. Examination of biopsy material is not a practical method for establishing the incidence of infestation in a community.

The most satisfactory method of studying biopsy or autopsy material for *Trichinella spiralis* is by simulating nature's process of digesting the muscle with liberation of the larvae for identification. Other methods have been used by various investigators. Bits of muscle have been pressed thin between glass slides and examined microscopically for encysted parasites. This is simple and rapid and yields highly satisfactory results when the muscle is heavily infested. Stained sections are essential for observing histologic changes in trichinous tissues but unless the parasites are present in large

numbers they will be missed if only a few slides are studied. Serial sections are not practical for survey work. The diaphragm has been found to be the most satisfactory muscle for studying the postmortem incidence of infestation with *Trichinella spiralis*.

METHODS

Diaphragms removed at autopsy were finely ground in a meat chopper. Fifty grams of the minced muscle from each case was mixed with 500 cc. of artificial "gastric juice" in a beaker and stirred in an incubator at 37 C. until digested. The juice was a freshly prepared aqueous solution of 0.7 per cent hydrochloric acid and 1 per cent granular pepsin. Our digesting device is described in detail elsewhere.⁴ The contents of multiple beakers were simultaneously stirred by wooden "tongue blades" kept in motion by the reciprocating action of a windshield wiper. This prevented metal from coming in contact with the acid solution and the wooden blades were discarded after use. All instruments and containers were scrupulously cleaned after each procedure, to prevent contamination.

The meat was digested in from four to five hours but often the mixture stood in the incubator over night with no observable deleterious effects. The mixture was then poured, according to McCoy's⁵ procedure through a 20 mesh brass wire sieve into a large glass funnel, which was closed by a rubber tube and pinchcock. The larvae settled rapidly to the bottom and we removed them by opening the pinchcock and drawing off a few cubic centimeters of fluid into a petri dish for microscopic examination. If the sediment contained so much debris that the larvae were not readily seen, they were rapidly washed free in water and the resulting sediment was again examined. Actual counts were made of the number of larvae in each positive case.

When the material was available, 50 Gm. of heart muscle from the cases presenting trichinous diaphragms were digested and examined for larvae.

OBSERVATIONS AND COMMENTS

The diaphragms from 225 consecutive autopsies in five hospitals in San Francisco were examined according to the methods outlined. Twenty-five were from new-born infants and were all negative for *Trichinella spiralis* and are not included in our statistical study of 200 cases. This is in accord with Augustine's⁶ experimental and clinical observations that prenatal trichinosis does not occur.

Twenty-three trichinous diaphragms were found in the first hundred cases and twenty-five in the second hundred, giving an average of 24 per cent for the series. Owing to the similarity of figures in each hundred cases, we did not continue the survey. Our percentage of positive results is in fair agreement with the few recent reports in other localities, except for the 3.5 per cent for New Orleans (table 1). Human¹ examined approximately 10 Gm. of muscle from each case. He undoubtedly would have found a much higher percentage had he used the 50 Gm. quantities digested by Queen² and us.

In the course of digestion the muscle and fibrous tissues were removed leaving oval encysted larvae.

shown in figure 1 As digestion continued the closely coiled larvae were liberated from their capsules, as seen in figures 2 and 3 They moved fairly slowly, coiling and uncoiling Living larvae were found in all the positive cases

The number of larvae found in the 50 Gm of trichinous diaphragms was usually small, being less than 20 in 79 per cent of the cases, between 20 and 100 in 12.5 per cent and more than 100 in 8.5 per cent The largest number was 3,800

Fig 2—Living larvae of *Trichinella spiralis* digested free from their capsules (X 65)

None of the clinical records of our positive cases revealed a definite history of trichinosis One man, aged 76 had complained of abdominal discomfort, nausea and occasional attacks of diarrhea following the ingestion of meat, but pork was not specifically mentioned The eosinophil count was 1 per cent Twenty-nine living larvae were found in this specimen In many of the case histories “rheumatic” or “muscular” or “joint” pains, “gastro-intestinal upsets” and the like were recorded, but these were as plentiful in the negative as in the positive cases However, considering the high incidence of positive results that were obtained, it is probable that some of the vague muscle aches and abdominal upsets which pass undiagnosed are actually light infestations of *Trichinella*

TABLE 1—The Incidence of Trichinosis at Autopsy in Various Localities of the United States

Year	Locality	Methods	Number of Cases	Per Cent Positive
1897	Buffalo (Thornbury University Medical Magazine Buffalo 1897)	Microscopic sections	21	14.3
1901	Buffalo (Williams H U The Frequency of Trichinosis in the United States J M Research 6 64-83 1901)	Pressed muscle	500	5.3
1931	Rochester N Y *	Digestion	344	17.5
1931	Boston *	Digestion	53	27.6
1934	Minneapolis (Riley W A and Schellley C H Trichinosis of Man a Common Infection J A M A 102:1917 [April 14] 1934)	Pressed muscle	117	17.1
1936	New Orleans *	Digestion	200	8.5
1936	San Francisco	Digestion	200	24.0

The ages of the 200 patients ranged from 2 to 87 years Table 2 shows the distribution in broad age groups The ages of subjects yielding positive results varied from 25 to 84 years

Although the series is not large, it is interesting to note that, in a comparison made between the number of cases in which examinations were made and the number of *Trichinella* infested diaphragms that were

found in each age group, there is an increasing incidence of positive cases Up to 25 years of age no subject yielding positive results was found, from 25 to 40 years of age 14.8 per cent gave positive results, from 40 to 75 years 26.6 per cent, and above 75 years 29.1 per cent This would bear out the logical assumption that the older an individual the greater the opportunity for trichinous infestation

Seventy per cent of the 200 diaphragms examined were from males and 30 per cent from females There was no variation in incidence of trichinosis according to sex

TABLE 2—The Incidence of Trichinosis by Age Groups in 200 Autopsies in San Francisco

Age Groups in Years	Cases Examined		Positive Cases		
	Number	Per Cent	Number	Per Cent of Total Positives	Per Cent of Total Cases
2-25	10	5.0	0	0.0	0.0
25-40	27	13.5	4	8.4	14.8
40-75	139	69.5	37	77.1	26.6
75-87	24	12.0	7	14.5	29.1
Totals	200	100.0	48	100.0	24.0

Differential leukocyte studies on stained blood smears were available in 58 per cent of the positive cases, with 4 per cent as the highest eosinophil count No eosinophils were seen in the differential count recorded for the case yielding 3,800 larvae Although the eosinophil count is the simplest and probably the most

Fig 3—Living larvae as seen in the sediment of well digested muscle (slightly reduced from a photomicrograph with a magnification of 25 diameters)

reliable clinical aid in the early diagnosis of trichinosis, Theiler, Augustine and Spink⁷ report counts of only 2 to 7 per cent in known cases from four to nine years after recovery The normal eosinophil counts in our positive cases may thus indicate long standing or possibly light infestations

7 Theiler, Hans, Augustine D L, and Spink, W W On the Persistence of Eosinophilia and on Immune Reactions in Human Trichinosis Several Years After Recovery Parasitology 27 345 (July) 1935

The heart muscle from fifteen cases with trichinous diaphragms was digested and examined for larvae, but none were found.

Stained sections of muscle fixed in formaldehyde from three trichinous diaphragms were examined microscopically by serial sections. The pieces of muscle averaged 1.5 by 1 by 0.4 cm. The entire block of tissue was cut into ribbons 15 microns thick. Each tenth section was stained. Since the breadth of an encysted larva is about 250 microns, the staining of each tenth section should have revealed portions of each larva present. Microscopic examination of all stained slides from the diaphragm, which contained 3,800 larvae by the digestion method, revealed only three capsules. Slides from a diaphragm containing 350 larvae by the digestion method also showed three while those from a muscle yielding sixty larvae by digestion were free of capsules. The inadequacy of the slide method is more strikingly shown when only one slide is examined. In a series of 500 autopsies one slide was prepared from each diaphragm and in only one instance was an encysted larva seen.

It is worth noting that whereas we found 24 per cent of 200 diaphragms positive by the digestion method, McCoy, Miller and Friedlander⁸ found only 6.4 per cent of forty-seven patients tested in San Francisco positive to the intradermal test for trichinosis. Possibly a larger series of examinations would show closer agreement. We expect to study this correlation. Vital statistics of the Department of Health of San Francisco for the years 1931 to 1935 show a reported incidence of trichinosis ranging from 0.0016 to 0.0044 per cent of the total population for each year. This striking discrepancy between the number of cases reported and the number of positive cases found at autopsy demonstrates that the milder forms and sporadic cases of the disease usually pass unrecognized.

It is impossible to detect infected pork by practical methods of meat inspection. Two out of ten specimens of fresh pork sausage purchased in first class markets in a heavily patronized shopping district in San Francisco contained living *Trichinella*. Therefore, under the present methods of meat inspection it is necessary for the consumer to assume the responsibility of preventing trichinosis by either avoiding or thoroughly cooking all fresh pork.

SUMMARY

1 Digestion of 200 human diaphragms obtained at autopsy in San Francisco from individuals ranging from 2 to 87 years of age revealed forty-eight (24 per cent) infected with *Trichinella spiralis*.

2 Examination of diaphragms from twenty-five new-born infants gave negative results.

3 Living larvae were found in all the positive cases.

4 The number of larvae was usually small, being less than twenty to each 50 Gm of muscle in 79 per cent of the cases.

5 None of the clinical records of the positive cases revealed a definite history of trichinosis.

6 The highest eosinophil count recorded was 4 per cent.

7 The heart muscle from fifteen patients with trichinous diaphragms was negative.

8 Microscopic examination of stained slides for *Trichinella* is inadequate.

9 Since there are no practical methods of inspection for trichinous meat, the consumer must assume the responsibility of preventing trichinosis by thorough cooking all fresh pork.

IMPERFORATE ANUS, BOWEL OPENING INTO URETHRA HYPOSPADIAS

A PRESENTATION OF NEW PLASTIC METHODS

HUGH H. YOUNG, M.D.
BALTIMORE

The case I am reporting here possesses extraordinary abnormalities of the intestinal and genito-urinary tract.

REPORT OF CASE

F. O. B. Jr., a youth aged 17, admitted May 24, 1933, had a hypospadias and also an imperforate anus at birth. Both the urine and the feces passed through the urethral meatus in the

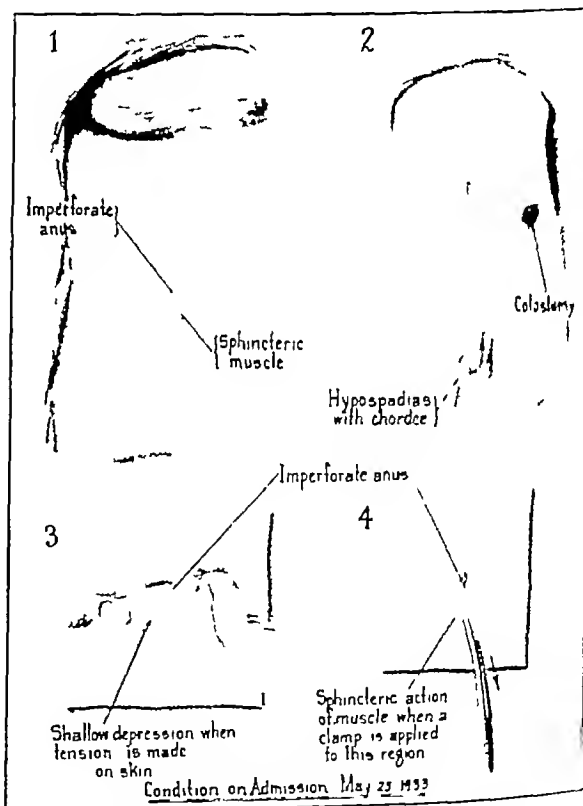

Fig. 1—Condition on admission: imperforate anus; sphincter retracted beneath skin; colostomy.

perineum. By means of laxatives the patient had little difficulty in evacuating the bowel through the urethra until he was 18 months of age when Dr. Arthur D. Bevan performed a temporary colostomy. A hernia developed and when the patient was 10 years old Dr. Bevan decided to make the colostomy permanent. About two years before the present admission an operation for hypospadias was carried out elsewhere but with no success.

From the James Buchanan Brady Urological Institute, Johns Hopkins Hospital.

Read before the Section on Surgery, General and Abdominal, at the Fifty-Seventh Annual Session of the American Medical Association, Kansas City, Mo., May 13, 1935.

⁸ McCoy, O. R., Miller, J. J., and Friedlander, R. D. The Use of an Intradermal Test in the Diagnosis of Trichinosis. *J. Immunol.* 24: 121 (Jan.) 1933.

On admission the patient voided at normal intervals through the urethral meatus in the perineum, fecal contents were evacuated every two days by means of an enema through the colostomy. His general health had always been splendid.

Fig 2—Sagittal section showing conditions present. Rectum opens into urinary tract below prostate. Urogenital sinus opens into scrotum.

Fig 3—Operative procedures employed to sever connection between bowel and urethra.

The penis was normal in size. There was present a hypospadias, the opening of the urethra being within the scrotum 7 cm from the summit of the glans. The testes, epididymides, vasa, and cords were apparently normal. The anal opening was absent. In the proper position for it was a slight dimple of

the skin and around this was a definite ring (fig 1). Touching this ring with a pin produced contraction which indicated that the anal sphincter was capable of functioning but with no bowel within it (imperforate anus).

An intravenous urogram showed no connection between the bladder and the rectum. A catheter was passed through the urinary meatus and 10 per cent sodium iodide was injected. A stereoscopic roentgenogram demonstrated that the fluid had passed into the rectum.

At cystoscopy an opening was found in the urethra 2.5 cm from the vesical orifice through which the cystoscope passed and revealed a fairly large rectum (fig 2).

A series of operations was planned: (1) to straighten the penis and complete the urethra to the glans; (2) to separate the rectum from the urinary tract and bring it out through the anal sphincter after forming a new anus; and (3) to close the colostomy and anastomose the previously separated ends of the intestine. These procedures were carried out serially.

Fig 4—Operation to bring rectum out through sphincter in normal position (continued). After the rectum was isolated a crucial incision was made in the dimple of the skin (5). Into this a clamp was inserted through the center of the sphincter which was easily visible. After marked dilation a circular area of skin was excised (6) and the bowel drawn out through the sphincter and new anal orifice (7).

A suprapubic cystostomy for drainage was performed June 2, 1933 (Young-Frontz). An operation was then carried out to cure the congenital chordee.

Convalescence was entirely satisfactory.

The second operation was performed June 16 (H H Y) including a perineal incision (fig 3) in front of the anal dimple, division of the central tendon, exposure of the lower blind end of the bowel, and isolation of the connection between the bowel and the urethra which seemed to be in the region of the triangular ligament (fig 3). In the dissection a tear was accidentally made into the rectum (fig 4). No sphincteric muscle was found around the attachment between the bowel and the urinary tract. Clamps were placed around the recto-urethral connection which was then divided and the urethra was closed with catgut.

Attention was next directed to the anus. Crucial incisions were made in the dimple (5, fig 4) and a Halsted clamp was inserted through the center of the subcutaneous muscular ring (sphincter) which was then dilated. A ring of skin 2 cm in

diameter was excised around the opening and the aperture dilated again with larger clamps by means of which the bowel was grasped and drawn down through the newly made anus. The rectal wall was redundant and was brought down through the sphincter and skin without tension (7, fig. 4). Four cardinal sutures of heavy chromic catgut which held the rectal muscle to the subcutaneous tissues were placed. The approximation of the bowel to the skin was then carried out (6, fig. 5), the redundant wall being excised.

There was no perineal leakage of urine. The anastomosis between the bowel and the skin healed by first intention.

The patient returned Jan. 24, 1934 (fourth admission). The penis was almost straight on erection. Suprapubic drainage and the colostomy cup had been entirely satisfactory. Large female urethral dilators were passed into the anus, and the index finger was introduced.

February 10 the Thiersch plastic operation (H. H. Y.) was performed to make a new urethra (fig. 6).

The patient was readmitted June 19 (fifth admission). He was able to hold 200 cc. of water in the rectum and evacuate it at will. The rectum and anal sphincter were apparently capable of functioning normally, and it seemed time to close the colostomy.

Dr. William F. Rienhoff, Jr. carried out this procedure June 29. The scar tissue around the colostomy opening was first excised. The bowel was freed from its surrounding structures. After a clamp had been applied to the proximal portion this part of the rectum was resected and the end turned in. This was reinforced by mattress sutures of silk. A lateral

One year later the patient returned for a check up. Defecation was normal and the anal sphincter functioned perfectly.

Space does not permit a discussion of the development of the rectum, the cloaca and the urogenital sinus or the abnormalities that produce atresia ani and urethral anomalies. It has also been necessary to omit references to the literature, but I believe that the operative technique

Fig. 6—Plastic operation to cure hypospadias (technic of Thiersch modified). A, triple mattress suture of fine silk to form urethra. B, same tied over a fine silver wire, placing of vertical mattress sutures over silver wire to approximate skin. Complete closure shown in central figure.

Fig. 5—Operation to construct anus (continued). Sutures of chromic catgut were placed through the bowel beneath the skin to hold the rectum in place (4), after which the skin and the mucosa were approximated by interrupted sutures of silk (6) and the redundant bowel progressively cut away.

anastomosis was then performed between the proximal and distal portions of the colon. The abdominal incision was closed without drainage.

Liquid bowel movements commenced the third day after operation. For a few days the patient had slight incontinence, but after a week he was able to defecate when the desire came on and he had perfect control. He recognized when he should have a bowel movement and defecation was quite normal. All urine was voided through the meatus at normal intervals. The conditions present are shown in figure 7.

described herewith has never been carried out in a similar case. Dr. Wyland Leadbetter has also made a careful study and reports that there are only eight cases of imperforate anus connecting with the urethra in which the operator divided and attempted to close the urethral opening and of these only one was successful. Among the cases in which operation was performed Dr. Leadbetter was unable to discover any in which the rectum was brought out through the dilated and otherwise uninjured anal sphincter. All operations were apparently performed through a median perineal incision, and no operator used the curved perineal incision, with exposure of the space, as in perineal proctotomy. There does not seem to be a single instance in which the recto-urethral orifice was seen with the cystoscope and therefore no reported case in which a cystoscope was passed into the rectum and the rectum studied cystoscopically, as in the case here reported.

CONCLUSIONS

In a remarkable case of imperforate anus the boy connected with the deep urethra or urogenital sinus through which liquid feces escaped for eighteen months. The patient had worn a colostomy cup for fifteen years. The anal sphincter, although inactive for seventeen years, was visible in normal position beneath the skin. By means of plastic operations it was possible to cure the congenital chordae and hypospadias and make a good urethra transplant the rectum, bring it out

through the sphincter in a newly made anal orifice, close the colostomy, anastomose the ends of the bowel and thus obtain normal defecation and urination. The fact that the rectum and anal sphincter, after years of disuse, soon began to function normally is indeed remarkable. As far as I am aware, the operative procedures and result in this case are unique.

ABSTRACT OF DISCUSSION

DR. JOHN R. CAULK, St. Louis. I can only compliment Dr. Young for his excellent results in these troublesome cases. It testifies to the efficacy of plastic surgery in the hands of a master. Reconstructive surgery must have a brilliant future. It has had such a deplorable past. It is easy for average surgeons to do some shunting operation, such as colostomy, urethrotomy or uretero-intestinal anastomosis, but they have accomplished little except the creation of a chronic invalid. While the search for the anal sphincter and the restoration of bowel continuity may appear on the face of it the most difficult part of the operation, the repair of the urethra is indeed the most uncertain in the hands of the average surgeon and, I imagine, the most tedious even in the hands of a man who knows plastic

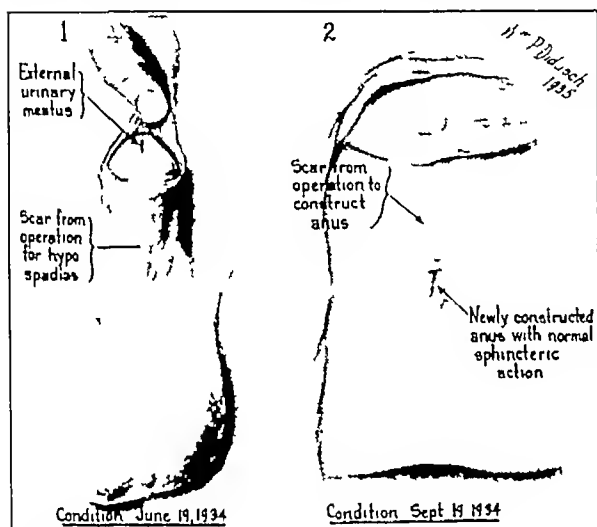

Fig. 7.—Ultimate result. Hypospadias cured, normally functioning bowel with continent anal sphincter.

procedures. In many of the extensive defects such as perineal or deep penoscrotal hypospadias or epispadias surgeons resort too quickly to urethero-intestinal anastomosis. This to my way of thinking offers little so far as the patient's future is concerned because the two important anatomic structures so vital to renal integrity are destroyed. These are (1) the non-compressing smooth bed in which the ureter lies in the bladder wall, and (2) the ureterovesical valve. The insertion of the ureter through the bowel musculature frequently results in compression of the outlet with resulting hydro-ureter, hydronephrosis and renal death. Destruction of the ureterovesical valve, nature's safeguard against ascending infection, makes renal infection imminent. It is therefore gratifying to see Dr. Young present a series of remarkable plastic operations and the results accomplished, particularly the one demonstrating an end result with restoration of nearly normal anatomic relation and normal physiologic function.

Allergy and Psychic Factors—There seems to be a growing realization however of the fact that in the so-called allergic diseases we are dealing not with disease entities in which allergens are the cause but with a mechanism in the development and maintenance of which psychic factors play a more or less dominant role.—Dunbar H. F. *Emotions and Bodily Changes*. New York: Columbia University Press, 1935.

A REVIEW OF THE GASTRIC ULCER PROBLEM

SARA M. JORDAN, M.D.
BOSTON

Interest in the problem of gastric ulcer is constantly stimulated by the following questions, which arise frequently in the diagnosis and treatment of the gastric lesion:

1. Is the visualized lesion actually organic?
2. Is it benign or malignant?
3. Is it healable by medical treatment, or would surgical treatment give more adequate insurance against its recurrence, or against malignant degeneration?
4. Is it as necessary to guard against recurrence of the gastric ulcer as if it were distal to the pyloric sphincter?

Some of these phases of the gastric ulcer problem have been discussed so frequently that to review them seems superfluous, but even the most frequently discussed points are sometimes profitably reviewed by the light of additional material and in conjunction with other phases of the problem. In this study 119 cases have been used in which the diagnosis of gastric ulcer has been made on a reasonable basis and checked either by surgical exploration, as in thirty-one cases, or by follow-up studies varying from a few months to eleven and one-half years after medical treatment. The sex incidence of this group was sixty-two men and fifty-seven women, which demonstrates the familiar high ratio of women in the incidence of gastric ulcer as compared with that in duodenal ulcer.

The first question, which not infrequently arises, is the actuality of the visualized lesion, this being entirely a question of interpretation of an x-ray defect. The confusing conditions that give rise to this question are spasm, adhesions, cicatrization of an old lesion and visualization of a loop of small intestine which distorts the contour of the stomach. The form of spasm that most frequently confounds the diagnosis is the prepyloric constriction, which simulates an annular carcinoma or an ulcer of the posterior wall. This type of constriction may occur independently of any organic lesion, or it may be associated with cholecystitis, appendicitis, duodenal ulcer, an ulcer of the middle of the stomach proximal to the spastic area, or a gastro-enterostomy stoma. It may be persistent in spite of all drugs ordinarily useful in relieving spasm and disappear only through one of two procedures: (1) treatment of the underlying disease when this is not ulcer, (2) long continued general and local relaxation attained by ulcer therapy. In not a few of these cases, when the prepyloric spasm has finally been relieved, the real lesion is found in the duodenal cap, and the stomach itself is found to be entirely normal. In others of these cases it must always remain doubtful whether an ulcer has actually been present anywhere in the gastroduodenal field or whether the spasm alone has produced symptoms, which, with the spasm, have been relieved by treatment. Most surgeons have had the experience of operating on patients suspected of having a prepyloric lesion on whom examinations are negative. On the other hand, study has shown that the persistent rigid spasm of the prepyloric area of the stomach is usually the result of a posterior wall lesion in that area. In the untreated stage an irregu-

larity in the contour, or a definitely visualized crater, often missed in the routine fluoroscopic examination, is likewise present, which localizes the actual lesion. With treatment, the irregularity or the crater and the rigidity of the spasm disappear if the lesion is benign, and a flexible type of spasm is seen which indicates the healing of the lesion. If adhesions occur with the healing, the appearance of spasm persists and the end result is visualized as an elongated type of pylorus. If there are no adhesions, there is a complete return

Fig. 1—Sex and age incidence in 119 cases of gastric ulcer. Male sixty two female fifty seven.

to normal in the appearance of the pyloric end of the stomach. Visualization of the mucosal relief and the detection of craters by palpation, together with gastroscopy, are important aids in the differential diagnosis of prepyloric spasm and organic lesion,

but even with these diagnostic aids there will undoubtedly always be a small group of cases that will require trial medical management and careful check up observations or exploratory surgery with actual visualization for positive differential diagnosis. Adhesions formed by cicatrization of the healing ulcer, or occasionally from the scar of an operated lesion, may so deform the stomach that with recurrent symptoms and visualized deformity of the prepyloric area, or especially of the middle part, it may be very difficult to determine whether a recurrent or new ulcer or a malignant lesion has developed, or whether the deformity represents only the old adhesion. The familiar hour glass deformity, found in twenty-four cases of our series, may be due to adhesive bands that firmly or gently constrict the middle part of the stomach or to adhesions of the cicatrix of the posterior wall ulcer to the adjacent pancreas. Both these explanations have been found by surgical exploration in certain cases of this group studied. In such cases the recrudescence of an ulcer or a new benign or malignant lesion is often exceedingly difficult to demonstrate by its actual crater because of the obscuring deformity produced by adhesions. Exploration during operations for other diseases such as removal of the gallbladder have demonstrated that what appeared to be a rather narrow isthmus in the hour glass deformity was actually a very slight narrowing of the lumen of the stomach by omental adhesions. In two of our cases, the healing of a posterior wall ulcer appears to tie by adhesions the prepyloric area of the pars media in such a way that without the data for tracing the chronological steps in the formation of the defect it would be difficult to diagnose the deformity. Another type of defect of contour is that produced by the silhouette of a loop of jejunum or third part of duodenum against the lesser curvature of the stomach. This may give the appearance of an irregular area suggesting carcinoma or of a smooth crater suggesting ulcer. In a case recently seen by me there is a diverticulum of the third part of the duodenum which when filled simulates an ulcer defect off the lesser curvature and cannot be displaced from this location. Such are the difficulties that may present themselves in the differentiation between a real and a phantom lesion and for the solu-

tion of these difficulties all possible diagnostic measures are often needed. Exploratory laparotomy must sometimes be the final procedure, but most cases can be diagnosed accurately if adequate use is made of repeated fluoroscopic examinations with spot film and of trial observations and treatment, checked by repeated radiologic examinations. In these cases, gastroscopy will undoubtedly be a most valuable aid.

The second of the questions involved in the problem of gastric ulcer—Is the lesion benign or malignant—concerns the gastric lesion which by x-ray examination is not an obvious carcinoma. In other words all gastric lesions should be definitely classified as malignant or potentially malignant, or as benign ulcers which are healing and are later healed. Ideal gastroenterology should include as part of its program the follow up of every gastric lesion, so that unhealed lesions may be detected. This statement implies that if a lesion heals it can be regarded as innocuous, which is, in my opinion, a fact, but certain conditional stipulations must also be stated. The first is that actual and complete healing must occur, and the second, that the stomach in which an ulcer has been found should be checked by its possessor and its medical guardian with especial care, so that recrudescences of the same lesion or new lesions can be found and followed.

In deciding whether the questionable lesion is benign or malignant, certain factors in the diagnostic data may be considered. The helpfulness of the history is our first consideration. The value of a history depends of course, on two important factors—the accuracy of observation, memory and reporting of the patient and

the development of the investigative sense of the questioner. A patient may be recorded to have lost weight when the true cause imposed restriction of diet is not recorded, or he may be said to have no appetite when he either fears the consequence of indulging his appetite or has an appetite only for foods that are not allowed him. He may be said to have vomited blood when only the traumatic fresh blood from the act of vomiting is found in the vomitus. Such may be the patent errors. The more subtle forms of mistakes

result from the inability of many individuals to recall details of their own ills even in a temporary remission of those ills. In general, however, certain facts in the history can at least be regarded with interest when a decision between malignancy or benignity must be made in the case of a gastric lesion. The history of short duration or of symptoms not compatible with ulcer symptoms is in favor of a malignant condition. A recent change in the character of symptoms has long been considered to be suggestive of a malignant con-

Fig. 3—Prepyloric ulcer and posterior wall ulcer showing changes with healing.

dition, and study of a larger group of malignant lesions confirmed this opinion. However, twenty-two cases in our series of gastric ulcer presented a history of less than a year, while twenty-three cases showed a recent definite change in the symptoms, chiefly, however, an increase in their severity. Nausea and vomiting are found in our cases of gastric ulcer more frequently than in duodenal ulcer, in this series of gastric ulcer cases in fifty instances. This is not due to an obstructive condition of the pylorus, for, in the cases studied, barium is abnormally retained in only twelve cases. It is apparently due to irritation, which causes pylorospasm with the intake of food. Probably for the same reason food relief of the distress is less common in gastric ulcer than in duodenal ulcer, twenty-nine patients of the series giving a history of no food relief. These two data in the history, presence of nausea or vomiting to a degree greater than in duodenal ulcer and the frequent absence of food relief are however not useful in differentiating the ulcer from the malignant lesion. They rather add to the difficulties of differentiation, since carcinoma of the stomach is often attended by these symptoms. The history of loss of appetite and loss of weight is likewise not particularly helpful anorexia, the classic symptom of malignancy, having been found in twenty-six of the gastric ulcer cases and severe loss of weight in fourteen cases. As far as the history is concerned therefore, the observations in this group of cases studied may be summarized to indicate that certain data are found which may be considered as differentiating between the duodenal and the gastric lesion but, because they occur in both the benign and the malignant gastric lesion are of no value in deciding the question of benignity or malignancy. These data are (1) the length of the history and recent change in symptoms (2) the absence of food relief and (3) the frequency of vomiting and loss of appetite and weight without obstruction.

The chemistry of the gastric contents, particularly the presence or absence of hydrochloric acid after a test meal is always of interest. In general it may be said that the gastric ulcer case usually presents free hydrochloric acid and the carcinoma usually shows

none. Exceptions are found in both groups, but acid in the carcinoma case is more frequently found than no acid in the ulcer case. Only three cases in this series showed achlorhydria, and this occurred only temporarily during the treatment. Stool examination for occult blood is definitely helpful in differentiating ulcer from carcinoma, if observations can be made with sufficient care and over a sufficiently long period. It is, of course, of no value if a quick decision must be made, for an ulcer case usually shows occult blood until it is almost healed, and an occasional negative stool is found in a carcinoma case. Furthermore, some time is usually required to obtain conditions under which stools can be accurately tested for occult blood, the casual examination being rarely of any value.

After the data of history and chemical changes have been analyzed and their adjuvant value estimated, the X-ray examinations assume the decisive role in differentiation. The important X-ray criteria are of two kinds (1) the original appearance of the lesion by X-rays and (2) changes in the original appearance of the lesion with trial treatment. It is undoubtedly true that the lesion of the pars media which appears in the original X-ray examination as the protruding crater off the lesser curvature in the pars media and without involvement of the posterior wall is practically always benign and shows a tendency to relatively quick healing, with synchronous diminution in the size of the crater. In the series studied, fifty-nine ulcers were of this type and the average time of proved healing was from three to four weeks. Fourteen of these cases were treated surgically. Proved healing is, in my opinion, demonstrated by the complete disappearance of the crater. It is believed that complete healing occurs when there is complete disappearance of the crater (1) because the clinical condition of the patient invariably conforms to the X-ray appearance of the lesion and (2) because surgical exploration during operations for intercurrent diseases has demonstrated the almost completely healed

Fig. 4—Three lesser curvatures showing changes in shape of crater in healing.

lesion and the completely healed lesion at stages correspondingly visualized by X-rays. The almost completely healed lesion, frequently termed a "dimple" by the roentgenologist was still palpable as a thickened area without a crater and with adjacent discretely palpable lymph nodes later microscopically diagnosed as chronic inflammatory while the completely healed lesion was seen and felt as the usual scar of an ulcer.

It is equally true that the less common prepyloric lesion is sometimes malignant and that the lesion of

the posterior wall, whether in the median or in the prepyloric area, shows much less tendency to heal and, perhaps because it heals less readily, a very definite tendency to become malignant. Twenty-one cases were prepyloric. Their healing time was usually longer, and eleven of these were treated surgically. It is possible, even probable, that the chronicity of the ulcer of the posterior wall depends on its proximity and adhesions to adjacent structures, notably the pancreas. In one case (fig 2) the ulcer was seen and palpated by the surgeon during a gallbladder operation and found to be an indurated lesion on the lesser curvature, without adhesions. In the following two and one-half years it gradually disappeared at first and recurred later in the same place and, when resected, was found to be larger and again indurated and now adherent to the pancreas. It is my opinion that certain of these ulcers of the posterior wall become a small group in the large category of gastric carcinomas. Two of the three cases of this series in which later carcinoma developed were ulcers of the posterior wall of the prepyloric area in which complete healing was never demonstrated because the patients could not be followed. Autopsy in one of these cases showed two lesions—a carcinoma of the posterior

Fig. 5—Two large lesions of the lesser curvature showing two types of healing

wall of the stomach and a malignant ulcer of the posterior wall of the stomach in the location of the previously demonstrated ulcer. The other ulcer case, which later developed into a carcinoma, was that of a woman, aged 55, who in 1929 had an ulcer of the posterior wall of the pars media of the stomach which healed and five years later recurred. A year following the recurrence and almost seven years after the original treatment, she was found to have extensive carcinoma of the pars media of the stomach. The involvement of the posterior wall is indicated radiologically by an extension of the lesser curvature crater down on the posterior surface, or a filling of a definite crater on the posterior wall, which is visualized with the patient lying in the supine position but is not visualized when the patient is standing or is in the prone position. There usually is also an incisura of the greater curvature or a constriction in the pars media of the hour glass type. A crater in the lesser curvature may or may not be visualized.

With all the diagnostic data (history, chemistry and x-ray examinations) at hand one is still not infrequently doubtful as to the benignity of the lesion. Two methods of safeguarding the patient against neglect of a present malignant condition or against future malignant degeneration of an ulcer are (1) a limited period

of trial management to determine the immediate reaction to treatment and (2) a careful follow up of all cases of gastric ulcer to detect recurrences and malignant degeneration. The length of time required to fulfil the three criteria of healing—the disappearance of symptoms, of occult blood in the stools and of the x-ray defect—varies, especially as far as the x-ray defect is concerned. Symptoms are usually relieved as soon as bed rest and treatment have been well started. Occult blood in the stools has usually completely disappeared within two to three weeks after the beginning of treatment. The x-ray defect shows a definite change within a few days, but its complete disappearance may require from three to eight weeks, and sometimes, in the case of the posterior wall lesion, even longer. In that time the crater on the lesser curvature should shrink in size which it usually does, first by a contraction of the base and then by a diminution in the depth of the crater until finally there is no interruption in the course of the peristaltic wave through the previously involved area. The rigid prepyloric spasm and crater should change to flexible spasm and no crater, and finally to a normal or an elongated pylorus. The crater of the posterior wall and the attendant rigid constriction of the pars media should disappear. These changes represent the healed ulcer (figs 3, 4 and 5). Thus the limited period of trial management has in such case proved both diagnostic and therapeutic. Thus, however is only the first step in the provision of insurance against a malignant condition.

The third question to be discussed in this review of cases is: Is the gastric ulcer healable by medical treatment and forgettable after healing, or would surgical treatment give more adequate insurance against its recurrence or against malignant degeneration? In the discussion of differentiation between malignant and benign lesions, it has already been stated that both anatomic and clinical evidence of healing has already been adequately coordinated with x-ray evidence to prove that complete healing of gastric lesions may occur. Such evidence was presented by eighty-eight cases in this series. In thirty-one cases operation was done (1) because the lesion was suspected of malignancy, which, however, was not found by microscopic examination or (2) because recurrence of the lesion was considered undesirable from the point of view of a future malignant condition. These are the usual indications for surgery in gastric ulcers as contrasted with those in duodenal ulcer, in which repeated hemorrhage and perforation occur much more frequently. The other surgical indication, uncontrollable distress, is rarely found in the gastric ulcer unless it is a posterior wall lesion with penetration into the pancreas. Recurrences, however, are evidences of chronicity, and chronic irritation in a field as prone to malignant conditions as the stomach should be regarded as highly undesirable. Especially is this the case in the lesion of the prepyloric area or of the posterior wall of the middle part of the stomach, where it may be assumed from this study that the dangers of malignancy are greater than along the magenstrasse itself. There is evidence in the histories of cases in this series to show that fully developed recurrences may be suddenly precipitated by factors such as colds, fatigue, indiscretions of diet, smoking and alcohol which respond just as quickly to medical treatment as did the original lesion and if these incidents involve the ulcer of the lesser curvature of the pars media it is my opinion that they are innocuous. Recurrent lesions of the prepyloric area

or of the posterior wall should, in my opinion, be regarded as potentially malefic

That surgical treatment gives greater security against future malignancy has always been assumed. This series contains three cases in which gastric ulcers have occurred in the lesser curvature of the stomach following gastro-enterostomy and two in which excision of gastric ulcers and plastic repair have been followed by the development of new ulcers. Adequate follow up evidence of radical resection will not be available until at least five to ten more years has passed, but so far it appears to accomplish the purpose of averting malignant degeneration by the excision of most of the ulcer bearing part of the stomach. Whether the mortality from a potential malignant growth is greater than the operative mortality of resection will be determined by the difficulties of the particular operation, the condition of the patient and the skill of the surgeon.

The final question here propounded, as to the necessity for prophylaxis against recurrent gastric ulcer as compared with that necessary in the case of duodenal ulcer, has been of interest to me, as I formerly believed that greater reliance could be placed on the healing of a gastric lesion than on that of a duodenal lesion, and greater freedom from restrictions could be enjoyed after treatment. Further experience has demonstrated the fact that those patients who have had a gastric ulcer and continue to live a so-called ulcer life after treatment are less prone to recurrences than those who con-

sider themselves ulcer proof and live accordingly. In only one respect has a difference been noted: the gastric ulcer case requires less neutralizing medication, probably because the hydrochloric acid is rarely above normal value, even with ulcer activity. To be secure, however, these patients must practice care in their diet, abstention from smoking and alcohol and, above all, avoidance of extreme fatigue and worry. In other words the shunning of certain temptations of the flesh and all vexations of the spirit is as important a guiding principle in gastric as in duodenal ulcer.

ABSTRACT OF DISCUSSION

DR. RUSSELL S. BOLES, Philadelphia. The differentiation between a disturbance of function and an organic lesion was admirably discussed by Dr. Jordan. I am convinced that the time has come to call a halt on functional diagnoses. It is well to remember that "pylorospasm," irritable duodenum and so on not infrequently indicate early organic disease. In determining whether a gastric ulcer is benign or malignant greater accuracy in diagnosis is obtained when such laboratory data as the acidity and the x-ray appearances are subjugated to general clinical considerations. After all, in most cases a good color, a good appetite and a maintenance of weight and strength would indicate a benign lesion, the contrary especially in older individuals, portends a malignant process. I subscribe to all that Dr. Jordan has said regarding the character and behavior of the lesions she noted but I know she will pardon a suggestion for a broader consideration of peptic ulcer. Preoccupation with a lesion may readily divert us from the disease itself of which the ulcer perhaps is but a local manifestation. The more I observe peptic ulcer disease the more I am impressed with the possibility of its being a form of peripheral vascular disease. The sequence of events in peripheral vascular disease is spasm, thrombosis, necrosis and finally ulceration. The predominance of certain types of peripheral vascular disease in the male sex, in the middle years or later, the influence of seasonal and barometric changes and the unquestioned effect of tobacco all, in a similar type of individual, bear strong testimony to the similarity of these

diseases. While x-ray appearances and acidity have a certain value in the diagnosis and differentiation of gastric lesions an exploration into newer fields is in order. Pharmacologic, pathologic and physiologic research of the peripheral circulation of the stomach might hold much of promise.

DR. SIDNEY A. PORTIS, Chicago. A gastro-enterologist is frequently concerned with the malignancy or benignancy of antral lesions or with the question of whether the roentgenologic evidence is a reflex manifestation from some extragastric lesion. Four factors are concerned in antral lesions: a high lying or midgastric lesion, causing a spasm of the antrum; an intrinsic lesion of the antrum; pressure from extragastric tumors more regular in outline or associated with perigastric adhesions; reflex spasm from the gallbladder, duodenal, especially posterior penetrating ulcers, and other extragastric lesions. Atropine and belladonna derivatives occasionally relieve this spasm but sometimes the reflex spasm persists in spite of antispasmodics. I found in my roentgenologic work that nonorganic spasms of the antrum completely disappear if while the patient is on a horizontal table he inhales the fumes of a crushed amyl nitrite pearl and is under the momentary influence of the drug. These lesions of the antrum offer great concern particularly because a gastric polypoid localized in this region is not uncommon, and therefore it is a question of clinical judgment as to just what should be done. The question of the midportion gastric ulcer is one that concerns us a great deal at the present time. Since the introduction of the gastroscope it has been possible to solve more clearly the problem of benignancy or malignancy without the exploratory operation. The mere healing of a gastric lesion is no definite criterion of its benignancy. Malignant gastric lesions may heal and the roentgenologic evidence almost completely disappear. If achlorhydria is present and there is no history of a previous achlorhydria before symptoms appeared it has always been an ominous symptom and is suggestive of an inoperable carcinoma, because achlorhydria is merely a manifestation of a cachexia. The continued presence of occult blood in the stool after medical management is suggestive evidence of malignancy because as a rule the blood completely disappears in cases of a benign lesion. The question as to medical or surgical treatment is again more a matter of opinion than of fact. I know of no gastro-enterologist, roentgenologist or surgeon who either at the operating table, in the fluoroscopic room, or from clinical experience can say with any degree of certainty that a given lesion is benign or malignant. The final diagnosis rests with the microscope. If we admit that 5 per cent and in some places even 10 per cent, of all gastric lesions are either malignant in their inception or become so during their life cycle it must frankly be said that there is at least a 5 per cent mortality in individuals with a gastric lesion beyond the age of 35. Therefore a patient with a gastric lesion is much safer when surgically treated.

DR. HENRY A. RAFSKY, New York. I would like to suggest to Dr. Portis to proceed cautiously with amyl nitrite in ulcer patients because most of them have hypotension. Dr. Jordan mentioned a point that should be emphasized, namely, the duration of the symptoms. Given a patient with an ulcer history, a comparatively large deformity on the lesser curvature and hydrochloric acid in the gastric contents, a long history usually indicates benignity, a short history malignancy. However each case of gastric ulcer must be individualized and, if treated medically, should be periodically checked for at least five years. Hemorrhagic gastritis may simulate or even complicate a gastric ulcer. During the past year I have seen at the Lenox Hill Hospital, two patients with ulcer histories who succumbed to severe gastric hemorrhages. In one a hemorrhagic gastritis and a prepyloric ulcer were present, and in the other a hemorrhagic gastritis, without any ulcer was found. I should like to ask Dr. Jordan what the incidence of combined gastric and duodenal ulcers was in her series. An attempt was made to treat a patient with intubation. When the tube did not pass the pylorus this method was discontinued. A Sippy dietetic regimen with alkalis was likewise unsuccessful. The surgeons did not think an operation was feasible in view of the size and location of the gastric ulcer. Injections of histidine monohydrochloride and a modified Sippy diet were then employed. The patient became symptom free

and was discharged feeling very well. I do not know whether the result was incidental or due to psychotherapy, nonspecific therapy or overcoming the amino acid deficiency. These facts are not mentioned to present any brief for any form of treatment but to show that in refractory gastric and duodenal ulcer patients more than one method may have to be employed to make these patients symptom free.

DR. WALTER L. PALMER, Chicago: I wish to make one point and that is the importance of an additional method of direct diagnosis mentioned by Dr. Jordan, namely, gastroscopy. Dr. Schindler talked to you yesterday of gastritis. It has been my good fortune to have his aid in the diagnosis and observation of a number of cases of gastric ulcer. We had hoped to be able to present a paper on that subject at this time but have had to defer it until a later date. Gastroscopy is of incalculable value in helping us to answer the three old questions always propounded by Dr. B. W. Sippy: 1. Is ulcer present? A negative gastroscopic examination is not absolute, but, on the other hand, when one sees an ulcer gastroscopically, it is definite and one is then able to say positively that it is not an old deformity but an active ulcer. 2. Is it benign? And here gastroscopy, to my surprise, has given definite and positive information thus far. I am forced to admit that in our experience Dr. Schindler has not yet made a mistake in his differentiation between a benign and a malignant lesion gastroscopically. 3. Is the lesion healed? When we follow the course of an ulcer with the gastroscope as well as with the x-rays and see it diminish in size and finally disappear so that we can no longer demonstrate it with either method, I, for one, am satisfied that the ulcer is benign and that it is healed.

DR. WILLIAM CARPENTER MACCARTY, Rochester, Minn.: I have been talking and writing about this subject for twenty-five years, and most of the things I have said and written have been misinterpreted and misquoted. I know of no group of diseases which requires more experience and intelligence in the handling than cancer and ulcer of the stomach, ulcer of the duodenum, cholecystitis and a few other conditions in the upper part of the abdomen. I have heard many papers on this subject in this country and in Europe. I don't know Dr. Jordan except by reputation but I am going to tell you that her paper is the most intelligent presentation I have heard in a long time. Her paper was extremely logical, tolerant, very sincere—she didn't get lost in her facts and reasoning, but her discussers did.

DR. SARA M. JORDAN, Boston: Dr. Boles mentioned peripheral vascular diseases as the cause of peptic ulcer and that immediately called to mind a patient who had had a massive hemorrhage in the duodenum and finally died after the second, uncontrollable hemorrhage in whose case our pathologist said undoubtedly the ulcer was that type of ulcer. Now there are ulcers and ulcers, and I feel certain that Dr. Boles's explanation of ulcer does fit in a certain group of ulcers, but I don't feel that it fits all of them. The question of faith in healing—Dr. Portis and I differ a great deal in that. Dr. Palmer, I am glad to notice agrees with me that when an ulcer is healed one can forget it as long as it is healed, as far as any question of malignancy goes. I do that with regard to any lesion in any other part of the body and I think it is perfectly possible to do the same with regard to lesions in the stomach. I agree with Dr. Portis that achlorhydria in a gastric ulcer is practically unknown. I had two cases which showed achlorhydria during the course of treatment. Dr. Rafsky asked about the incidence of gastric and duodenal ulcer and the combination of the two. I haven't the figures but my impression is that about 5 per cent of our gastric ulcers have an associated duodenal ulcer. I have felt that gastroscopy is an absolute need in the diagnosis of the gastric lesion and I congratulate Dr. Palmer on having had this help already. We are prepared now to call it to our aid. There was just one disappointing thing in a conversation I had with Dr. Schindler yesterday. I had hoped that gastroscopy would be able to help us in the prepyloric lesion but I found he was not as hopeful as I was about that particular lesion. He said that it certainly will tell whether spasm is present or not but whether a crater is also present is not always possible to determine even with gastroscopy.

OBSERVATIONS ON THE ETIOLOGIC RELATIONSHIP OF ACHYLIA GASTRICA TO PERNICIOUS ANEMIA

V. FURTHER EVIDENCE FOR THE ESSENTIAL PARTICIPATION OF EXTRINSIC FACTOR IN HEMATOPOIETIC RESPONSES TO MIXTURES OF BEEF MUSCLE AND GASTRIC JUICE AND TO HOG STOMACH MUCOSA

W. B. CASTLE, M.D.
AND
THOMAS HALE HAM, M.D.
BOSTON

Observations on patients with Addisonian pernicious anemia have appeared to us to demonstrate that the immediate basis of the anemia is a "conditioned" defect of nutrition. Thus, patients suffering from pernicious anemia are seemingly unable to derive from food some substance essential for normal function of bone marrow. The nutritional defect in such patients is apparently caused by the failure of a reaction which occurs in the normal individual between a substance in the food (extrinsic factor) and a substance in the normal gastric secretion (intrinsic factor). This conclusion is based on the following evidence derived from previous observations¹ on cases of Addisonian pernicious anemia:

1. The daily administration of (extrinsic factor) 200 Gm. of beef muscle is without significant effect on blood formation.

2. The daily administration of (intrinsic factor) from 150 to 300 cc. of normal human gastric juice is without significant effect on blood formation.

3. If, however, such amounts of each substance are administered daily in such a way as to permit contact either before or after administration to the patient, clinical improvement and evidence of increased blood formation are usually apparent within ten days and are progressive for the duration of such therapy.

From the Thorndike Memorial Laboratory, Second and Fourth Medical Services (Harvard), Boston City Hospital and the Department of Medicine, Harvard Medical School.

The expenses of this investigation were defrayed in part by a grant from the Proctor Fund of Harvard University for the Study of Chronic Disease and by the J. K. Lilly Gift to the Harvard Medical School.

Owing to lack of space this article has been abbreviated in *The Journal* by the omission of a section of the text and corresponding bibliography. The complete paper will appear in the authors' reprint.

The observations on certain patients were made possible through the kind cooperation of members of the staff of the First and Third Medical Services (Tufts) of the Boston City Hospital. We are indebted to Miss Margaret Evans and to Miss Eleanor Fleming for assistance in performing the blood studies.

Apparent confirmation of these basic observations has been obtained by various workers, notably Groen,² Hartfall and Wits,³ Helmer, Fouts and Zervas,⁴ Middleton and Stiehm,⁵ Miller and Rhoads,⁶ Reimann,⁷ Singer,⁸ Ungley and James⁹ and Wilkinson and Klein,¹⁰ who have agreed with us in supposing the necessity of both an extrinsic and an intrinsic factor for such increased blood production in pernicious anemia. In a recent paper, however, Greenspon¹¹ has presented the results of experiments from which he has drawn the conclusion that a food (extrinsic) factor is unessential to the production of the positive effects on blood formation in pernicious anemia which we reported from incubated mixtures of beef muscle and gastric juice. He believes that our negative results with normal human gastric juice alone were due to destruction of an "antipernicious anemia principle" by peptic action during the preliminary incubation usually employed. As a corollary, it was inferred by Greenspon that when gastric juice was incubated with beef muscle "the native pepsin in the gastric juice must have been adsorbed by the ground beef" and thus "the beef served to protect the antipernicious anemia principle and not as a substrate for the action of an enzyme-like 'intrinsic factor'."

Previous evidence exists, however, which would appear to render Greenspon's conclusions unlikely. In our former observations^{1b} on patient 11, gastric juice which was not incubated before administration yielded negative results. Middleton and Stiehm⁵ and also Groen² have obtained similar negative results. Nevertheless, according to Greenspon's theory the activity of such unneutralized gastric juice might have been destroyed by peptic hydrolysis *in vivo* after administration to the patient. Therefore these observations are not necessarily conclusive. The experiments of Helmer, Fouts and Zervas⁴ can scarcely be so criticized, however, since the gastric juice employed by them was depepsimized and brought to a p_H of 4.7 to 5 before administration. In case 8 of their series the daily administration of 150 cc of such gastric juice was ineffective.

It is thus not certain that Greenspon's experiments throw doubt on the conclusions that we have drawn. Furthermore for reasons that will be presented later, it seems to us that, unless the necessity for a food factor is conceded, our observations as well as his own do not necessarily disclose the immediate etiologic mechanism in Addisonian pernicious anemia. Moreover with-

out invoking a food factor, it is difficult to find a ready explanation of the etiologic relationship to pernicious anemia of certain other types of macrocytic anemia which likewise respond to the administration of liver or stomach preparations. For these reasons, a repetition of certain of Greenspon's experiments was undertaken as well as a critical analysis of our former observations.

METHODS

The ten patients included in the present observations were all typical cases of Addisonian pernicious anemia. Each had gastric anacidity and an initial red blood cell count of less than 2 million per cubic millimeter. In distinguishing between negative and positive effects on blood formation, use was made of the reticulocyte response that occurs with positive effects on blood formation in suitable patients with pernicious anemia. For this purpose the reticulocyte response was used in all our former observations as well as in Greenspon's¹¹ experiments. A full discussion of the significance of such reticulocyte responses has recently been published.¹² The methods of blood counting and of reticulocyte staining were those employed in our previous studies. Unless otherwise specified, the normal human gastric juice (150 cc) was secreted by a healthy fasting individual after the injection of 0.5 mg of histamine, was then filtered through coarse cloth and placed in the icebox. The patients were maintained on the basal diets used in former observations, which contained no meat, eggs, liver or kidney. Chicken and fish were allowed once or twice a week. In cases 62, 63, 64, 66, 68 and 69 the basal diet was further restricted during the periods of observation and consisted of white bread, rice, macaroni, butter, potato, ice cream, tea, coffee and sugar.

OBSERVATIONS

Normal human gastric juice does not contain an "antipernicious anemia principle" effective on oral administration without contact with food (extrinsic) factor

As already pointed out, Greenspon¹¹ does not share this view but considers that gastric juice contains an "antipernicious anemia principle" effective when fed alone. He bases his belief partly on the following direct experimental evidence:

Two normal subjects, after having been given 60 grains (4 Gm) of calcium carbonate orally as a neutralizing agent, were injected with histamine in order to stimulate the flow of gastric juice. By means of a Rehfuess tube the gastric juice was then aspirated and collected in a glass beaker containing ice and surrounded by ice. Care was taken immediately to adjust the reaction of the juice to neutrality and to maintain it so, until it was given to a pernicious anemia patient who had been selected for the testing of this material. The patient was fed about 250 cc of this cold neutralized gastric juice each day. It was given in the morning, on an empty stomach, and no food was allowed for the following four hours, in order to avoid the introduction of the so-called extrinsic factor.

In one patient with pernicious anemia and an initial red blood cell level of 2.6 million per cubic millimeter, Greenspon found a reticulocyte peak of 14 per cent on the seventh day of this regimen.

The technique of Greenspon's experiment was exactly followed in observations on patients 62, 63 and 64.¹³

* Transfusion of 2.0 cc of blood

except that no ice was put into the gastric juice, exactly 250 cc was administered, and the time interval before food was lengthened to six hours. Patient 66 was given daily 150 cc of normal human gastric juice neutralized only immediately before administration. No significant effect on reticulocyte or red blood cell production was observed during periods of ten days in patients 62, 63 and 66 and during a period of twenty-eight days in patient 64 (table 1). None of the patients were clinically improved and the condition of patient 64 necessitated a transfusion of 250 cc of blood on the fourteenth day. Similar negative results

from observations with gastric juice neutralized by the method of Greenspon have recently been reported by Flood and West¹⁴, Hanes, Hansen-Prüss and Edwards¹⁵, Ungley and Moffett,¹⁶ and Fitz-Hugh and Creskoff.^{10a}

The immediately succeeding period of observation in cases 62, 63, 64 and 66 demonstrates the ability of each patient to react positively. Patients 62 and 63 were given a meal containing 200 Gm of beef muscle simultaneously with 250 cc of gastric juice unneutralized until immediately before administration at noon each day. Patient 64 responded to the daily administration of 10 Gm of ventriculin, as did patient 66 to the administration of a mixture of gastric juice and boiled hog stomach mucosa. The details of the blood counts are presented in table 1. A consideration of the nature of the diet given Greenspon's patient suggests the probable explanation for his isolated positive result with neutralized gastric juice fed alone. Since meat,^{1b} eggs⁸ and whole grain cereals¹ have been shown to yield positive results when administered with gastric juice to patients with pernicious anemia, patients 62, 63, 64 and 66 were given none of these foods in the special basal diet, specified under methods. Dr Greenspon has kindly informed us that, on the contrary, the only dietary restriction imposed on his patient was the omission of liver and kidney. The patient may thus have received meat, eggs or whole grain cereals in the hospital diet.

Moreover, if such substances were present in the diet used by Greenspon, the administration of the gastric juice to the fasting patient only four hours before the succeeding meal is not a precaution necessarily adequate to prevent effective contact between gastric juice and food (extrinsic) factor. This is shown by the observations on patient 70. This patient received each morning 200 Gm of beef muscle. Six hours later he was given 100 cc of gastric juice collected as usual in our experiments and neutralized only immediately before administration. As will be seen from the data presented in table 1, a reticulocyte peak of 9 per cent resulted on the twelfth day of this regimen. The initial level of the red blood cells was 1.57, and on the fourteenth day the count reached 2.45 million per cubic millimeter. Clinical improvement was obvious. It is therefore clear that effective interaction can occur between extrinsic and intrinsic factors given six hours apart and so may have occurred in the four hour separation of the gastric juice from the next meal employed by Greenspon.

Furthermore, since the gastric juice used in this particular experiment produced positive responses in conjunction with beef muscle, it is clear that the special precautions advocated by Greenspon to prevent peptic activity are not essential to the preservation of the intrinsic factor. Additional evidence for this is obtained in the positive responses occurring with mixtures of gastric juice and extrinsic factor in the final periods in cases 62, 63, 65, 66, 68 and 69 and in the first period in case 67 (table 1). In all these instances gastric juice was collected as in our former observations, with no attempt to maintain its neutrality and so to prevent peptic activity.

The activity of desiccated hog stomach mucosa is due to the presence of both intrinsic and extrinsic factors.

We¹⁰ have observed in a few instances that positive effects on blood formation in pernicious anemia were obtained from the daily administration of as little as 30 Gm of fresh hog stomach mucosa. Greenspon¹¹ states that "since Castle's theory is founded on the belief that the addition of beef or some other source of extrinsic factor is necessary for the production of

the antipernicious anemia principle, these positive results with gastric mucosa alone require explanation." Now, since the mucosa is obviously not entirely composed of gastric juice, it is clear that something besides intrinsic factor is present in it. If that something else were a source of extrinsic factor, the possibility of an effective interaction occurring could not be excluded. Greenspon's argument that since gastric mucosa alone is effective, normal human gastric juice alone must also be effective is therefore not logical.

The following observation demonstrates that by a procedure known to destroy intrinsic factor in normal human gastric juice, hog stomach mucosa is rendered inert. To patient 7a was given daily 200 Gm of hog stomach mucosa which had been incubated in the presence of hydrochloric acid and native pepsin at p_H 2.5 to 3.5 for at least forty-eight hours at 37.5 C. No evidence of increased blood formation was observed during a first period of twelve days, although the patient subsequently responded in a second period to the daily oral administration of liver extract-Lilly (N N R) derived from 600 Gm of liver (table 1).

The following observations show that extrinsic factor is present in hog stomach mucosa. About 5 Kg of hog stomach was boiled for two hours on a water bath, then cooled, finely minced and together with the liquor obtained, 2,500 cc of water, 90 Gm of pepsin, and sufficient concentrated hydrochloric acid to maintain an acidity of less than p_H 2.5, was incubated at 37.5 C for seventy-two hours. At the end of that time the liquefied material was concentrated by vacuum distillation until 100 Gm was equivalent to 200 Gm of original mucosa. In this process there were thus employed two procedures known to destroy the activity of hog stomach mucosa,¹² first boiling for at least five minutes and, second, digestion with pepsin and hydrochloric acid for forty-eight hours at 37.5 C.

To patient 66 in the second period and to patient 67 in the first period were given daily 100 Gm of this inactivated hog stomach mucosa concentrate and 150 cc of gastric juice immediately after admixture and neutralization with concentrated sodium hydroxide. As will be seen in table 1, patient 66 responded moderately with a reticulocyte peak of 7.5 per cent on the tenth day of the regimen. At this time the blood nonprotein nitrogen, which had been slightly elevated throughout, reached 73.8 mg per hundred cubic centimeters, and the observation was discontinued. Patient 67 responded to a similar regimen with a reticulocyte peak of 35.9 per cent on the twelfth day. From an initial level of 0.82 million the red blood cells increased to 1.85 million per cubic millimeter on the twentieth day. Clinical improvement was correspondingly striking. Hog stomach mucosa therefore contains extrinsic factor and the probable basis for the activity of this material or, as suggested before, of whole hog stomach,¹³ depends on the presence of both a thermostable (extrinsic) factor and a thermolabile (intrinsic) factor.

Incubation of normal human gastric juice for two hours at 37.5 C inactivates only a portion of the intrinsic factor.

Greenspon¹¹ states that the well known hematopoietic activity of ventriculin (desiccated hog stomach) is completely destroyed in the presence of pepsin and hydrochloric acid by incubation at 38 C for two hours.

or longer. The reaction of the incubated mixture was acid to congo red. From this observation he infers that in our experiments in which acid and pepsin containing gastric juice was incubated for two hours at 37.5 C its "antipernicious anemia principle" was similarly destroyed. He presents, however, no direct evidence for this conclusion from observations with incubated gastric juice.

That the incubation of normal human gastric juice under the conditions of former observations^{1b} destroys only a portion of its content of intrinsic factor is shown by the positive effects on blood formation in the second period in case 63 and the first period in case 65 (table 1). Two hundred and fifty cubic centimeters of normal human gastric juice containing active pepsin, as shown by Mett's tubes, and having a natural p_{H} of about 1.5, was incubated for two hours at 37.5 C. Immediately thereafter the gastric juice was neutralized and given daily to each patient coincidentally with a meal containing 200 Gm of beef muscle. In case 62 the gastric juice was incubated for only one hour and a similar positive result was observed in the second period.

Since we^{1b} had previously shown, however, that the incubation of normal human gastric juice for three days at 40 C completely abolished its content of intrinsic factor, it seemed very likely that some destruction of this component would be produced by incubation for two hours at 37.5 C. Accordingly, in the third period in case 63 and in the second period in case 65 the conditions of the preceding period were exactly reproduced except that the gastric juice was not incubated but was given each day immediately after neutralization and coincidentally with a meal containing 200 Gm of beef muscle. In the third period in case 63 there was a second reticulocyte response reaching 14.5 per cent on the tenth day, and in case 65 a second peak of reticulocytes of 15.9 per cent was attained on the tenth day of this regimen. The occurrence of such second rises of reticulocytes indicates that the material given in these periods was more effective than that given in the preceding periods.¹² Greenspon's belief in the destructive action of peptic hydrolysis on an "antipernicious anemia principle" is thus sustained in that a two hour period of incubation is shown to be detrimental to intrinsic factor. However, since removal of pepsin without change in other properties of the gastric juice was not undertaken, our observations clearly do not permit the further definition of the nature of the destructive process as necessarily peptic hydrolysis.

Beef muscle and gastric juice administered without opportunity for contact are wholly ineffective.

Since the intrinsic factor of normal human gastric juice is partially destroyed by incubation for two hours at 37.5 C at p_{H} 1.5 the completely negative results of the observations^{1b} in the control periods in cases 13, 15 and 17 may be questioned. In these observations such incubated gastric juice was given to the patient each day sufficiently long before the beef muscle as presumably to diminish greatly any opportunity for contact between these substances within the alimentary tract.

A repetition of these observations was undertaken without preliminary incubation of the gastric juice. During the first period in case 69 200 Gm of beef muscle was given to the patient at 8 o'clock in the

morning. Twelve hours later 150 cc of gastric juice was neutralized and immediately given. This regimen was repeated daily for twelve days without detectable effect on blood production, as shown in table 1. In the immediately succeeding second period, however, when each day similar quantities of neutral gastric juice and beef muscle were given together, a reticulocyte peak of 20.6 per cent was reached on the tenth day and the red blood cells increased from an initial level of 1.34 to 1.95 million per cubic millimeter on the sixteenth day. In order that the amount of both beef muscle and gastric juice administered in each period of twelve days might be the same, these substances were not given after the twelfth day of the second period.

To patient 68 were given on the odd numbered days of the first period 300 Gm of beef muscle and on the even numbered days 150 cc of neutral gastric juice. In all, six administrations of each substance were made on alternate days during the twelve days of this first period. No detectable effect on blood production was observed. During the immediately succeeding period of twelve days 300 Gm of beef muscle and 150 cc of gastric juice neutralized immediately before administration were given together every other day for six such administrations. A moderate effect on blood production occurred. The reticulocytes reached a peak of 7.4 per cent on the sixteenth day and the red blood cells did not increase. This relatively slight effect on reticulocyte production is probably explained by the presence of exstis with fever complicating the patient's condition and by the fact that since the material was administered only on alternate days the amount given was spread over twice as long a period as in observations in which daily administration was practiced.

The observations on patients 68 and 69 demonstrate that the conclusions reached on the basis of former observations^{1b} on patients 13, 15 and 17 were correct, namely, if beef muscle and gastric juice are administered without opportunity for contact, they are not effective. It is obvious, therefore, that the activity of mixtures of beef muscle and gastric juice cannot be due to the simple addition of two subthreshold substances but requires an interaction between them.

Former experiments apparently demonstrating the absence of intrinsic factor from certain substances are not necessarily valid.

Observations apparently demonstrating the negative effects of gastric juice incubated with various substances were made in case 5 (cornstarch),^{1a} case 19 (washed casein),^{1b} case 24 (beef muscle protein)^{1c} case 27 (wheat gluten), case 51b (animal nucleic acid) cases 52, 53 and 54 (spleen pulp), cases 58 and 59 (nucleoprotein) and cases 59a, 60 and 61 (yeast nucleic acid).^{1e} Since incubation of 250 cc of gastric juice for two hours at 37.5 C in the presence of native pepsin and hydrochloric acid at a reaction of p_{H} 1.5 detectably diminishes its content of intrinsic factor, the apparently negative results of these former observations need reconsideration.

In table 2 are summarized the amounts of gastric juice, the nature of the substrate, and the reaction and duration of the incubation period in the foregoing cases. Patient 5 was given daily the entire incubated gastric contents of a normal man removed one hour after the ingestion of a meal of 300 Gm of cornstarch. Since the incubation period in the observation on this patient lasted six hours at a reaction of p_{H} 1.5 to 2, the negative result cannot be accepted. It is probable, however, from the nature of the basal diet used in all our obser-

^{1c} Case 27—W. F. Townsend, W. C. and Heath, C. W. Further Observations on the Etiological Relation of Melvin Castle to Pernicious Anemia. *J. Clin. Invest.* 15: 219-220 (Aug.) 1936.

vations that refined carbohydrate does not contain extrinsic factor. The negative result of observations on patient 19, who was given daily 50 Gm of washed casein (A. H. Thomas Company) incubated with 300 cc. of gastric juice from three to five hours at p_{H} 2.5-3.5, likewise cannot be accepted because of the prolonged incubation period.

The negative results with spleen pulp and gastric juice in cases 53 and 54 we now believe cannot be accepted, owing to the fact that the observations were made on patients in another city to which the material had to be transported, subject to delay. In former unpublished observations with incubated mixtures of beef muscle and gastric juice known to be fully effective under usual conditions, negative results were obtained when the material was so transported. In the first periods in cases 50 and 51, and in the second period in case 58, positive results were obtained from the daily administration of 50 Gm or more of spleen pulp or a subfraction after incubation with from 50 to 75 cc of gastric juice for two hours at p_{H} 7. Therefore, the negative result in patient 52, who received 100 Gm of spleen pulp incubated for two hours with 75 cc of gastric juice at p_{H} 7, seems to be clear cut. It is thus probable that, as was formerly stated, the divergent results of these observations with spleen pulp are due to variations in the content of extrinsic factor of the spleen.

In cases 24, 27, 52, 58, 59a and 60, the incubation period did not exceed two hours. Assuming the correctness of Greenspon's belief that peptic activity is responsible for the inactivation of gastric juice, the conditions (table 2) of none of these incubation procedures could have been as favorable for destruction of the intrinsic factor as those obtaining during incubation of gastric juice alone for two hours. In the latter case the reaction (p_{H} 1.5) was almost optimal for peptic hydrolysis and there was no substrate present potentially capable of adsorbing pepsin and so affording protection for the intrinsic factor.

In the observations in cases 52, 59, 59a and 60 in which only 75 cc of gastric juice was employed, the reaction of the incubated mixture was p_{H} 6 to 7. In cases 51b and 61 only 50 cc of gastric juice was incubated for four hours at p_{H} 7 with the substrates. It is possible that, although incubation of 250 cc of gastric juice for two hours under optimal conditions for peptic activity only partially destroyed its content of intrinsic factor, the inactivation of a smaller quantity of gastric juice would be sufficiently great to produce the negative results observed. It is also possible that the temperature alone and not the peptic hydrolysis suggested by Greenspon is responsible for the partial inactivation of the intrinsic factor observed. Helmer, Fouts and Zerfas,⁴ however, have obtained moderately positive effects from the daily administration of as little as 10 and 25 cc respectively of gastric juice incubated for four hours at 47°C with liver extract-Lilly (N. N. R.) derived from 100 Gm of liver. The daily administration of such an amount of that liver extract alone is essentially ineffective. Because of these facts it does not seem probable that the reduction of the amounts of gastric juice employed in some of these observations or the incubation in some instances for as long as four hours at p_{H} 7 could have been responsible for the negative results. Nevertheless because of the variability of response to oral administration among patients with pernicious anemia negative results

unless obtained under optimal conditions for interaction between intrinsic and extrinsic factors cannot be accepted as confidently as positive responses. For this reason the negative observations with washed casein and with certain other substances are being repeated without preliminary incubation.

Unfortunately, criticism may also be justified in respect to the negative results of others who have likewise incubated certain substances for over two hours with acid gastric juice. Thus Diehl and Kühnau²⁰ and Groen² incubated lactoflavin^{20a} for three and four hours respectively with gastric juice and obtained no effect on blood production in pernicious anemia. The negative result obtained by Wills and Naish²¹ with an extract of egg white incubated with gastric juice for two hours, and confirmed by Groen² with egg white after a four hour incubation period, contrasts with the positive result reported by Miller and Rhoads⁶ after an incubation period of only one hour. On the other hand those substances giving negative results in patients with tropical macrocytic anemia may safely be accepted as lacking in extrinsic factor provided the

* Derived from 200 Gm of beef muscle.

positive effects with other substances are due to the natural presence of intrinsic factor in the gastric juice of these patients.²² Thus, Wills²³ found that dried yeast, a watery extract of yeast, a vitamin B₂ preparation derived from egg white, and a preparation of vitamins B₁ and B₂ adsorbed on acid clay, in contrast to various preparations of autolyzed yeast (marmite), had no blood-forming activity in tropical macrocytic anemia. In confirmation of this the Lassens²⁴ found that pressed top yeast and watery extracts of such yeast before or after autoclaving for one hour at 25 atmospheres did not lead to increased blood production in pernicious anemia after incubation with gastric juice for two hours.

20 Diehl F. and Kühnau J. Ist Vitamin B der therapeutisch wirkende äussere Faktor beim Morbus Biermer? Deutsches Arch f. Klin. Med. 176: 149 (Dec. 12) 1933.

20a We have, however, now entirely confirmed these negative results by giving a mixture of 150 cc of neutralized gastric juice and 20 mg of lactoflavin daily for five days without preliminary incubation. We are indebted to Vitah Products Inc. for supplying the lactoflavin.

COMMENT

When it is shown that for the secretion of the normal stomach to be effective in pernicious anemia a food factor is essential, the demonstration that a disturbance of the stomach is a primary factor in the immediate causation of the disease becomes possible on purely experimental grounds. Whether the fact of failure of the secretion of the stomach in pernicious anemia were known or not a repetition of the observations which we have conducted with beef muscle and gastric juice would, we believe, lead to the conclusions that we have reached.

Briefly, these experiments have shown that in pernicious anemia the oral administration of either beef muscle or gastric juice alone is without effect. The oral administration of the gastric contents of a normal subject removed after the ingestion of a meal of beef muscle^{1a} or the oral administration of mixtures of gastric juice with beef muscle^{1b}, eggs,⁸ autolyzed yeast³⁷, wheat germ^{1c}, rice polishings³⁸ or tomato extract² has been shown to produce increased blood formation in pernicious anemia. A similar process would clearly take place in the normal subject in the natural course of the digestion of certain foods.

Our conception of the experimentally demonstrable factors normally involved in the production of the substance that is deficient in the liver of patients with pernicious³⁵ and related macrocytic anemias³⁶ is represented by the schematic formula

$$\frac{F \times G}{I} = L \cdot E$$

Here *F* stands for food (extrinsic) factor, *G* for gastric (intrinsic) factor and *I* for intestinal impermeability or any defect causing malabsorption or destruction of those substances or a product of their effective interaction. *L · E* stands for "liver extract," the independently effective thermostable factor found in mammalian liver, kidney and certain other organs. Probably in none of the anemias referred to is any factor on the left of the equation completely normal and in every instance there is a variable participation of defects of one or both of the factors in the numerator³⁹ or some increase of the denominator value⁴⁰. Any or all such changes from the normal will, however, result in a decrease of "liver extract" which if sufficiently great, may allow the development of a macrocytic anemia which will respond to the parenteral administration of liver extract derived from the liver of a normal animal.

If the dominant defect is of food (extrinsic) factor, the anemia will respond both to orally administered extrinsic factor and to liver extract (e. g. macrocytic anemia of pregnancy in the tropics⁴¹ and elsewhere^{39b} or of certain cases of sprue³⁶ and idiopathic steatorrhea⁴²). The presence of some intrinsic factor in the stomach probably explains the occurrence of "spontaneous remissions" in certain cases of pernicious

anemia⁴³ as well as the usual recovery following delivery of patients with the pernicious anemia of pregnancy^{39b}. Likewise the partial success of former methods of treatment with high protein diets in both pernicious anemia^{1d} and sprue³⁶ was probably due to a similar effect. On the other hand, the concept of a defect of an independently active antipernicious anemia principle secreted by the stomach, as proposed by Morris²⁵ and by Greenspon,¹¹ does not satisfactorily explain the immediate etiologic mechanism of those instances of macrocytic anemia in which intrinsic factor is demonstrably present in the gastric contents³⁶. If the dominant defect is of gastric (intrinsic) factor, the anemia will not respond to orally administered extrinsic factor unless gastric juice is given simultaneously but will respond to liver extract administered orally or parenterally (e. g., Addisonian pernicious anemia).

The existence of an essential preliminary reaction between food and gastric juice does not, however, preclude the possibility of defects of other subsequent and essential reactions within or without the alimentary tract. If intestinal impermeability is sufficiently increased, the patient will not respond normally to mixtures of extrinsic and intrinsic factor or to stomach or liver preparations given by mouth but will respond to parenterally administered liver extract (e. g., macrocytic anemia of chronic sprue³⁶ or of intestinal stenoses or short circuits⁴⁴). In theory at least, failure or inhibition of any essential link in the further metabolism within the body will likewise diminish the supply of liver extract available to the bone marrow⁴⁵. It is certainly clear that infections¹² may have an inhibitory effect on the action of liver extract in pernicious anemia. This concept of the etiologic relationships between pernicious anemia and other types of macrocytic anemia which likewise respond to the parenteral administration of liver extract has been fully discussed elsewhere⁴⁶.

CONCLUSIONS

The following observations on patients with pernicious anemia fail to sustain the conclusions of Greenspon:

1 Normal human gastric juice does not contain, on oral administration, an "antipernicious anemia principle" effective without contact with food (extrinsic) factor.

2 Hog stomach mucosa contains both a thermostable (extrinsic) factor and a thermolabile (intrinsic) factor presumably responsible for the activity of such mucosa and of whole desiccated hog stomach.

3 Incubation of normal human gastric juice for two hours at 37.5 C. in the presence of native pepsin and hydrochloric acid inactivates only a portion of its content of intrinsic factor.

4 Beef muscle (extrinsic factor) and gastric juice (intrinsic factor) administered without opportunity for contact are not effective in pernicious anemia.

Greenspon's recent experiments have led to the following modified conclusions in respect to former observations

1 The negative results of the administration of substances after incubation with gastric juice for longer periods than two hours at 37.5 C at an acid reaction cannot be accepted

2 Lack of extrinsic factor in substances so incubated with gastric juice is not established by negative results

3 Preliminary incubations should not be employed in testing the blood-forming activity in pernicious anemia of mixtures of gastric juice and various substrates

Clinical Notes, Suggestions and New Instruments

TRIGGER FINGER IN CHILDREN

S A JAHSS M.D. NEW YORK

Trigger finger, while fairly common in the adult, is rather rare in children. The digit involved is always the thumb, whereas in the adult any finger may be the seat of this trouble, usually the third or fourth finger. Because of its rarity, I have never yet seen a case referred to me that had previously been diagnosed correctly. Most often the diagnosis has been "congenital contraction" of the thumb. The reason for this is quite obvious when one hears the almost stereotyped and meager history given by the mother to the doctor: "My child holds the end of the thumb bent and cannot straighten it. If I try to straighten it, the child cries and pulls the hand away." In fact, such was the history when I saw my first case. In six of the nine cases to be reported that was the only history given. Not one of the mothers knew exactly how long this state of affairs had been present, one said a few weeks, another a few months, while most of them claimed that it must have been present since birth. This last group was only rationalizing. In one case the mother was able to "open" the finger accompanied by a snapping sound. It remained "open" until the child actively flexed the thumb and then it went back into the fixed "bent" position. The child herself could not voluntarily "open" the thumb.

An understanding of the pathology is necessary for a clear conception of the symptoms. There is present a thickening of the tendon of the flexor longus pollicis near the base of the

locking of the tendon begins only after the distal phalanx has been flexed at least 60 to 75 degrees, the range of released flexion is small, as the angle of greatest flexion at the interphalangeal joint is 90 degrees and the tip of the thumb describes an arc of only 15 to 30 degrees. Now when extension is attempted the same snapping phenomenon takes place. In order to extend, the thickened tendon must be forced through the narrowed opening by the extensor longus pollicis. It is this sudden rapid and snapping flexion and extension of the distal phalanx that has given this condition the name of trigger finger or snapping thumb. The length of the sudden extension is greater as the tip of the thumb describes an arc of from 60 to 75 degrees. There are therefore always two snapping motions of the thumb one on flexion and one on extension. On palpation, one can feel this snapping quite easily.

There finally comes a time when the extensor muscle is unable to overcome the mechanical obstruction and the terminal phalanx remains locked in the flexed position.

Prolonged effort on the part of the patient to extend this terminal phalanx may lead to a stretching of the anterior ligament at the metacarpophalangeal joint, with a resultant hyperextension of this joint, which with the flexion of the interphalangeal joint, looks like the picture one sees in cases of congenital contraction. But congenital contractions usually involve the other fingers, with the flexion at the proximal interphalangeal joint and the extension at the distal interphalangeal joint.

A typical case. Distal phalanx locked in flexion. The angle of greatest extension is 150 degrees. There is 35 degrees of hyperextension between the proximal phalanx and the metacarpal. The ink line at the base of the thumb outlines the bulge immediately anterior which is the bulbous portion of the flexor longus pollicis.

THE CASES OF TRIGGER FINGER

Patient	Sex	Age	Right	Left	Bilateral
A. A.	♂	16 mo	1		
A. D.	♂	1			1
M. F.	♀	2	1		
W. S.	♀	6		1	
D. K.	♀	11½		1	
G. M.	♀	2			1
S. G.	♀	2		1	
C. S.	♀	2			1
H. G.	♀	2½ mo	1		
C. I.	♀	2	1		

proximal phalanx. This thickening is usually fusiform but may be nodular. The sheath of the tendon opposite the metacarpophalangeal articulation is not elastic owing to the presence of the palmar fascia, and therefore offers resistance to the free excursion of the bulbous portion of the tendon on active flexion and extension. This constant irritation of both tendon and sheath leads to an actual thickening of the sheath at this point with a concomitant narrowing of the lumen. The tendon also becomes more bulbous until such a time when the thickened tendon is wider than the opening in the sheath. Now, as the distal phalanx is flexed marked effort of the flexor longus pollicis is necessary to pull the widened tendon through the narrow opening. When it does pass through it does so suddenly that the thumb snaps shut. Since the

On palpation over the palmar aspect of the head of the metacarpal, in addition to feeling the snapping, one can also feel the thickened part of the tendon making its longitudinal excursion. This thickening is felt as a hard nodular mass and is fairly tender. It is easily palpable, as the head of the metacarpal is quite prominent because of hyperextension at this joint.

When the distal phalanx is locked in flexion the movement of this mass is hard to elicit, as there is only about 15 to 30 degrees of active motion possible at this time and only active flexion and extension will produce this excursion. When passive motion is substituted instead it tends only to relax and make taut that part of the tendon which is distal to the obstruction and which in itself is normal.

This series comprises ten operative cases. I say operative, because fifteen cases were actually seen but five of the patients refused to enter the hospital. Since the absolute diagnosis could be corroborated only by operation, the cases in which operation was not performed were not included in this report.

The age incidence ranged from 3½ months to 15 years. The history given by the mother of the 15 year old girl was that "she has had this condition since birth."

Six of the patients were females and four were males.

Seven cases were unilateral, of which four were right and three left. In three cases both thumbs were involved.

There is only one treatment and that is surgical. It consists of dividing the thickened and constricted sheath longitudinally until the fusiform swelling of the tendon moves freely on passive motion. In closing the wound, only the skin is sutured. The child is encouraged to move the thumb immediately. The thickened sheath usually cuts like gristle. A section taken from the sheath of one of these cases for pathologic examination shows hyalinized connective tissue with fibrous villi. The first patient was operated on nine years ago and the last one in August 1936.

C. P., a girl, aged 2 years, had the right thumb involved. The history was as typically vague as in the other nine cases. The operation was performed on August 3. Active motion of the distal phalanx is painless and normal in range.

SUMMARY

Trigger finger in children is an uncommon condition and is most often confused with congenital contraction of the thumb. It is amenable only to operative treatment, as a mechanical factor must be overcome.

No recurrences have taken place.

Special Article

THE PHARMACOPEIA AND THE PHYSICIAN

THE USE OF LOCAL ANESTHETICS

JOHN S. LUNDY, MD

ROCHESTER, MINN.

This is one of a series of articles written by eminent clinicians for the purpose of extending information concerning the official medicines. The twenty-four articles in this series have been planned and developed through the cooperation of the U. S. Pharmacopeial Committee of Revision and THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION—ED

Local anesthetics depend for their success primarily on the skill with which they are used,¹ although the relative nontoxicity of such agents and any idiosyncrasy of the patient to them are also important factors. When idiosyncrasy is suspected, one may test the patient's skin by the patch method and thereby obtain valuable information; other tests have been devised, but not one is safer than the patch test. The skill of the administrator depends on previous training and on the opportunity to keep in practice. For that reason no one is skilful in all methods of local anesthesia, and it seems wise to recommend that satisfactory methods already employed should not be forsaken for others that are new and may seem promising but which obviously will seldom be used.

For purposes of brevity, and because they can be found readily elsewhere, descriptions of the technic of such various methods of regional anesthesia as abdominal block,² brachial plexus block (supraclavicular

route³), cervical block,⁴ sacral block⁵, held block,⁶ infiltration,⁷ spinal anesthesia,⁸ peridural anesthesia,⁹ para vertebral block,^{10a} and block of cranial nerves for operations on the head¹¹ and nerve blocks for orthopedic operations,¹⁰ for dental operations,¹² in obstetrics¹³ and for diagnosis,¹⁴ prognosis and therapeutics, are not included here, the page numbers in the books referred to being appended to references in the bibliography.¹⁵

Infiltration of tissue to be incised is the most successful method for common use. Precautions should be taken, however, to avoid using the wrong drug or using it in the wrong concentration; further, the use of vasoconstrictors in injections of the digits, in the presence of hypertension, or when patients are suffering from exophthalmic goiter, should be avoided. Trauma from the needle with which the solution is injected should be held to the minimum. Some of the alleged poor healing of wounds is not so much due to the agent used, except when the drug is used in too concentrated a form, as to the trauma caused during introduction of the needle into the tissue.

The dosage of local anesthetic agents employed should be such that there will be no question as to its safety. Since the dose of local anesthetic agents varies, several factors may be involved in deciding on the correct dosage. This is illustrated in my remarks on procaine hydrochloride.

In 1924 a committee appointed by the American Medical Association with Dr. Emil Mayer as chairman reported on "The Toxic Effects Following the Use of Local Anesthetics."¹⁶ The report of that committee might well be read by those who intend to use local anesthetics. Certain changes have occurred in the years since this committee's report was published, so that

certain portions of the article are not up to date, most of it, however, is as true today as when it was published. Certain points should again be stressed at this time. For example, it was recommended that cocaine should not be injected under submucous tissue or subcutaneously, and also that cocaine paste or mud should not be used as a preoperative measure. Local anesthetics should not be injected into the urethra which has been traumatized recently by instrumentation. The committee was of the opinion that local anesthetics might be applied in the following concentrations and total amounts: "Cocaine in the mouth and epipharynx (preoperative) 5 per cent, in the nose, not over 10 per cent, and in total amounts of from 10 to 15 minims, containing from 1 to 1½ grains, in the eye, not over 5 per cent, in the larynx and bronchi, not over 20 per cent—preferably 10 per cent in two applications—and not over 15 minims total, containing from 1 to 1½ grains. Procaine should not be used in greater concentration than 1 per cent, apothecine not greater than 2 per cent, and not more than 1½ grains, butyn should not be injected but may be applied in 2 per cent solution. Epinephrine serves a valuable purpose in causing a bloodless field and in delaying the absorption of the local anesthetics, especially procaine, but the addition of epinephrine in amounts of 1 mg [I would assume this to mean 1 cc of 1:1,000 solution] or more to a solution of cocaine often results in a greater degree of toxicity than that from cocaine alone when rapid absorption takes place, hence, the use of larger doses of epinephrine with cocaine is deemed unsafe and epinephrine should not be used in greater concentration than 1:10,000 and of this not more than 10 minims with cocaine. Somewhat larger total amounts of epinephrine may be used with solutions of procaine, but not more than 1 mg of epinephrine should be used, and even this dose may be unsafe in patients suffering with hyperthyroidism."

There are certain properties which a local anesthetic should have to be of practical value, namely, (1) anesthetic properties, (2) solubility in water, (3) relative nontoxicity, (4) ease of sterilization, (5) freedom from irritating qualities, and (6) compatibility with a vasoconstrictor. In selecting a local anesthetic for a given purpose one can judge rather quickly the suitability of the drug for the purpose by grading its usefulness on the basis of these six points and by estimating how fully the drug meets the requirements in each of these criteria. The U. S. Pharmacopeia lists drugs that are not patented or are no longer patented, and such drugs have earned their place there by virtue of their long periods of usefulness. These drugs will be discussed first, and there will then follow brief comments on certain newer agents not yet listed in the Pharmacopeia.

COCAINE (COCAINE)¹⁷ $C_{17}H_{21}O_4N$

When cocaine hydrochloride is to be used as a local anesthetic for instillation into the eye, 1 or 2 drops of a 4 per cent solution is used. As a local infiltration anesthetic for tonsillectomy about 10 or 15 cc of a 0.2 per cent solution is used. In order to anesthetize the larynx preliminary to induction of general anesthesia and the introduction of an intratracheal tube, a 5 to 10 per cent solution of cocaine is sprayed into the nose, the patient being requested to inhale. Cocaine hydrochloride is used as a local anesthetic in the urethra in concentrations of 0.25 per cent, about 5 cc being used. It is used

in the nose in the form of the so-called cocaine pack and also as cocaine mud. It is used in a concentration of 20 per cent or less as a surface anesthetic in the oropharynx, larynx and trachea and for esophagoscopy, it is also used as a surface anesthetic in the pharynx.

Cocaine hydrochloride has been used in dilute solution as an infiltration anesthetic for many types of superficial operations, and it has been used intraspinally in 2 per cent concentration and in amounts of from 0.5 to 1 cc. The difference in its effect intraspinally was that the dose had to be small enough so that anesthesia was produced without motor paralysis. The danger in using cocaine, of course, is that some people are susceptible to it and symptoms of poisoning develop from even a small dose, such symptoms being shortness of breath, increased pulse rate, a pronounced period of excitement, tremor, and sometimes convulsions. If the dose is overwhelming, cardiac inhibition will take place during the convulsions.

Cocaine hydrochloride can be incorporated into gels for superficial dressings, but the dose applied at one time must be small and toxic effects must be watched for. Barbiturates should be used prior to the administration of cocaine as a means of minimizing the severity of convulsions, or to minimize them should they develop. Barbiturates need not be given in doses large enough to produce vertigo in order to be helpful, and if a toxic reaction does develop a soluble barbiturate should be injected intravenously in sufficient amounts to control convulsions.

Destruction of cocaine hydrochloride in the body is relatively slow, which accounts for the more frequent accidents with it. It produces vasoconstriction, whereas synthetic anesthetics do not. Cocaine is a mydriatic. It is incompatible with alkalis and with sodium borate. It is not antiseptic and is a habit-forming drug. The internal dose is 0.015 Gm (one-fourth grain).

The value of having a solution of a suitable soluble barbiturate immediately available in the syringe has been demonstrated in the case of a woman who had taken a dose of cocaine between 0.5 and 1 Gm and convulsions had begun. Immediately after administration of the antidote the convulsions stopped.

ETHYLIS AMINOBENZOAS, OR BENZOCAINE (INTRODUCED AS "ANESTHESIN") $C_9H_9NH_2COO(C_2H_5)$

Benzocaine is used as a local anesthetic for ulcers, wounds and mucous surfaces, as a dusting powder or ointment. It is also used internally to relieve pain in gastric ulcer and cancer. The dose is from 5 to 8 grains (0.3 to 5 Gm) internally.

BUTESIN (BUTYL PARA-AMINO BENZOATE) $C_{11}H_{13}NH_2COO(C_4H_9)$

A preparation that is used widely consists of a compound of butesin and trinitrophenol (picric acid). Since 1924 it has been listed in New and Nonofficial Remedies as "butesin picrate" and it was advised for use in the treatment of burns, ulcers and other denuded painful lesions of the skin. The ointment should contain the drug in 1 per cent concentration.

Externally butesin is applied as a dusting powder, either pure or diluted. It may also be used in the form of suppositories.

PHENACAINE HYDROCHLORIDUM (HOLOCAINE)¹⁷ $C_9H_9N_2O_2 \cdot HCl \cdot H_2O$

Holocaine is a local anesthetic like cocaine but it is more quickly effective. Five minims of a 1 per cent aqueous solution instilled into the eye usually causes

¹⁷ Pharmacopeia of the United States. Eleventh Decennial Revision.

anesthesia in from one to ten minutes. The patient may complain, however, of smarting. The drug is antiseptic and anesthetic. Solutions of it are permanent and are not injured by boiling. It is not a mydriatic.

PROCAINAE HYDROCHLORIDUM, OR PROCAINE HYDROCHLORIDE (ALSO CALLED "PROCAINE" AND INTRODUCED IN MEDICINE AS 'NOVOCAINE')¹
 $C_{15}H_{20}O_2N, HCl$

Procaine hydrochloride is the best and safest of the synthetic local anesthetic agents. It is not very efficient as a surface anesthetic, but when used for that purpose it is sometimes used in small amounts up to a 10 per cent concentration. It is especially useful for infiltration anesthesia and it is effective in solutions of 0.5 per cent. When preliminary medication has been given in sufficient doses to produce a marked effect, even a 0.25 per cent solution of procaine hydrochloride is effective for infiltration anesthesia. When small amounts of procaine hydrochloride are to be used a 1 per cent solution may be preferred, especially if one wishes to minimize the amount of edema and distortion of the tissue to be incised.

Intravenous injection of a small dose of the drug is not without danger. I have observed an adult woman to be thrown into a convulsion by the intravenous injection of 3 cc. of a 1 per cent solution of procaine hydrochloride, yet this patient tolerated the average amount of the drug when subsequent injection was carried out with the careful avoidance of intravenous injection.

Block anesthesia of certain large nerve trunks such as the sciatic nerve and brachial plexus, may require a 2 per cent solution in order to accomplish satisfactory anesthesia, however, only small doses of such a concentration may be used. In spinal anesthesia the dose varies from as low as 30 or 40 mg. for operations on the anus, up to doses of 200 mg. for large vigorous men when an upper abdominal operation may last more than an hour. The principal contraindication to the subdural use of procaine hydrochloride is debility, and the more marked the debility the more definite the contraindication. Regardless of whether the debility is marked by one or more symptoms, such as, for example, if the hemoglobin is less than 50 per cent, spinal anesthesia is contraindicated except in small doses and under certain special circumstances. Patients with disease of the central nervous system and some with unstable nervous systems are, for medicolegal reasons, unsuitable for spinal anesthesia.

Some of the untoward symptoms encountered during spinal anesthesia are probably brought about by the systemic effect of procaine hydrochloride in the blood stream.¹⁸ Procaine hydrochloride is very quickly absorbed from the spinal fluid and if it reaches a sufficient concentration in the blood stream, it is sure to produce certain systemic effects such as nausea, vomiting and exaggeration of the fall in blood pressure. It may also produce other symptoms which are as yet not recognized as being due to this systemic effect. Procaine hydrochloride is absorbed from the spinal fluid, according to Nowak, fast enough so that the decomposition products appear in the urine in twelve minutes. It is rather commonly observed that nausea following the injection of procaine into the spinal fluid appears on the average in about twelve minutes, whereas the most marked point in the fall in blood pressure will appear on the average of about twenty-

two minutes after injection of procaine hydrochloride subdurally. These observations coincide with my theory that part of the untoward result during spinal anesthesia is due to the presence of procaine in toxic quantities in the circulating blood. Since Eggleston and Hatcher, and Dunlop, demonstrated that procaine is largely destroyed by the liver,¹⁹ it occurred to me that, if the speed of circulation could be regulated by ephedrine, the rate of absorption of procaine from the spinal fluid could be delayed more easily and the rate of detoxication in the liver could be slowed, thus producing longer anesthesia. To accomplish this purpose we have intentionally tried to lower the blood pressure of the average adult patient to from 80 to 90 mm. of mercury systolic by using 25 instead of 50 mg. of ephedrine hydrochloride. If the blood pressure of a patient should fall below 80 mm. systolic during or subsequent to spinal anesthesia, from 0.5 to 1 cc. of epinephrine in 1:1,000 solution can be given intramuscularly, or, if more immediate measures are desired, 25 mg. of ephedrine can be given intravenously.

For sacral block, for the average adult, not more than 100 cc. of a 1 per cent solution of procaine should be used. For deep cervical block a 1 per cent solution is used not exceeding 50 or 60 cc. in amount, for superficial cervical block 20 cc. of a 1 per cent solution may be used on each side. For extensive bilateral paravertebral block, about 5 cc. of a 1 per cent solution is injected around each nerve root, the total amount of solution injected not exceeding 100 cc. For dental block a 2 per cent solution is used, and usually from 5 to 10 cc. is injected. When there is pain from an abscessed tooth or from some similar condition it may be necessary to double the concentration of the solution, a 3 or 4 per cent solution of procaine being necessary.

When procaine hydrochloride is to be instilled into the urethra, one must be certain that the lining membrane of the urethra is intact, otherwise instillation would act as an intravenous injection and would be almost as dangerous. In such cases absorption would be rapid and the symptoms would simulate those following intravenous injection of too large a dose of procaine hydrochloride. This is especially true because in order to produce any degree of satisfactory anesthesia one must use a 5 to 10 per cent solution of procaine hydrochloride in the urethra. While such concentrations preclude use of a large volume of solution only so much of the solution should be used as will bring about the required degree of anesthesia.

The question²⁰ of the dosage of procaine hydrochloride to be used is frequently raised, and there are several factors which should be considered in judging whether a certain dose of procaine hydrochloride will be safe for a given patient. Since the answer must state facts concerning the concentration and amount of solution, the time consumed in its injection and the condition, size and age of the patient, I shall for purposes of brevity attempt to combine these factors into a formula which in a general way in regional anesthesia can be taken as an index of the reaction of the subject

$$\frac{CA}{RT} = \text{Reaction}$$

C is the concentration of procaine hydrochloride solution, A the amount of solution, R the time consumed for injection and T the patient's tolerance for the drug.

¹⁹ Sollmann Torald. *A Manual of Pharmacology*, ed. 4 Philadelphia W. B. Saunders Company 1934 p. 351.
²⁰ Lundy J. S. *Balanced Anesthesia* Minnesota Med. 9: 399-404 (July) 1926.

under the circumstances of its use in a given instance. If this index assumes too large a value, an untoward reaction results. Examples of values which are within safe limits will be given later. The degree of tolerance is estimated on a basis of 1 to 4, T1 meaning a low tolerance between T2 and T3, T2+, an average tolerance, and T4 a high tolerance.

Tolerance is estimated from the age, weight, blood pressure, pulse rate, and hemoglobin. It varies inversely, for example, with variations from the mean adult age, which may be taken to lie in general between the ages of 25 and 50 years, in other words, the greater the variation from the mean of those ages, the lower the tolerance. Tolerance varies directly with the weight, regardless of whether the patient is of normal development or is overweight. Normal blood pressure and pulse rate indicate average tolerance, the greater the variation from normal in these respects, the lower the tolerance. Tolerance is therefore a function of these five factors. The greater the body weight and the higher the value for hemoglobin, within normal limits, the greater the tolerance. On the other hand, the greater the variation from the mean age and the greater the departure from normal blood pressure and pulse rate, the less the tolerance. Specific examples of such combinations for different tolerances are shown below.

Tolerance	Weight	Hemoglobin	Age	Blood Pressure		Pulse Rate
				Systolic	Diastolic	
T ₁	100	40	60	110	60	96
T ₂ +	150	80	40	120	80	72
T ₄	200	95	30	130	85	64

From this formula the tolerance is estimated at the beginning of injection. If untoward results occur in spite of these precautions, the explanation may be found in several causes. Rough handling or pain may either directly or indirectly be responsible. Shock to persons susceptible to pain may be sufficient to lower their tolerance to the drug injected, or the apprehension aroused by the anesthetist's lack of skill may lead to evidence of intolerance. In many cases injection can be continued under light general anesthesia without any reaction, and tolerance is often raised by the substitution of a more skilful and confident anesthetist. Sudden untoward reactions usually are the result of direct injection into a blood vessel.

Besides these cases in which lowered tolerance is explainable there is a small number in which there is no apparent reason for the subnormal tolerance. The general robustness of the patient, his usual occupation, the particular disease he is suffering from or any functional abnormality which cannot be estimated or which may not be sufficient to be classified as a specific disease all have some influence on tolerance.

The formula is therefore provisional, it serves as a guide at the outset, and in most cases it can be followed throughout if injection is made carefully and skilfully. The reaction to the first few cubic centimeters of the

1% 100 cc 1/2 hr T2+	0.5% 200 cc 1/4 hr T1+	0.5% 200 cc 1/2 hr T1	2% 50 cc 1/2 hr T3
2% 40 cc 1/2 hr T2+	0.5% 500 cc 1/2 hr T3+	0.5% 100 cc 1/2 hr T2+	2% 7 cc 1/2 hr T2+

anesthetic is the test of its accuracy, and if there is any untoward reaction the formula must be altered. Untoward reactions may be avoided by the slow injection of the anesthetic, provided the needle has been properly placed. The relative effects of various solutions can be compared by means of the formula previously given. The values shown here are examples of the circumstances under which an injection would prob-

ably produce anesthesia without any untoward reactions. The degree of the untoward reaction to procaine hydrochloride varies directly with the rate of absorption of the drug. It is obvious, therefore, that if one used 100 cc of 1 per cent solution of procaine in a given instance one would not ordinarily use more than 40 cc of 2 per cent solution yet might use as much as 300 cc of 0.5 per cent solution under the same circumstances.

Epinephrine is generally believed to prolong the local anesthetic action of drugs such as procaine hydrochloride. There are certain conditions, however, in which its use is contraindicated, for example as has been pointed out before, for patients with exophthalmic goiter. The dental operator must also be most careful in the use of epinephrine, since it is usually in concentrated form when he uses it—that is he will add 1 or 2 drops of a strong solution of epinephrine to 1 or 2 cc of the solution of the local anesthetic to be injected. An untoward and occasionally very severe reaction may develop. Surgeons and anesthetists who add epinephrine to the local anesthetic solution occasionally encounter a patient who apparently has an idiosyncrasy to epinephrine, or perhaps too much of this agent may be given. I myself use about 6 minims (0.4 cc) of a 1:1,000 solution of epinephrine chloride or 1 cc of 1:2,600 to each 100 cc of procaine hydrochloride solution, regardless of the strength of the procaine hydrochloride solution, unless I think its use is contraindicated by the patient's general condition or unless an untoward reaction develops following injection of the first part of the solution. Probably the most satisfactory way to add epinephrine is from sterile ampules.

QUININAE ET URAE HYDROCHLORIDUM (QUININE AND UREA HYDROCHLORIDE)¹⁶ C₂₀H₂₄O₄N HCl CO(NH₂)₂ HCl 5H₂O

Quinine and urea hydrochloride should not be used for local anesthesia in stronger concentration than 0.5 per cent, as a stronger concentration than this may produce destruction of tissue. Injection should be made slowly in order to avoid a fall in blood pressure, which may reach a dangerously low level if the drug is injected intravenously. When the drug is injected hypodermically, it produces an anesthetic action which may be very prolonged, sometimes for several days. It is used because of its prolonged effect in operations on the anus, especially for hemorrhoids. It should not be used in diseased tissue or in concentrated solutions in healthy tissue. For application to mucous membranes, solutions varying in strength from 10 to 20 per cent should be used. For intramuscular injection, 1 Gm in 10 cc may be employed. Care should be exercised not to inject near important nerves.

CHLOROBUTANOL (CHLORETONE)¹⁷ C₈H₉OCl₃

Chlorobutanol as a local anesthetic is used principally to secure temporary relief from irritations and lesions in the gastric mucosa. Part of its effect, of course, is systemic. It may be used preliminary to the oral administration of ether. The dose is 10 grains (0.6 Gm).

ANTIPYRINA (ANTIPYRINE)¹⁷ C₁₁H₉O₃N

Antipyrine illustrates the close association in chemical structure between the antipyretics and the anesthetics. Antipyrine by mouth is effective in doses of 15 grains (1 Gm). On mucous membranes of the

nose and throat it has a local anesthetic effect when used in 5 per cent solution or when used as a dusting powder. It has been used in combination with small quantities of cocaine for the milder types of acute rhinitis or laryngitis. It has also been used as a local anesthetic for cystoscopy.

AETHYLIS CHLORIDUM (ETHYL CHLORIDE)¹⁷
C2H5Cl

Ethyl chloride is used as a local anesthetic and depends for its action on the physical property of freezing. Since it is very inflammable, precautions against fire are necessary in using it. It is slightly soluble in water and is freely soluble in alcohol and ether. Its specific gravity is 0.921 at 0°C, its boiling point from 12 to 13°C. Ethyl chloride is allowed to escape from its container by holding the container so that the valve is at the dependent end. The tube should be held at such a distance from the area to be anesthetized that the stream of ethyl chloride breaks into a spray at the surface of the skin. The stream should not strike the skin before it has vaporized into spray form.

There are two methods of anesthetizing the area to be incised. One is to freeze solidly the spot to be incised, and the other is to freeze a ring of tissue around the tissue to be incised. The freezing that produces the anesthesia and solidifies the tissue at the site of the incision makes extra pressure with the scalpel necessary and often painful. By freezing a ring of tissue around the area of incision it can be incised with less pressure. In attempting to use ethyl chloride as a local anesthetic in dental operations one must take the precaution of having the patient hold his breath, to avoid inhaling the vapor, if a condition of general anesthesia is to be avoided. General anesthesia with ethyl chloride can be dangerous.

MAGNESII SULFAS (MAGNESIUM SULFATE)¹⁷
MgSO4.7H2O

Magnesium sulfate has been used by lumbar subdural injection to produce spinal anesthesia in cases of tetanus. If injected intravenously or intramuscularly, it depresses the muscles and the central and peripheral nervous systems, and it may arrest respiration. Concentrated solutions of the drug have been used in the form of local applications for various inflammatory conditions such as sprains, burns and erysipelas, with allegedly beneficial results. In tetanus six daily intramuscular injections of 0.6 cc (10 minims) of a 25 per cent solution of crystalline magnesium sulfate for each kilogram of body weight may be given, or in severe cases 0.1 cc (1½ minims) of a 25 per cent solution for each kilogram of weight may be given intraspinally.²

MENTHOL¹⁷
C10H18O

Menthol affects the nerve endings that register perception of cold and it thus indirectly acts as a local anesthetic. It is used in neuralgia or headache particularly, in the form of "menthol pencils," as a cooling counterirritant, being rubbed over the painful area. As an antipruritic it is applied in an ointment or oily solution containing from 1 to 2 per cent of the drug. It is sometimes employed internally for the relief of gastric pains. It may be used in a warm mixture with camphor and olive oil for earache. The formula that has been used is menthol 7 grains (0.45 Gm.) camphor 7 grains and olive oil 1 ounce (30 cc.)

PHENOL¹⁷
C6H6O

Phenol is employed as a local anesthetic to relieve itching and is used in a 1 per cent solution or in ointment. A fraction of a drop of phenol applied to the skin will make it possible to introduce through this point a hypodermic needle with relatively little pain. It is preferable, however, to raise a wheal with procaine hydrochloride in the superficial area of the skin. Phenol is used in a 5 per cent solution with warm glycerin as a local anesthetic, in the form of ear drops for such conditions as otitis media, occasionally myringotomy is attempted, but anesthesia under such conditions is often insufficient. Because of its cauterizing properties, it is seldom used in other ways as a local anesthetic. The dose is 0.06 Gm. (1 grain). Phenol is antiseptic.

NEW DRUGS

The following discussion perhaps might well have been omitted, but the recent rapid progress in the development of local anesthetics was brought about and encouraged by certain demands, some of which are at least partly satisfied by some of the new drugs. Examples of these follow. The demand for a surface anesthetic, for example, has produced the drug butyn, which has been used for many years.

PARA-AMINO BENZOYL γ DINORMAL BUTYL AMINO PROPANOL SULFATE (BUTYN)²¹
[NH2]C6H4CO2(CH2)3N(C2H5)2.H2SO4

Good surface anesthetics are not common. One that is used with considerable satisfaction is butyn. It is used as a surface anesthetic in 2 per cent solution. It is used for anesthetizing the throat and nose by spraying, a small amount of 5 or 10 per cent solution being used. In a 5 or 10 per cent solution as a spray, butyn takes the place of a 10 to 20 per cent cocaine spray for anesthetizing the throat and larynx prior to the introduction of the intratracheal tube under general anesthesia. Butyn is also used with considerable satisfaction by ophthalmologists in an ophthalmic ointment of 2 per cent concentration.

In the use of butyn one should be on guard for idiosyncrasy, since occasions have developed when it seemed that the patient was hypersensitive to butyn. The butyn solution is somewhat irritating when instilled into the eye, and for that reason it has not become as popular as it would have otherwise. Butyn is not antiseptic. It may be used in gels and ointments, in 0.5 or 1 per cent concentration. Butyn is not habit forming.

BENZOYL γ (2 METHYLPIPERIDINO) PROPANOL HYDROCHLORIDE (METYCAINE)²¹
C6H5COO(CH2)3NC5H11.HCl

Metycaine is a good addition to the list of local anesthetic agents. It may be used as a surface anesthetic, for injection or for block anesthesia. It is quite a different substance chemically from cocaine, butyn or procaine hydrochloride. It is a little more toxic than procaine hydrochloride, but a little less of it is required and a correspondingly smaller dose may be used. It has been used rather successfully by dentists and others who develop a sensitivity to procaine hydrochloride and get a so-called procaine hydrochloride or novocain dermatitis. The potency of metycaine compared to procaine hydrochloride in clinical practice is about as 7.5 is to 10, that is, if 100 mg of procaine hydrochloride should be selected for intraspinal administration, 75 mg of metycaine would be approximately equivalent. And

thetia is said to last a little longer with metycaine than with procaine hydrochloride

Because of its chemical composition and usefulness, metycaine fills a need in anesthesia not filled by any other drug, and for that reason it is discussed briefly here. It has been used in 4 per cent concentration in an ophthalmic ointment base. It has also been used in gels and ointments in 5 per cent concentration.

Another surface anesthetic that has been introduced recently and that has a more prolonged action than those already mentioned is pantocain.²² This drug is ten times as toxic as procaine hydrochloride but is effective in one-tenth as great a dose. It has been used as a spinal anesthetic with considerable satisfaction, but it cannot be considered as safe as procaine hydrochloride. Its use might well be avoided by the inexperienced person. It is used as a surface anesthetic by instillation into the eye. It has also been admixed with procaine hydrochloride in varying proportions, and it may be incorporated in gels and ointments in 1 per cent concentration for application superficially for the relief of pain.

One other surface anesthetic is diothane. This drug has been used in 1 per cent concentration for cystoscopy and for anesthetizing the urethra. It has also been used in ointments and gels with considerable satisfaction, the concentration being 1 per cent. Untoward results appear to be uncommon, but the thirty-minute period necessary for development of good anesthesia, together with the cost of the drug, offers a practical objection to its use. I have purposely omitted nupercaine from this discussion.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING ARTICLE.

HOWARD A. CARTER, Secretary

THE INTERRUPTED LOW FREQUENCY AND THE CONSTANT ELECTRIC CURRENT IN MEDICINE

Currents belonging to this classification are widely used in medical practice and are unquestionably of value in the treatment of a limited number of conditions.

Since many machines on the market deliver several types of current, the most common types may be mentioned. The interrupted low frequency current may be unidirectional or alternating. The unidirectional currents include the ordinary galvanic current, which may be interrupted by various methods. The sinusoidal current may also be unidirectional, or in other words, one half wave of an alternating current is suppressed. The alternating currents of low frequency include the faradic and the alternating sinusoidal current. Turrell¹ and Kovacs² have described the various types of current in detail.

INTERRUPTED LOW FREQUENCY CURRENT

The theory of the action of interrupted low frequency current on the tissues is based on several well known chemical principles. Salts in solutions dissociate into

positively or negatively charged ions, which are capable of conducting the electric current. The cell protoplasm contains in addition to the inorganic ions colloidal particles, which are in suspension or solution and which may themselves be electrically charged. When the current is passed through the tissues the electrochemical changes produced may stimulate nerves or cause muscles to contract. Since muscle contraction is easily produced by interrupted currents of low frequency, they are used to treat any condition in which the exercise of muscle by electrical stimulation is desired, as in certain diseases of the nervous system.

Electrical stimulation of muscles is usually employed with other valuable physical therapeutic agents such as dry heat, massage, muscle splinting and reeducational exercises. It has to be used with these other procedures intelligently or the use of electricity may prove definitely harmful. For example, in poliomyelitis, electrical stimulation improperly used may overfatigue the weakened muscle and stimulate the tone of stronger muscles, thus interfering with muscle balance. Experiments on animals by Chor³ have verified the clinical observations on the harmful effects of electrical stimulation of paralyzed muscles in the early stage of impairment.

In peripheral nerve disease, electrical stimulation, by providing muscular exercise, may prevent atrophy and fibrosis of the muscle while the nerve is regenerating, but further experimental work is necessary before final conclusions can be made. Hartman⁴ showed that, following treatment by galvanic stimulation, there was no material difference in the atrophy of muscles between the treated and untreated denervated muscles. Bourbon⁵ advises the employment of galvanic stimulation in facial paralysis.

Galvanic stimulation is also used in the flaccid stage of hemiplegias (early), myelitis and other upper motor neuron lesions when the muscles are flaccid. Its use is of little value in combined cord sclerosis, progressive muscular atrophy and myasthenia gravis (Weisenburg and Alpers⁶). In cerebrospastic paralysis, Ryerson⁷ and Gordon and Brown⁸ are of the opinion that any form of electrical stimulation is contraindicated. Pollock⁹ states

The only requirement of electrotherapy is that it shall produce a contraction of the paralyzed muscle. Obviously, this cannot be brought about by stimulation with the faradic current, as the duration of each shock is too short in relation to the changed chronaxia of the nerve and muscle. Galvanic current must, therefore, be used. It may be used in the simple form of a continuous current, or in the form of sinusoidal currents of various types of waves.

Faradic current is used to stimulate muscles that are poor in tone but have a normal nerve supply. It was formerly much used in exercising muscles in patients undergoing the Weir Mitchell treatment of the psycho-

neuroses. In such cases exercise and massage are probably of as much value. Painful faradic stimulation has also been used in hysterical individuals as a means of fortifying or inducing suggestion. Turrell¹ has emphasized the danger that can arise from the use of the faradic current because of its tetanizing effect. This can produce overfatigue and diminished blood supply in the muscle.

Pollock⁹ says

Sinusoidal current and other forms of wave currents have only the advantage of relative painlessness. There is a seeming advantage in the fact that at times a larger electrode is used and rhythmic contractions are produced in large muscle groups. This is a disadvantage and care should be exercised to stimulate only the parietic muscles.

THE CONSTANT CURRENT

The constant, direct or galvanic current, in addition to being used for muscle or nerve stimulation, already described, is used to deposit the ions of certain salts in solution on or in the tissues. For soluble salts this process is spoken of as "common ion transfer." The term "electrophoresis" applies to the movement of colloid particles which are either electrically charged or have absorbed charged particles. The salts of heavy metals such as copper, zinc or tin are frequently used to moisten the electrodes, and the positively charged ions of zinc, for example, will move toward the cathode when the current is passed through the tissues. Locally these ions may produce precipitation of protein at one of the electrodes depending on polarity, giving the effect of cauterization. This form of treatment has been used on the mucous membranes in the field of proctology, otorhinology and gynecology. The introduction of certain drugs into the tissues from which they may be absorbed into the blood stream and exert systemic effects offers another use of this procedure. The process just described has been referred to in the literature as "ionization," a term that is entirely erroneous. It is preferable to speak of this electrochemical phenomenon as "common ion transfer" or "electrophoresis," depending on the type of electrolyte employed. It is electrochemically incorrect and clinically misleading to speak of this method as "surgical ionization" when a caustic effect is desired and as "medical ionization" when drugs are introduced by this method for systemic effects.

It has been claimed that certain potent pharmacologic agents such as histamine may be introduced into the body by the constant current. A few reports concerning this matter have appeared in recent medical literature. These workers¹⁰ are enthusiastic, but their work seems to lack adequate control. They also have expressed the belief that it produces a greater local vasodilatory effect in the joint over which it is introduced. This point can be little more than pure conjecture.

Kling¹¹ has used histamine by iontophoresis. He has expressed the opinion that this method is superior to the subcutaneous injection of the drug or to the effect of histamine ointment massaged into the skin. Kling has discussed the systemic reaction which may be dangerous if the current is not properly controlled.

Kotkis, Melchionna and their co-workers¹² were able to demonstrate experimentally on dogs that the action of acetyl-beta-methyl-choline chloride introduced by common ion transfer was not a locally controlled reaction but a systemic reaction. They "undertook this experimental study on account of some very marked general reactions resulting from the routine clinical administration of acetyl-beta-methyl-choline chloride by iontophoresis in chronic arthritis." They claimed that the rapidity of action and duration of the effects varied directly with the intensity (milliamperage) and duration of the current. These reports would seem to indicate that this method of treatment may be suitable for certain circulatory or joint conditions, provided further controlled clinical studies give these same results, but that the method in the hands of the inexperienced is not without certain dangers.

The constant current may produce reflex vasodilatation by its stimulating action of sensory nerve endings. It may thus act on the skin like other counterirritants, such as a blister or ultraviolet radiation. Some believe that the constant current is superior to most counterirritants, because it can produce a gradual and more constant action on the skin without destructive effects.

Except in a few conditions, the recent literature would not give an unbiased reader the impression that in the fields of proctology, gynecology and otorhinology local destruction of tissue by this method has any particular superiority over other methods of treatment. As a matter of fact, few clinicians have compared the results obtained by this method with those obtained by other methods in the same type of case, so that evaluation from a strictly scientific point of view is difficult.

Electrolysis is used extensively in dermatologic practice. For hypertrichosis, exceedingly thin needles specially made for the purpose are obtainable. Some physicians prefer to use multiple needles. However, the majority prefer a single needle because of better control of result. The inactive positive electrode is of the sponge type, it should be wet with sodium chloride solution and may be held in the patient's hand.

MacKee¹³ considers electrolysis to be the best treatment for the spider nevus. All that is necessary, he states, is to puncture the central dark spot with the point of the needle. There should be no scar. He states that in telangiectasia, when the vessels are small and not too numerous, they may be occluded as a result of electrolysis and that, if this is carefully done, there will be little or no scarring.

In the field of proctology a survey by questionnaire was conducted by the American Proctological Society in the year 1934. The purpose of this survey was to determine the value of physical therapy in rectal diseases. The results of this survey, reported by Kallet¹⁴ indicated that the use of the direct current as already described, in proctology was very unsatisfactory and did not give as good results as other simpler and less time-consuming methods. Reports by Black,¹⁵ DeBere¹⁶

and Terrell¹⁷ state that in hemorrhoids and pruritus the direct current is not a satisfactory method of treatment

The use of common ion transfer of salts of heavy metals in gynecology is not as prevalent as it was several decades ago. Few reports appear in the recent literature. From theoretical considerations of the action of the electric current there is no doubt that cauterization of the mucous membranes can be accomplished by this procedure. The value of the method would depend on its safety, effectiveness and adaptability as compared with other methods used in the same type of case. Common ion transfer of copper salts in cervicitis is a method of cauterization which cannot be justly evaluated until further reports reveal how the results obtained by that method compare with those obtained in similar cases treated by surgical methods, the cautery or local drug cauterization.

In otorhinolaryngology, the same type of therapy has not only been more widely used in recent years but has found favor in the reports of many authors. The method is used in hay fever and allergic conditions, hyperesthetic rhinitis, intumescent rhinitis and chronic otorrhea. In rhinology, Hollander,¹⁸ the Alexanders,¹⁹ Volk,²⁰ Alden,²¹ Demetriades,²² Franklin,²³ Warwick,²⁴ Stovin,²⁵ Hurlburt,²⁶ Miller,²⁷ Cottle,²⁸ Tobey,²⁹ and Garfin and Pearl³⁰ feel that this method used on the nasal mucous membranes gives satisfactory results in the treatment of hay fever and rhinitis of allergic or vasomotor origin. Fibrosis of the submucosa of the nasal mucous membranes without permanent destruction of surface epithelium has been produced by common ion transfer of zinc salts. This has been proved histologically in both animal and man (Alden²¹).

It is questionable whether the effect of this method is anything more than a cauterization of the nasal mucous membrane. Schall³¹ states that Palmer treated "a group of thirty patients with vasomotor rhinitis by a local application of concentrated phenol. The immediate effect of this treatment was exactly that which was obtained by the galvanic instrument of Warwick, in that the mucous membrane showed a grayish white discoloration followed by edema and obstruction with hypersecretion. Palmer had excellent cooperation from his patients, as they voluntarily permitted biopsies to be taken. The microscopic examination revealed that

there was an increase in the connective tissue of the tunica propria with a diminution of the edema and vascularity. Of thirty cases treated by Palmer, twenty-four showed definite improvement and twelve were free from symptoms for periods of from three to nine months.

Fenton bluntly states that "ionization as such does not do anything more than damage the mucosal tissues of the sinuses."

Most of these authors feel that proper case selection is essential to good results. Hollander²² believes that the introduction of ionic zinc in allergic rhinitis is only palliative and not curative. The results obtained in seasonal hay fever, according to the same author, are less satisfactory, whereas in nonallergic nasal cases the results are excellent.

It would be highly desirable to know what is the consensus among allergists concerning the use of this method on the nasal mucous membranes in allergic disorders. The recent report by Duke³³ tends to throw doubt on claims made for the method, especially in the year 1933, when the amount of pollen in the atmosphere was much below the usual amount. The work of the Alexanders¹⁹ suggests that the relief obtained by this method is due to the mechanical removal of antibodies from the nasal mucous membranes. They further contend that the results are better if patients have no reagins in the blood. The usual methods of treatment used by allergists are also not uniformly satisfactory or entirely free of danger. The conclusion reached by Hurd³⁴ concerning the entire question of this method in rhinology is conservative but not destructive. He is of the opinion that the method has not been used long enough at the present time for determination of its actual value and dangers. Ramirez³⁵ has reported disappointing results obtained by this procedure in the treatment of hay fever, but in the treatment of non-specific perennial vasomotor rhinitis the results have been satisfactory.

In otology sufficient evidence on the use of this method is not available to place it on a firm scientific basis, according to Hollander,³⁶ although he admits that it may be good in selected cases. It seems to be of the most value in treating chronic purulent otitis media or chronic otorrhea. Favorable reports have been made by Friel,³⁷ Granberry,³⁸ MacFarlan,³⁹ Jobson⁴⁰ and many others. Lierle⁴¹ does not give the favorable and often enthusiastic report made by some of the other investigators. In the entire field of otorhinolaryngology, further work in the future will place this electrical method in its proper niche among the many therapeutic methods used.

POTASSIUM METABOLISM AND ADRENAL INSUFFICIENCY

In the short time that has elapsed since the discovery of the hormone of the adrenal cortex, various conjectures concerning its physiologic functions have been advanced. It has been regarded as a general cellular hormone, as regulating the volume and fluid content of the blood, and, most recently, as having a specific regulatory effect on the excretion of sodium by the kidney. The latter concept is supported by a wealth of experimental and clinical evidence, which was reviewed by Loeb¹ in *THE JOURNAL* a year ago. The most striking feature of experimental and clinical adrenal insufficiency is loss of sodium ions from blood and tissue with equivalent loss of extracellular fluid. The condition may be corrected by the administration of sodium salts and adrenal cortex extract, singly or in combination. However, it has been found difficult to maintain adrenalectomized animals and patients who have Addison's disease in an entirely normal condition and with a normal blood electrolyte pattern by supplying sodium ions alone, a fact which has extended the scope of investigation to a consideration of the other metabolic disturbances accompanying adrenal insufficiency.

Abnormalities of potassium metabolism have proved difficult to reconcile with current ideas, although it has been conceded that alterations in the sodium-potassium ratio in blood and tissue may be important. The serum potassium of the experimentally adrenalectomized animal and of patients who are in the crises of Addison's disease is elevated, the increment exceeding that which could be explained on the basis of loss of fluid and hemoconcentration but rarely reaching the levels noted in potassium poisoning. These increases in serum potassium are not necessarily parallel to the degree of depletion of sodium and may at times be present even when other electrolytes of the blood have been returned to normal by the administration of

sodium salts. Allers² and Kendall³ were first to show that adrenalectomized animals could be thrown into crises of adrenal insufficiency by the addition of potassium to their diet, even while adequate supplies of sodium salts were provided, and, conversely, that a low intake of potassium in the diet was of great importance in maintaining such animals in optimal condition, with normal blood electrolytes. Their studies have been confirmed and extended by Zwemer and Truszkowski,⁴ who also have demonstrated the extreme sensitivity of adrenalectomized animals to potassium salts. These investigators have produced experimental potassium poisoning of normal animals by repeated intraperitoneal injections of potassium chloride; they found that the condition has symptoms and signs which differ in no important respect from those seen in adrenal insufficiency. Such studies seem to indicate that at least one additional function of the adrenal cortex is a regulatory one on potassium metabolism.

Proceeding from the experimental laboratory to the field of clinical medicine, there is ample evidence to support this contention. Observations⁵ on patients with Addison's disease demonstrate that a low intake of potassium will protect the patient to a considerable extent against withdrawal of sodium salts, a procedure which almost invariably precipitates a crisis of adrenal insufficiency with corresponding changes in the electrolytes of the blood. Likewise, even a high intake of sodium alone will not suffice to prevent such crises if sufficient potassium salts are administered, and even moderate reductions in the daily salt ration have been shown to provoke symptoms unless the potassium content of the diet is simultaneously reduced. Analysis of the electrolyte balance in these cases indicates that a high intake of potassium is associated with rapid loss of sodium and chloride, while a low intake of potassium favors the retention of these ions. There is some evidence to show that sufficient quantities of adrenal cortex extract appear to minimize the effect of a high intake of potassium and to reduce the loss of sodium which takes place under these conditions.

Studies on sodium balance in adrenal insufficiency will have to be reconsidered with respect to the intake of potassium, which is capable of greatly modifying the excretion or retention of sodium, other factors remaining constant. If deprivation of sodium is to be used as a diagnostic procedure in suspected cases of Addison's disease, the potassium content of the diet will have to be determined if the results are to be properly interpreted. It would appear that patients who have

Addison's disease should be greatly benefited by a low dietary intake of potassium. Observations in a limited number of cases already have shown that such treatment is of decided advantage, the treated patients require less extract and sodium salts and are less subject to sudden relapses.

A clear explanation of the interrelationships of sodium and potassium metabolism in their bearing on adrenal cortical function is not yet available. The hormone may simply protect an organism against the toxic action of potassium salts, it may favor elimination of potassium by the kidney and thus prevent the accumulation of this ion in quantities sufficiently great to exert a toxic action, or it may have a direct effect on tissue cells, preventing the liberation of the intracellular electrolytes, chief of which is potassium. Until more evidence is obtained, investigators of the physiology of the adrenal glands doubtless will continue to follow the advice of von Sachs, who counseled that "the object of true investigation is to make unsparing discovery of existing contradictions and to question the facts until our conceptions are cleared up, and if necessary the whole theory and general view is replaced by a better."

THE NEW YORK DIABETES ASSOCIATION

Late in 1935 the New York Diabetes Association was organized to function as part of the New York Tuberculosis and Health Association. This association was an outgrowth of the current realization that diabetes, for which highly effective means of control are available, should not cause the tragedies for which it continues to be responsible. The objectives in general are educational—of the general public, of diabetic patients and of physicians. The association seeks to inform the public of the common symptoms of diabetes, the necessity for early and adequate medical care, and the relative parts played in diabetes by insulin, obesity, lack of physical activity, and heredity. Attempts are being made to teach diabetic patients the effectiveness of diet and insulin therapy in making life a normal one, the fallaciousness of common fears concerning the use of insulin, the importance of continuous medical supervision, the dangerous nature of advertised nostrums, the necessity for proper care of the feet, and the advisability of those who are taking insulin carrying a card stating this fact and giving the identification and dosage. The organization is also interested in making insulin available within the means of all who require it, the improvement of surgical service, the investigation of clinic and hospital facilities, the improvement of record keeping in diabetes clinics, the execution of original statistical studies, and cooperation with the dental profession.

In the first annual report,¹ dated March 1936, there is a discussion of the progress made toward these

objectives and the further lines of work indicated by the early experiences of the association. Committees dealing with the special objectives outlined seem to be, in the main, an effective method of organization. Under the direction of the committee on internal medicine, a survey of the diabetic clinics in New York City was made. This committee planned the first meeting of the clinical section and projected a series of eleven pamphlets for the education of physicians, some of which have already been published. The committee also initiated studies of nostrums and new remedies, of the history and physical examination, and of plans and diets used in diabetic clinics, and also collaborated with the chairman of the committee on lay education in the preparation of a pamphlet on helpful information for the diabetic patient. The committee on surgery studied by means of a mail questionnaire the organization of diabetic surgery in the general hospitals of greater New York. The Committee on Lay Education has published a booklet of helpful information for diabetic patients printed by the department of health and adhering strictly to professional limitations. A study of the incidence of diabetes in certain groups, namely, (a) colleges and universities, (b) industrial groups, and (c) the New York State National Guard, was begun by the Committee on Statistics. Further statistical studies under the auspices of this committee were either completed or in progress at the time of the annual report. The other major activities of the association during its first year consist in the publication of two brief notes for the medical profession on the treatment of diabetic ketosis and on insulin. An exhibit was prepared in cooperation with the New York City department of health to show the magnitude of the diabetes problem in New York, the various causative factors involved and some of the steps that are being taken toward the control of this disorder. These charts were shown initially at the annual session of the American Medical Association and have since been shown at a number of other meetings. A directory of the diabetes and metabolism clinics of New York City has been compiled. Several radio addresses have been given, and one, that by James Ralph Scott, which is a general discussion of the diabetes problem for the public, is included in the mimeograph collection of the association.

Although the initial organization of this association has been aided by a private grant, there is very little in the work proposed that could not be similarly initiated in other large cities throughout the country. If this is done, however, pooling of information and avoidance of duplication should be seriously considered. The exact extent of the need for the various activities outlined is not yet clearly evident, though it is obvious that, in a disease which can be controlled as definitely as diabetes, the need of educational and economic study must be considerable. The large scale effort that is evidenced by the organization and initial reports of this

¹ Publications of New York Diabetes Association 386 Fourth Avenue New York.

association will doubtless receive wide interest and study. The tremendous medical and economic gain which must accrue from this work probably will not be realized, however, until after the activities have been in force for several years.

WATER FILTRATION VS CHLORINATION

A tendency is manifest in some quarters to advocate filtration of public water supplies as against chlorination. In the interests of public health and clear thinking, it seems worth while to examine the merits of this discussion. The value of chlorination in preventing water-borne infections needs no defense, as shown by the experience of many American municipalities using chlorinated water during the past ten years. Is filtration to be preferred? Filtration of a public water supply cannot guarantee the continued safety of that supply. In point of fact, some of the classic outbreaks of water-borne diseases, such as the Altona, Germany, cholera epidemic of 1892, have been caused by supplies supposedly guarded by a filtration process. In most instances today, wherever large water supplies are filtered, it is thought advisable to chlorinate the effluent as an additional or final safeguard. In general, if a community had to depend for health protection on filtration alone or chlorination alone, chlorination probably would be chosen.

Filtration possesses one obvious advantage—it can clarify a turbid water. There is no doubt that clear water makes a strong esthetic appeal. The expense of gratifying this feeling by clarifying the whole public supply is, however, considerable. Crystal clear water is not necessary for all household purposes. Where money is an object, the value of a clear water supply would probably be balanced against the urgency of other community needs.

Any method of water treatment calls for unceasing expert supervision. No water supply, whether it is initially pure or is well purified, can be trusted to take care of itself. Wolman and Gorman¹ have done a great service in pointing out the inadequacy of administrative control over the safety of water supplies in the United States and Canada. Failure to prevent the contamination of initially pure ground or surface water supplies and especially the failure to recognize the danger of cross connections between the pipes of the public water supplies and the pipes supplying water for industrial purposes or for fire protection have caused hundreds of outbreaks of water-borne disease. Wolman and Gorman conclude that "defects in collection, treatment, storage or distribution of water for public consumption are responsible for over three fourths of the water-borne illness reported in the United States during the decade 1920 to 1929. Approximately 40 per cent of the outbreaks were due to these defects and not

to the pollution of the raw water at its source." The analysis of these waters makes it plain that no method of collection, treatment or distribution is fool proof and that constant checking for defects is highly desirable.

A clear water is not necessarily free from disease germs. Neither is a water that is at times slightly turbid necessarily death dealing. If a bacteriologically safe drinking water is desired, it may be obtained by chlorination. If clarity is essential, filtration may be employed at somewhat greater expense.

Current Comment

THE RÔLE OF RENAL ISCHEMIA IN HYPERTENSION

Hypertension for scores of years has eluded the concerted efforts of many capable investigators, but, with the recent introduction by Goldblatt¹ of reliable means of producing sustained increase in blood pressure of experimental animals, progress has been rapid. The method consists in reducing the blood flow to the kidneys by compression of the renal arteries, this is accomplished with adjustable silver clamps of ingenious design applied to the vessels with specially devised instruments. The increase in blood pressure thus produced lasts indefinitely. Use of the Goldblatt clamp therefore enables workers for the first time to investigate the phenomena associated with hypertension and to differentiate etiologic from secondary factors. Although but a short time has elapsed since this fundamental contribution was described in the literature, the results of the Western Reserve investigators¹ have already been confirmed and amplified in many other laboratories. Wood and Cash² conclude, from their extensive studies, "Of several methods hitherto used to produce sustained arterial hypertension in dogs, renal ischemia, as accomplished by the Goldblatt clamp, has proven to be the most reliable and effective procedure." There is thus no doubt that a highly significant step has been made toward the solution of the problem posed by this serious degenerative disease of middle age. The earlier studies on this question were concerned with the production of systolic hypertension, this may reach from 200 to 245 mm of mercury, occasionally approaching 300 mm.³ More recent investigations,⁴ especially those of Wood and Cash, have demonstrated conclusively that renal ischemia produces a definite continued rise in diastolic pressure also. The similarity of the condition induced experimentally in animals to that occurring in human beings is thus evident. The rise in pressure is apparently not due to a

nervous mechanism, excision of the splanchnic nerves⁵ or denervation of the kidneys⁶ does not prevent or ameliorate the syndrome. A humoral mechanism is probably implicated, as suggested by Goldblatt, studies now in progress should provide an early answer to this question.

Association News

RADIO BROADCASTS

The American Medical Association and the National Broadcasting Company are presenting the second series of dramatized health broadcasts under the title *Your Health*. The first broadcast in the new series, the thirty-second dramatized cooperative broadcast under the title *Your Health* was given October 13. The theme for 1936-1937 differs slightly from the topic in the first series, which was "medical emergencies and how they are met." The new series is built around the central idea that "100,000 American physicians in great cities and tiny villages, who are members of the American Medical Association and of county and state medical societies, stand ready, day and night, to serve American people in sickness and in health."

The program will go out on the Blue network instead of the Red, as originally announced. The announcement cards that were sent out when the program was planned for the Red network can be changed simply by substituting the word "Blue" for "Red" where it occurs.

The topics are announced monthly in advance in *Hygeia* the Health Magazine, and three weeks in advance in each issue of *THE JOURNAL*. The topics and speakers for the next three programs are as follows:

November 3 Community Sanitation Morris Fishbein M D
November 10 Noise Morris Fishbein M D
November 17 Football Injuries Morris Fishbein M D

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ALABAMA

Poliomyelitis Epidemic Ended—It was reported October 8 that the epidemic of infantile paralysis was at an end and that 100 WPA nurses had been withdrawn.

Society News—At a meeting of the Northwestern division of the Medical Association of Alabama in Florence, October 15, the speakers included Drs. Horton R. Casparis, Nashville, Tenn., on "Allergy in Children"; Frank L. Chénault, Decatur, "Skeletal Traction"; Joseph E. Hirsh, Birmingham, "Diagnosis and Treatment of Coronary Thrombosis"; James G. Daves, Cullman, "Tuberculosis As I Have Found It," and Price Clayton, Russellville, "Hypertension Without Edema."

ARKANSAS

District Meetings—At the semiannual meeting of the Third District Medical Society in Forrest City, October 16, the speakers were Drs. Otis S. Warr, Memphis, Tenn., "Diagnosis and Management of Acute Circulatory Failure"; Walter A. Ruch, Memphis, "Maternal Mortality"; Silas C. Fulmer, Little Rock, "Hypertension"; and Edward Clay Mitchell, Memphis, "Urinary Infections in the Child."—The First Councilor Medical Society was addressed in Paragould, October 15, by Drs. Fenton L. Husbands, Blytheville, on "Modern Management of Traumatic Surgery"; Elmer E. Francis, Memphis, "The Ruptured Appendix"; Benjamin F. Turner, Memphis, "Medical Ethics and Medical Economics"; Charles T. Cham-

berlain, Fort Smith, "Heart Disease Secondary to Chronic Pulmonary Disease," and Thomas P. Foltz, Fort Smith, "Bronchiectasis."—At a meeting of the Fifth Councilor District Medical Society in Mount Holly, October 8, Drs. George B. Fletcher, Hot Springs National Park, discussed medical problems in Arkansas; Sidney J. Wolfermann, Fort Smith, duodenal ulcer; William R. Brookshier, Fort Smith, present status of radium therapy; and Ralph Bowen, Oklahoma City, recent advances in allergy.

CALIFORNIA

Society News—The Sacramento Society for Medical Improvement was addressed, September 15, by Dr. Edmund W. Butler, San Francisco, on "Injuries of the Chest and Abdomen That May Cause Early Death—Diagnosis and Treatment."—Dr. Hugh J. Bolinger, Lodi, addressed the San Joaquin County Medical Society, September 3, on "Psychoanalysis from the Viewpoint of the General Practitioner," and Dr. Charles P. L. Majhe, San Francisco, "Diagnosis and Treatment of Obstructive Lesions of the Kidney."—Dr. Clarence T. Roome, Santa Barbara, among others addressed the Santa Barbara County Medical Society, September 14, on "Aseptic Meningitis."—At a meeting of the Solano County Medical Society recently Dr. Joseph E. Tillotson, Woodland, spoke on "Fractures and the Causes of Poor and Fibrous Union."

Annual Symposium on Heart Disease—The heart committee of the San Francisco County Medical Society will hold its seventh annual postgraduate symposium on heart disease, November 18-19. There will be morning, afternoon and evening sessions covering the various aspects of heart disease including diagnosis, prognosis and treatment. Recent advances in cardiology will be reviewed and evaluated and clinics with practical demonstrations will be held. At the committee's annual meeting, November 19, Dr. John C. Ruddock, Los Angeles, president of the California Heart Association, will give an illustrated address, and Dr. Eugene S. Kilgore, San Francisco, will discuss the cardiac cripple in industry. Further information may be obtained from the secretary, Dr. William Dock, 604 Mission Street, San Francisco.

ILLINOIS

Society News—Dr. Clayton J. Lundy, Chicago, addressed the Kankakee County Medical Society, October 8, on angina pectoris.—The Adams County Medical Society was addressed, October 12, by Dr. Helmuth H. Kramolowsky, St. Louis, on "Importance of Urologic Diagnostic Procedures."—Dr. William C. Stude, St. Louis, discussed "Indications and Technique of Hysterectomy" before the Peoria City Medical Society, October 20.—At a meeting of the Will-Grundy County Medical Society in Joliet, October 14, Dr. Edward D. Allen, Chicago, spoke on "The Influence of Medical and Surgical Disease on Obstetric and Fetal Mortality."—Dr. Merritt Paul Starr, Chicago, discussed endocrinology before the McHenry County Medical Society, October 14.

Chicago

Personal—Cloyd James Head, president of the Year Book Publishers, Inc., died, October 14, aged 77. Death was caused by pellagra thought to have been secondary to a metastasizing tumor discovered post mortem in the intestinal wall near the appendix. In 1901 Mr. Head, with his brother, the late Dr. Gustavus P. Head, founded the Practical Medicine Series of Year Books.

Society News—Dr. Joseph Imre Jr., Budapest, addressed the Chicago Ophthalmological Society, October 19, on the operation for detachment of the retina and plastic surgery of the eyelids.—Dr. Walter Schiller, Vienna, spoke before the Chicago Gynecological Society, October 23, on "Pathology of the Cervix." Dr. Frank W. Lynch, professor of obstetrics and gynecology, University of California Medical School, San Francisco, also spoke, among others.—The Chicago Laryngological and Otolological Society was addressed by Drs. Lawrence J. Lawson, Evanston, Ill., on "Osteomyelitis of the Sphenoid Bone with Report of Two Cases"; Robert B. Lewy, "Intravenous Use of Local Anesthetic Agents in the Treatment of Trinitus Aurium"; and Robert Sonnenschein, "Brief Consideration of the History of the Development of Mastoidectomy."—The Chicago League for the Hard of Hearing sponsored a series of programs in observance of National Hearing Week, October 25-31.—Dr. Peter Bassoe will deliver the presidential address before the twenty-first annual meeting of the Institute of Medicine of Chicago, December 1; his paper is entitled "A Sketch of the Development of Psychiatry and Neurology in Chicago."

IOWA

Annual Clinic—The University of Iowa College of Medicine, Iowa City, will present its annual clinic, November 12-14. The speakers will be

Dr. Philip C. Jeans, Syphilis
Dr. Cecil S. O'Brien, Ophthalmology in the General Practice of Medicine
Dr. Ernest E. Irons, Chicago Pneumonia
Dr. Ruben Nomland, Epitheliomas of the Skin, Diagnosis and Treatment
Dr. Nathaniel G. Alcock, Genito-Urinary Diseases
Dr. Vernon C. David, Chicago Peritonitis
Dr. Everett D. Plass, Obstetrics
Dr. Andrew H. Woods, The Lesser Degrees of Mania and Melancholia
Dr. William Malamud, Neurasthenia.
Dr. Arthur Steindler, Diagnosis and Treatment of Compression Paraplegia
Dr. Dean M. Lierle, Otolaryngology
Dr. Clarence E. Van Epps, Neurology

Dr. Fred M. Smith will direct a symposium on peptic ulcer, while demonstrations and clinics on low back pain, arthritis, osteomyelitis of the spine, fracture deformity of the upper extremity, subdeltoid bursitis, treatment of infantile paralysis, fractures, pulmonary tuberculosis and special diagnostic measures in neurosurgery will form the remainder of the program. A smoker will be held at the Fine Arts Building Friday evening, and visiting physicians will attend the Purdue-Iowa football game Saturday.

KANSAS

Personal—Dr. Ralph M. Fellows, Topeka, has been appointed superintendent of the Osawatimie State Hospital to succeed Dr. Francis A. Carmichael, who resigned August 1.

Venereal Disease Committee—The Kansas Medical Society will appoint a committee on venereal diseases to act in an advisory capacity to the state board of health in the development and execution of programs throughout Kansas. This action followed a conference between representatives of the state board of health and the state medical society.

Society News—Dr. Charles F. Taylor, Norton, discussed pulmonary tuberculosis before the Sedgwick County Medical Society, Wichita, October 20. Drs. David W. Basham and Edwin H. Terrill, Wichita, spoke on aberrant thyroid and pernicious anemia, respectively, at the October 13 meeting.—The Atchison County Medical Society sponsored a diphtheria immunization campaign during October.—Dr. Oliver C. Wenger, St. Louis, U. S. Public Health Service, discussed "Diagnosis and Treatment of Syphilis" before the Shawnee County Medical Society, September 8.—The Washington County Medical Society was addressed in Washington, September 15, by Dr. Franklin R. Croson, Clay Center, on "Acute Intestinal Obstruction".—At a meeting of the Ford County Medical Society in Dodge City, September 11, Drs. Thomas G. Orr, Kansas City, Mo., and Lewis G. Allen, Kansas City, discussed "Diseases of the Biliary Tract" and "Radiologic Diagnosis of Conditions of the Upper Abdomen" respectively.—Dr. Lewis W. Angle discussed intestinal obstruction before the Wyandotte County Medical Society, Kansas City, October 19, and Dr. Lawrence E. Growney, abdominal pain.

KENTUCKY

State Medical Election—Dr. Henry Gilbert Reynolds, Paducah, was named president-elect of the Kentucky State Medical Association at its annual meeting in Paducah, October 9, and Dr. Joseph D. Northcutt, Covington, was installed as president. The 1937 meeting will be in Berea. Vice presidents elected were Drs. James H. Pritchett, Louisville, Harland V. Usher, Sedalia, and Branhram B. Baughman, Frankfort. It was voted to place oil portraits of Dr. Arthur T. McCormack, Louisville, secretary of the association for many years, and of his father, the late Dr. Joseph N. McCormack, in the memorial building to Dr. Ephraim McDowell at Danville. The elder Dr. McCormack, who died in 1922, was a pioneer in public health work, he was for several years a member of the House of Delegates of the American Medical Association and assisted in the reorganization of the Association in the early years of the century.

MAINE

Society News—Dr. Edwin T. Wyman, Boston, discussed the acute stage of infantile paralysis before a joint meeting of the Penobscot, Somerset and Piscataquis county medical societies August 13. Dr. Arthur T. Legg, Boston, gave an illustrated address on the orthopedic treatment of the disease.—William T. Bovie, Ph.D., of Colby College, Waterville, addressed the Kennebec County Medical Association, September 10, on "Effect of Light on Plant Growth."

Board in Charge of State Journal—With the resignation of Dr. Edwin W. Gehring, Portland, as editor-in-chief of the *Maine Medical Journal*, it was decided to turn the management of the journal over to the editorial board which, although appointed a few years ago, has never been active. Six members, one from each councilor district, constitute the board. At a meeting, September 13, Dr. Frank H. Jackson, Houlton, was chosen chairman. Dr. Gehring became editor for one year in 1935, following the expiration of his term of office as president of the Maine Medical Association.

MASSACHUSETTS

Personal—Dr. Albert M. Wigglesworth, for eleven years on the staff of the U. S. Veterans' Hospital, Rutland Heights, has been transferred to the veterans hospital at Otten, N. C.—Dr. Arthur Berk has been appointed an assistant professor of psychiatry at Tufts College Medical School, Boston.

Society News—Dr. William Richard Ohler, Boston, will discuss "The Clinical Interpretation of Laboratory Procedures" before the Pentucket Association of Physicians, Haverhill, November 12.—Dr. Allen O. Whipple, New York, will address the William Harvey Society of the Tufts College Medical School, November 6, on "Recent Advances in Surgery of the Pancreas." Dr. Frederick J. Taussig, St. Louis, discussed "The Control of Abortion" before the society, October 20.

Sedgwick Medal Awarded to Dr. Russell—Dr. Frederick F. Russell, lecturer in preventive medicine and hygiene and epidemiology, Harvard University Medical School, and professor of preventive medicine and epidemiology, Harvard School of Public Health, Boston, has been awarded the Sedgwick Memorial Medal of the American Public Health Association. The medal is given annually for distinguished service in public health. Dr. Russell was formerly general director of the International Health Board of the Rockefeller Foundation (*THE JOURNAL*, July 20, 1935, p. 209).

Memorial to Dr. Bullard—A plaque was dedicated to the memory of the late Dr. William Norton Bullard, September 19, on the ninth floor of the Medical Building at the Boston City Hospital, Boston. The floor is given over to the William Norton Bullard Memorial Laboratories and the offices of the neurologic unit. The presentation of the plaque was by Mrs. Bullard, the speakers included Drs. Stanley Cobb, Bullard professor of neuropathology, James W. Manary, superintendent of the hospital, Donald Munro, chief of the neurosurgical service, and Merrill Moore. Dr. Bullard, who was connected with the hospital from 1886 to 1906, established the chair in neurology at Harvard which now bears his name. He died in 1931.

MICHIGAN

Department of Industrial Hygiene—A bureau of industrial hygiene has been created in the Michigan Department of Health, with John M. Hepler, C.E., as director. A preliminary survey of plant conditions to determine the scope of existing industrial hazards, the location of potential hazards, and to evaluate the need for preventive measures is being undertaken by the bureau. One phase of the program will be the collection and analysis of case records of industrial diseases.

Society News—Dr. Everett D. Plass, Iowa City, addressed the medical section of the Wayne County Medical Society, October 12, on "The Induction of Labor." The society was addressed at a general meeting, October 19, by Dr. Roy W. Scott, Cleveland, on "Latent Syphilis as a Cause of Heart Disease."—At a meeting of the Kalamazoo Academy of Medicine, October 20, Dr. James H. Maxwell, Ann Arbor, spoke on "Dysphagia."—Dr. Paul S. Barker, Ann Arbor, discussed "The Use of Digitalis" before the Oakland County Medical Society in Pontiac, October 20.—Keys were presented to the fourteen living past presidents of the Michigan State Medical Society at the society's annual president's dinner, September 23.

MISSOURI

Symposium on Oxygen Therapy—The Jackson County Medical Society, Kansas City, conducted a symposium on oxygen therapy, October 13. Dr. Alexander J. Kotkis introduced the following speakers:

Alrick B. Hertzman, Ph.D., St. Louis, Physiology of Oxygen Want
J. I. Banash, consulting engineer, Chicago, Mechanical Considerations of Oxygen Therapy Apparatus.
Dr. M. Herbert Barker, Chicago, The Clinical Response to Oxygen Therapy.

The society was addressed, October 27, among others, by Drs. Morris Polsky and Paul F. Stookey, Kansas City, on "Primary Syphilis in the Female."

Social Hygiene Week—The Missouri Social Hygiene Association is sponsoring a social hygiene week in St. Louis November 1-7. There will be five open meetings with the following speakers:

Dr. Richard S. Weiss November 1. A Tribute to the Pioneers of Social Hygiene.
Drs. Park J. White Jr., Jean V. Cooke and John V. Lawrence Mrs. Pearl Case Blough and Rev. Truman B. Douglass November 4. A New Outlook on Age Old Problems.
Dr. Llewellyn Sale November 5 (subject not announced).
Dr. Paul J. Zentay November 6. Are We Facing the Realities in Social Hygiene?

There will be a conference on sex education at Washington University School of Medicine, November 7.

NEBRASKA

Personal—Dr. Charles McMartin has been appointed chairman and head of the department of surgery at Creighton University School of Medicine, Omaha. Dr. McMartin, who was professor of dermatology and urology, has been acting chairman of the department. Dr. Clayton F. Andrews, Lincoln, has been appointed to the medical advisory board of the compensation court of Nebraska.

Society News—Speakers before the Madison Six Counties Medical Society at West Point, September 15, were Drs. Alfred W. Adson and Andrew B. Rivers, both of Rochester, Minn., on "Diagnosis and Treatment of Spinal Cord Tumors" and "Treatment of Peptic Ulcer" respectively. The Gage County Medical Society has new quarters in the Lutheran Hospital, Beatrice, at the first meeting of the season, September 9. Dr. Clifford P. Fall led the discussion of obstetric complications. Dr. Ralph Bowen, Oklahoma City, addressed the Elkhorn Valley Medical Society in Norfolk, among others, recently, on "Recent Advances in Allergy." The Southwest Nebraska Medical Society was addressed, September 17, by Drs. Charles M. Swab on "Eye Strain Symptom Complex" and James W. Martin, "Fracture of the Leg." Both are of Omaha. Drs. Thomas P. Findley Jr., St. Louis, and Payson S. Adams addressed the Omaha-Douglas County Medical Society, Omaha, October 13, on "Clinical and Experimental Studies in Diseases of the Kidneys" and "Conservative Treatment of Surgical Kidney Disease" respectively.

NEW YORK

Eastman Memorial Lecture—Archibald V. Hill, Sc.D., Foulerton professor of research, Royal Society Institute of Physiology, University College, London, gave the Eastman Memorial Lecture at the University of Rochester School of Medicine and Dentistry, October 11. The subject of the lecture, established in memory of the late George Eastman, head of the Eastman Kodak Company and a benefactor of the university, was "Nerve Excitation."

Society News—Dr. Abraham J. Rongy, New York, addressed the Mount Vernon Medical Society, October 8, on ectopic pregnancy. At a meeting of the Syracuse Academy of Medicine, October 20, Drs. John Van Duyn II and John C. Frey spoke on "The Significance of Low Marrow Reserve" and "Relation of Blood Pressure to Vomiting in Spinal Anesthesia" respectively. Dr. George B. Andrews presented an unusual case of jaundice. Dr. Richard H. Overholt, Boston, addressed the Chautauqua County Medical Society, Chautauqua, September 22, on "Diseases of the Chest and Their Surgical Treatment." Dr. Theron W. Kilmer, police surgeon, Hempstead, L. I., addressed the Medical Society of the County of Monroe, October 13, on "The Drunken Driver." Dr. John Alkman will address the Rochester Pathological Society, November 19, on "Cyanosis of the New-Born."

New York City

First Adam Miller Lecture—Sir Joseph Barcroft, professor of physiology, Cambridge University, gave the first Adam Miller Memorial Lecture at Long Island College of Medicine, October 8, on "Development of Fetal Respiratory Movements." The lectureship was established in honor of the late Adam M. Miller, who was professor of anatomy at the college from 1914 to 1935 and dean from 1921 to 1935.

United Hospital Campaign—The United Hospital Fund of New York will seek to obtain \$2,800,000 in its 1936 appeal for funds according to the New York Times. The deficits of the seventy-nine recipients of the fund total \$2,881,643. Stuart M. Crocker, vice president of the International General Electric Company, has been named chairman of the 1936 campaign, which is expected to open in November. It was stated that 1936 showed the first decline in hospital deficits since 1929.

Society News—At a meeting of the Bronx County Medical Society, October 21, Dr. Clarence J. O'Connor made his inaugural address as president, and the work of the state medical society was discussed by Drs. Floyd S. Winslow, Rochester, N. Y., president of the state society, Peter Irving, secretary, Terry M. Townsend, president of the first district branch, and Mr. Dwight Anderson, director of public relations. Dr. George Gray Ward addressed the Bronx Gynecological and Obstetrical Society, October 26, on "Plastic Surgery for Genital Prolapse." Dr. Charles G. Darlington addressed the Bronx Pathological Society, October 20, on "So-Called Dental Tumors." A symposium on obstetrics was presented at a meeting of the Medical Society of the County of Queens, October 27, with Dr. Edward S. Godfrey Jr., Albany, state commissioner of health, as the guest speaker and ten minute papers by Drs. Harriet M. White, Richmond Hill, Henry C. Eichacker, Brooklyn, Walter H. Kerby, Woodhaven, James P. McManus, Hollis, George J. J. Lawrence, Flushing, and Moses Cohen, Long Island City, members of the committee on maternal welfare. Justices Bernard L. Shientag and Meier Steinbrink addressed the meeting of the Medical Society of the County of New York, October 26, on "Medicolegal Aspects of Trauma."

Report on Emergency Medical Relief—More than 426,750 persons on relief have received medical care from the Emergency Relief Bureau since its medical and nursing service was inaugurated in December 1932, according to a recent report. The cost of caring for these persons was \$3,002,194.07. From January 1 to June 30 of this year the bureau gave medical care to 127,318 cases at a cost of \$658,046.42. In 1935 it cared for 169,573 families at a cost of \$1,130,271.84. In 1934 99,777 relief cases received medical aid at a cost of \$881,927.95, while in 1933, the first year of the service, 30,082 families were given medical attention at a cost of \$331,947.86. The average medical case cost during the first six months of 1936 was \$5.24, a reduction of 47 per cent as compared with the average cost in 1933 which was about \$11.13. In 1934 the average per capita cost was \$8.84 and in 1935 \$6.66. The medical and nursing service maintains a panel of 4,000 physicians and one of 1,800 pharmacists, who sign an agreement with the bureau to serve relief recipients. These physicians, regardless of the fees they receive in private practice, receive \$2 for a relief visit and are called in rotation by the bureau. When a physician is called he is given the name of a pharmacy to which he may send the patient if it is necessary to write a prescription. Nurses are recruited from existing visiting nurse organizations. About 850 persons suffering from chronic ailments, who are unable to attend dispensaries and who must be hospitalized are now being cared for by a service established during the latter part of 1935. Now they are visited as often as is necessary by a physician or a nurse.

NORTH CAROLINA

Citizen's Health Committee Formed—A health conservation committee has been organized in Edgecombe County under the direction of the health officer, Dr. Lorenzo L. Parks. Membership of the committee is comprised of representatives of various clubs and organizations. Dr. Parks has been named secretary of the committee, which will serve in a liaison capacity between lay agencies and the health department.

Extension Course in Medicine—The extension division of the University of North Carolina and the school of medicine are cooperating in a graduate course of six lectures at Goldsboro for physicians in the eastern section of the state. Dr. Charles Reid Edwards, professor of clinical surgery, University of Maryland School of Medicine, gave the first lecture in the series, September 24. Subsequent talks, given on Thursday evenings, include the following:

Dr. Charles M. Byrnes, Baltimore. Vascular Diseases of the Brain.
Dr. Warren T. Vaughan, Richmond, Va. Allergy.
Dr. Thomas Fitz Hugh Jr., Philadelphia. Common Forms of Anemia.

This was a joint meeting with the Lehigh and Bucks county medical societies and the Lehigh Valley Homeopathic Medical Society—An obstetric institute was conducted at the meeting of the Cambria County Medical Society, Johnstown, October 15, by Drs Josiah R. Eisaman, Charles E. Ziegler and William Paul Dodds, all of Pittsburgh—Dr Ralph E. Herendeen, New York, addressed the Lehigh County Medical Society, Allentown, September 8, on "What the General Practitioner Should Know of the Roentgen Therapy of Neoplasm"—Dr Ray P. Moyer, health officer of Pittsburgh, was elected president of the Pennsylvania Public Health Association at its twelfth annual meeting in Harrisburg in September

Philadelphia

Program of College of Physicians—Dr Thomas Parran, Surgeon General, U S Public Health Service, will deliver the James M. Anders Lecture of the College of Physicians of Philadelphia, November 4, on "Syphilis from the Public Health Point of View." The first lecture of the season, one of the Mary Scott Newbold Lectures, was delivered October 7, by Dr Thomas M. Rivers, New York, on "Virus Diseases of the Central Nervous System." Other lectures announced for the year are

- December 2, Mutter Lecture Dr George P. Muller The Relation of Benign Breast Lesions to Ovarian Dysfunction.
- January 6 Nathan Lewis Hatfield Lecture Dr David P. Barr St. Louis Parathyroids and Their Role in Health and Disease.
- February 3, Nathan Lewis Hatfield Lecture, Dr Leonard Colebrook London Control of Hemolytic Streptococcal Infection with Particular Reference to Puerperal Fever
- March 3 Nathan Lewis Hatfield Lecture Dr George H. Whipple Rochester N. Y. Hemoglobin and Plasma Protein Construction Within the Body as Influenced by Various Factors
- April 7 Mary Scott Newbold Lecture Dr Hector Mortimer Montreal Canada Significance of Cranial Lesions in Clinical Medicine
- May 5 Mary Scott Newbold Lecture Dr Alphonse R. Dochez New York, Agents of Upper Respiratory Infection

Society News—Drs John P. Scott and Samuel X. Radbill among others, addressed the Philadelphia Pediatric Society October 13, on "Streptococcus Meningitis with Recovery Following Mastoidectomy and the Use of Lyophilized Convalescent Scarlet Fever Serum Intraspinaly"—Among the speakers who addressed the Physiological Society of Philadelphia, October 19, were Drs Arthur M. Walker, Carl F. Schmidt, Kendall A. Elsom and Charles G. Johnston on "Renal Blood Flow and Creatinine Clearances of Unanesthetized Rabbits and Dogs as Influenced by Water, by Pituitrin and by Xanthine and Mercurial Diuretics"—Prevention of heart disease was the subject for the meeting of the Philadelphia County Medical Society, October 28. The speakers were Drs Edward Weiss on hypertension, Charles C. Wolferth, coronary artery disease, William D. Stroud, rheumatic heart disease and John H. Stokes, syphilitic heart disease.—At a meeting of the Philadelphia Neurological Society, October 23, Drs Joseph C. Yaskin and Karl Kornblum presented a paper on Neurological Aspects of Petrositis" and Dr Carl F. Schmidt, "Intrinsic Regulation of the Cerebral Circulation"—Drs Kenneth E. Appel and James A. Flaherty, among others, addressed the Philadelphia Psychiatric Society, October 3, on "Hormone Studies in Homosexuality"

RHODE ISLAND

Society News—Drs William P. Buffum, Providence, and John C. Corrigan, Fall River, Mass., addressed the Providence Medical Association October 5 on 'The Role of House Dust in Bronchial Asthma' and 'The Incidence and Management of Anemia of Pregnancy' respectively—The Washington County Medical Society was addressed at the Westerly Hospital, Westerly, October 14, by Dr Murray S. Danforth, Providence on 'Injuries and Diseases of the Spine.'—At the quarterly meeting of the Rhode Island Medical Society at Howard, September 3, the speakers were Drs Arthur H. Harrington, Providence, on 'History of Treatment of the Insane in Rhode Island', Rawser P. Crank, Howard 'Problems in the Neuropathology of Mental Disease', and Harold W. Williams formerly of Schenectady, N. Y. "Bedside Manners and Psychiatry"

TENNESSEE

Society News—Dr Thomas D. McKinney, Nashville, addressed the Davidson County Medical Society, Nashville, September 15, on "Surgery of the Sympathetic Nervous System"—Speakers at the first fall meeting of the Dyer, Lake and Crockett Counties Medical Society were Drs James E. Wilson Jr, Nashville, on 'Trachoma in Dyer County', Maccenar B. Hendrix, Memphis, "Preoperative Treatment of Acute Abdominal Diseases", Edward Guy Campbell, Memphis, "Lobar Pneumonia," and Isaac G. Duncan, Memphis, 'Hematuria.'—Dr Josiah J. Ashby, Nashville, addressed the Giles County Medical Society, August 20, on "After-Treatment of Infantile Paralysis"—Drs John Marsh Frere and Jesse B. Swafford, Chattanooga, addressed the Hamilton County Medical Society, September 17, on "Diverticulum of the Cardiac End of the Stomach" and "General Paralysis of the Insane" respectively—Drs Lee K. Gibson and Edward T. West, Johnson City, addressed the Washington County Medical Society, September 3, on "Thyroid Diseases" and "Cancer of the Rectum and Sigmoid" respectively—Drs John C. King and William D. Stinson, Memphis, addressed the Memphis and Shelby County Medical Society, August 4, on "Management of Carcinoma of the Breast" and "Nonsurgical Treatment of Nasal Polyps" respectively

VERMONT

State Medical Election—Dr William G. Ricker, St. Johnsbury, was elected president of the Vermont State Medical Society at the annual meeting in Burlington, October 15. Dr Waldo J. Upton, Burlington, was made vice president and Dr Arthur B. Soule Jr, Burlington, secretary. Dr Ricker has been secretary for many years.

VIRGINIA

State Medical Election—Dr George F. Simpson, Purcellville, was chosen president-elect of the Medical Society of Virginia at its annual meeting in Staunton, October 14, and Dr James M. Hutcheson, Richmond, was installed as president. Vice presidents elected were Drs Joseph T. Buxton, Newport News, Hugh H. Trout, Roanoke, and Guy R. Fisher, Staunton. Miss Agnes V. Edwards, Richmond, was reelected executive secretary.

Health Educational Work—J. C. Funk, LL.B., formerly of the Pennsylvania State Department of Health, Harrisburg, and more recently with the U. S. Public Health Service, Washington, D. C., has been placed in charge of the educational work of the state department of health. The appointment has been made possible by an increased appropriation authorized by the last general assembly. WASHINGTON

Obstetrics and Gynecology Meeting—The Pacific Coast Society of Obstetrics and Gynecology will meet in Seattle November 11-14, with headquarters at the Olympic Hotel. The preliminary program lists the following speakers:

- Dr Paul G. Flotoh Seattle The Superior Hypogastric Plexus and Its Relation to Gynecology (clinic)
- Dr Albert M. Vollmer San Francisco Results of Sympathectomy for Dysmenorrhea
- Dr Theodore W. Adams Portland Ore. Vesicovaginal Fistula
- Dr Donald G. Tollefson Los Angeles Uterine Inertia in the First Stage of Labor
- Dr Hans F. Schluter Sacramento The Fetal Heart
- Dr John W. Sherrick Oakland Cesarean Section in Private Practice
- Dr Lyle G. McNelle Los Angeles Diagnosis and Treatment of Abdominal Pregnancy
- Dr C. Frederick Fluhmann San Francisco Studies on Amenorrhea
- Dr Alice F. Maxwell San Francisco Hormones of Ovarian Tumors
- Dr Hans Von Geldern San Francisco Incidence of Carcinoma in the Fibroid Uterus
- Dr Bernard J. Hanley Los Angeles Breech Presentation

Dr Albert L. Mathieu, Portland, Ore., will conduct a symposium on hydatidiform mole and chorio-epithelioma.

WISCONSIN

Personal—Dr Stephen E. Gavin, Fond du Lac, who was installed as president of the State Medical Society of Wisconsin at the meeting in Madison in September, was honored at a testimonial dinner September 17 at St. Agnes Hospital, Fond du Lac, of which he is acting chief of staff. T. A. Hardgrove, DDS, was toastmaster, and numerous speakers paid tribute to Dr Gavin—Dr Llewellyn R. Cole, assistant physician in the department of student health at the University of Wisconsin, Madison, has been appointed director to succeed Dr Charles E. Lyght, who has been made director of health

at Carleton College, Northfield, Minn.—Dr Kenneth E Lemer, Madison, has been promoted to be assistant professor of surgery at the University of Wisconsin Medical School

GENERAL

News of Epidemics—Twenty-one cases of typhoid in children with one death were reported in Astoria, L I, October 12 The cause had not been determined—Twenty-one active cases of infantile paralysis were reported in Toledo, Ohio, October 8 thirty-five cases have occurred this season. Several school grades were quarantined and about 300 children were under observation after having been exposed to the infection.—Eight persons have died in an outbreak of typhoid at Carlisle, Pa, it was reported October 12 It began with infection among road workers who are said to have drunk from a contaminated well—Seven inmates of the Columbus State Hospital, Columbus, Ohio, died in an outbreak of typhoid, the source of which remains undetermined, fifty others were still seriously ill September 28—The state health department of Tennessee announced October 7 that 283 cases of infantile paralysis had occurred in the state since the first of the year, all but five since July 1 There have been nineteen deaths

Meeting of Southwestern Association.—The twenty-third annual meeting of the Southwestern Medical Association, formerly the Medical and Surgical Association of the Southwest will be held at the Hotel Cortez in El Paso, November 19-21 There will be general assemblies, round table discussions and clinics, conducted by eight invited guests The guests and their subjects for the general assemblies are as follows

Dr Harold Brunn	San Francisco	Pelvic Appendicitis	Lobectomy
Dr Ralph A Kinsella	St. Louis	Career of the Heart	Differential Diagnosis of Rheumatic Fever
Dr Isadore Cohn	New Orleans	Osteomyelitis	Fractures of the Upper Extremity
Dr Nelse F Ockerblad	Kansas City Mo	The Problem of Gross Blood in the Urine	Differential Diagnosis of Retroperitoneal Lesions
Dr James T Case	Chicago	Diagnostic Application of X Rays in Digestive Disorders	Röntgenology in the Diagnosis and Management of Biliary Tract Disorders
Dr Warren T Vaughan	Richmond Va	Newer Methods in the Diagnosis and Treatment of Food Allergy	How to Use and Interpret Laboratory Reports
Dr Thomas E Carmody	Denver	Relation of the Oral Cavity to Otolaryngology and General Medicine	Treatment of Diseases of Accessory Sinuses
Dr Willard R Cooke	Galveston Texas	The Relief of Pain in Labor	Metabolic Disturbances in Pregnancy

Dr James J Gorman, El Paso, is president of the association and Dr Chester R. Swackhamer, Superior, Ariz, president-elect

Society News—Dr Harry S Gradle, Chicago, was chosen president elect of the American Academy of Ophthalmology and Otolaryngology at the annual meeting in New York, October 1 Dr Lee Wallace Dean, St. Louis, was installed as president, and the following were elected vice presidents Drs Bernard Samuels New York, Wilson Johnston, Portland Ore., and Frank L Ryerson, Detroit. Dr William P Wherry Omaha, was reelected executive secretary and treasurer The 1937 meeting will be in Detroit.—Dr Lucius C Kingman Providence, R I was elected president of the New England Surgical Association at its annual meeting in Bridgeport, Conn, September 25-26 Dr Walter G Phippen, Salem, Mass., was elected vice president and Dr John M Birnie Springfield, Mass., secretary The 1937 meeting will be held in Providence.—The Society of American Bacteriologists will hold its thirty eighth annual meeting at the Hotel Lincoln Indianapolis, December 28-30—Dr Frederic A Besley, Waukegan, Ill., was chosen president elect of the American College of Surgeons at its annual election in Philadelphia, October 22, and Dr Eugene H Pool, New York, was installed as president The college will hold its next annual meeting in Chicago, the week of October 25—Dr Harry J Corper, Denver, was elected president of the Rocky Mountain Tuberculosis Conference at its meeting in Albuquerque, N M September 28-29 Dr Charles A Thomas Tucson Ariz, was made vice president and Dr Arnold Minnig Denver, secretary The next meeting will be in Tucson in 1938—The annual roll call of the American Red Cross will be conducted from Armistice Day to Thanksgiving Day, November 26

CANADA

University News—Dr Robert G Inkster professor of anatomy, University of Manitoba Faculty of Medicine, Winnipeg, has been appointed university anatomist at Trinity College, Dublin Ireland—Dr Charles B Weld assistant professor of physiology University of Toronto Faculty of Medicine, has been appointed professor He was graduated in 1929 from Toronto

Faculty Changes at Toronto—The following appointments and promotions in the staff of the University of Toronto Faculty of Medicine have recently been announced

Guy F Marrian, Sc D	promoted to be professor of biochemistry
Dr Thomas F Nicholson	promoted to be associate professor of pathological chemistry
Dr Dudley A Irwin	appointed associate professor of medical research
Dr Milton H Brown	assistant professor of hygiene and preventive medicine
Dr Herbert A Detweiler	assistant professor of medicine and clinical medicine
Dr Thomas A J Duff	assistant professor of surgery
Dr Wilbur R Franks	George E Hall and C C Lucas
assistant professors of medical research	

Personal—Dr S Clarence Peterson, Winnipeg, has been appointed director of venereal disease control for British Columbia This department in the provincial health department is to be reorganized and the government has increased its appropriation from \$30,000 to \$45,000 Dr Peterson had a similar position in Manitoba and was also at the University of Manitoba Faculty of Medicine—Dr Stewart S Skinner has retired as chief medical officer of the Lancaster Hospital St John, N B under the department of pensions and national health Dr Henry D Reid, federal quarantine officer at Partridge Island, St John, succeeded him.

Government Services

Changes in Public Health Service

Drs William E McLellan and Henry L Peckham Jr have been appointed and commissioned as assistant surgeons in the regular corps of the public health service Drs Robert A Jones and Herbert R Collins have been appointed and commissioned as surgeon and passed assistant surgeon, respectively, in the reserve corps of the service

Hospitals for Indians

Construction will soon begin on a combination sanatorium and general hospital for the Indian Service, near Tahluha, Okla, which, when completed, will have a capacity of 225 beds The project is being financed by a PWA allotment of \$947,900 The facilities will be used largely by Indians of southeastern Oklahoma, members of the Choctaw and Chickasaw Nations, but will be available also for other Indians of the Five Civilized Tribes and of other tribes resident within the state. Announcement is made also of an Indian sanatorium to be erected at Rapid City, S D with accommodations for about 115 patients This project will be maintained for Sioux Indians

R O T C Units in Medical Schools Reestablished

In accordance with an act of the Seventy-Fourth Congress, arrangements have been made for the reestablishment of R O T C units at the following medical schools

Baylor University College of Medicine	Dallas Texas
Boston University School of Medicine	Boston
University of California Medical School	San Francisco
Georgetown University School of Medicine	Washington D C
George Washington University School of Medicine	Washington D C
State University of Iowa College of Medicine	Iowa City
Jefferson Medical College	Philadelphia
University of Michigan Medical School	Ann Arbor Mich
University of Minnesota Medical School	Minneapolis
Ohio State University College of Medicine	Columbus Ohio
University of Oregon Medical School	Portland Ore
University of Pittsburgh School of Medicine	Pittsburgh
St Louis University School of Medicine	St Louis
University of Vermont College of Medicine	Burlington Vt
Medical College of Virginia	Richmond Va
Washington University School of Medicine	St Louis
Western Reserve University School of Medicine	Cleveland
Syracuse University College of Medicine	Syracuse N Y
University of Pennsylvania School of Medicine	Philadelphia

Next year the remainder of the thirty-one units authorized by the war department will be organized In compliance with the National Defense Act of 1920, R O T C units were established in twenty-four class A medical schools between 1920 and 1922 Their purpose was to train medical students for medicomilitary duties and to prepare them for commissions in the medical reserve corps As a result more than 6000 medical graduates were so trained and commissioned and in the course of time have constituted more than 50 per cent of the yearly additions to the medical reserve corps In 1931 and for three succeeding years the army appropriations acts carried the provision that eventually legislated the medical department R O T C units out of existence, so that in June 1935 the last classes were graduated and commissioned.

The Strain of Modern Civilization

Lord Horder opened the discussion on the subject, the Strain of Modern Civilization, before a large audience in the section of physiology of the annual meeting of the British Association for the Advancement of Science. He said that from the early days of the primitive curse life had always imposed a strain on mankind. That was the penalty we paid for living at all. There was, however, implicit in the title of the discussion the suggestion that the stress of modern life had new elements and was excessive. Clinical observation undoubtedly revealed the effects of strain. Functional diseases, as against organic, had increased, whether in the field of the nervous system proper, the heart and blood vessels, or in that of the internal secreting glands. Behind the screen of headache, indigestion and fatigue inquiry revealed the anxiety factor. In the sphere of microbic diseases we had new diseases for old. There was an increase of those more subtle germ diseases called "subinfections," in which the virulence of the microbe was low while the susceptibility of the host was high. In many of these the germ came from within and not from without.

As to the cause, it was almost platitudinous to speak of the anxiety connected with the competition of living and the equally grave sense of international insecurity, of the pace at which we lived and of the precariousness of life itself in the streets so that we seemed to live by accident rather than to die by it, of the monotony and drabness inherent in the long hours of physical and mental effort of many workers, of the exciting nature of our amusements, and of noise, needless, stupid, provocative. He would add another cause, more subtle but none the less recognizable, the slackening of the moral code in the sphere of increased freedom of both sexes.

THE VALUE OF SCIENCE

There was a notion afoot that in the last analysis science was largely responsible for much of the strain of modern life. This unloading on science he regarded as a mere pusillanimity. It was not too much science but too little science that had helped to get us into this trouble. Science had loaded man with benefits, but he had shown a carelessness and a prodigality in their use which was pathetic. One need not drive a car so fast that it killed nor make a loud speaker so loud that it deafened.

Among the remedies for the ill effects of the strain of modern life he placed, first, more science and especially science directed toward the study and development of the mind and spirit of man. We should guard and support all those amenities which were in existence or struggling on behalf of the artisan, the laborer, the shopman, the housewife—slum clearance, playing fields, national parks, pictures, music, museums, libraries, and quiet for the brain worker and others.

THE DANGER TO CIVILIZATION

It is seldom that a physician makes a political pronouncement, and however eminent he might be one from such a source would not receive much attention. However, what Lord Horder said has received widespread notice in the press. He saw little hope for the people through mass movements whether Fascist or Communist. When individual freedom had been sacrificed he saw no chance of achieving that control in the spiritual sphere through which he believed salvation could come to the human race. What matter the color of men's shirts if these were soon to be their shrouds? A plague on both your blouses, he said to the accompaniment of cheers. Concerning

numbers, he was much more interested in the quality than the quantity of our people. When the clash came, if come it must, between two hordes of the new barbarians—civilized barbarians if they liked—it might well be that the salvaging of the world or its doom might depend on whether northern and western Europe and America had been able to preserve an individualized society or, like the two opposed masses in the dictator countries, had yielded to the tremendous pressure of what might prove to be a bastard civilization and had caught the infection of despair. If our own individualities refused to be tub thumped or intimidated into a pulp, all might be well. He had not attempted prognosis. He could only state his faith in the individual and in the enormous potentialities of the human spirit. Was it not a handful of individuals who guided the vast experiment proceeding in the east of Europe, another handful that drilled humanity in the center, and one individual alone who balanced himself dramatically as on a tight rope before the breathless crowd of the South? If physicians had a political color, like lawyers, it must needs be Liberal. A rebirth of that spirit in British political life would be one of the best medicines that our strained lives could have administered to them.

Overworked Hospital Nurses

In a long correspondence in the *Times*, attention is drawn to the unsatisfactory conditions under which many hospital nurses work. The hours are long, with only short periods of rest. As they are standing most of the time, the physical strain must be great. The *Times* itself has joined in the discussion in an editorial in which it is claimed that nurses should have more, not less, leisure than ward maids, also that the pay of many nurses, amounting to no more than 24 cents a day, is quite inadequate. The father of a nurse complains that the wage of a responsible nurse endowed with technical knowledge, skill and initiative is little more than that of the ward maid. Many nurses are exceptionally well educated. Had they chosen other callings they would not have to do menial work that is allotted to some probationers. They take nursing for the love of it and this should not be made an instrument for their exploitation. A surgeon says that when probationers or junior nurses break down it is because their work must be combined with exhausting study. A registered nurse writes that every student nurse should have at least one day a week free from study and ward work. The mother of a probationer who broke down after eight months' training in one of the London hospitals complains that probationers work for seventy hours a week in the wards, on their feet practically the whole time, and sometimes for six hours on end with only ten minutes break. Study on the top of this arduous work may be "the last straw," and even without it probationers would be liable to break down. The suggestion has been made that much of the work done by hospital nurses, such as cleaning, sewing, fetching and carrying and ordinary waiting on patients, might be handed over to ward maids and so lighten their labor.

Radiotherapy in Cancer of the Cervix

At the Edinburgh Obstetric Society Sir Comyns Berkeley, who is director of the radium center of the London County Council, to which all cases are sent for radiotherapy from all the municipal hospitals of London, said that the results of radiotherapy in cancer of the uterus were not so good as they should be, because early diagnosis was the exception. The patients did not come to the surgeon or radiologist earlier because pain was a late symptom and in the nodular variety of cancer of the cervix bleeding was a late symptom. They were usually responsible for the delay but in a proportion of cases the physician neglected to make a vaginal examination and diagnosed the bleeding as due to the menopause. Women should be taught the great importance of taking advice for any irregularity of menstruation and insisting on an internal

examination When the physician found that an erosion of the cervix did not clear up quickly he should take the necessary steps to exclude cancer

Sir Comyns Berkeley followed the Stockholm radium technic and during 1934 and 1935 supplemented it with x-ray treatment The absolute survival rate for five years of the patients treated from 1928 to 1930 was as follows stage 1, 50 per cent, stage 2, 19 per cent, stage 3, 14 per cent, stage 4, 5 per cent The results are worse than those obtained at some centers but the cases treated were also worse, being drawn from the infirmary class Many patients in stage 4 obtained great relief from their sufferings and the majority some relief When they died, they did so as a rule from internal metastases, a death which was far less distressing than if the growth were spreading locally with all the horrors of foul discharges, continuous bleeding, and in some cases escape of urine and feces from holes in the bladder and rectum Moreover, it occasionally happened that cases treated with the idea of palliation and cases incompletely treated were cured.

In the radium treatment a general anesthetic should always be given, because it enabled a more detailed examination to be made. Efficient application, even with a multiplicity of applicators, was by no means always easy Whether x-rays should supplement radium was still disputed The radium bomb had a definite place in extensive cases Reliable statistics of the results were still needed and could be obtained only by an efficient follow-up system A bimannual examination did not always indicate the real amount of spread, for example, to the bladder On the other hand, parametrial masses, suggesting malignant extension, often proved to be inflammatory

A New Cabinet Position—Secretary of Leisure

Not only has the passage of recent laws to improve social conditions in France and its colonies resulted in increased wages and a forty hour week for workers, but every employer is now obliged to grant a vacation, with full pay, of one week for those who have been in his employ for less than a year, and two weeks for those employed over a year The Socialists and Communists together have constituted a majority in the legislature since May 1936 and have created a cabinet position known as a "secretary of leisure," whose duty it shall be to encourage physical education and to aid the workers to spend to the greatest advantage their nonemployed time and especially their paid vacation periods Information is provided as to where to go, at all seasons of the year, and special railroad or bus round trip rates in all directions, even to foreign countries, are arranged for G Lavalee in the *Concours médical*, May 27, suggests to the "secretary of leisure" that sport competitions, theaters which follow provincial circuits, and increased use of the radio are not innovations but that a serious effort should be made to supervise the omnipresent saloon lest the leisure hours be spent there. At least one or two thousand saloons ought to be suppressed to prevent the free Saturdays and Sundays being passed there by the worker

As to the radio improvements, few of the younger generation will be content to sit all the afternoon to listen to a radio program.

Opposition to Forced Retirement Law for Physicians

In a recent letter it was stated that a bill, termed the "Pomaret law," had been introduced in the French legislature according to which the members of all professions will be obliged to surrender their diplomas at the age of 65 and discontinue their work without any recompense in the form of a pension from the state. Violent opposition to such a proposal

is appearing from all sides, and a medical journalist said that he would be eligible for retirement in three months and then either be ready for the soup line by 1939 or be obliged, like so many unemployed here in Paris, to earn a living by singing in the streets Maurice Mordagne, the leader of the medical students' union, quotes such a letter received by him, in an article in the August 22 *Presse médicale*, which reflects the reaction of the professors and medical journalists on the forced retirement bill As to the faculties, Professor Villard of Montpellier is quoted as saying that the medical profession in France does not seem to have awakened to the potential dangers of such a bill if passed Many physicians would be obliged either to die of hunger or seek asylum in a charitable institution Another professor of the Paris medical school who is familiar with conditions in smaller communities states that the applications of such a law would give temporary relief in an overcrowded profession only if some measures were adopted to reduce materially the numbers of licenses to practice granted annually Professor Sergent stated that every effort must be made to fight against the dangers of state medicine, which threatens to reestablish the serfdom suppressed by the French Revolution.

The proposed law would affect not only members of the technical (physicians, dentists, architects, engineers) but also those of nontechnical professions (teachers in liberal arts) hence Professor Fedel of one of the high schools is quoted as saying that many discoveries have been made by men and women above the age of 65 The campaign to retire such individuals without pension at that age is being led by ignorant opportunists and recently naturalized foreigners Why not apply such a law to holders of public offices, many of whom have rendered the state invaluable service after the age of 65? Many physicians even at 70 are still active and in possession of all their faculties, thus rendering indispensable aid by their advice, gained through many years of experience, to younger colleagues Professor Faure, gynecologist, cited instance after instance of men of 70 or over who were a contradiction of the statement made by the supporters of the bill that a surgeon ought not to operate after the age of 65

The syndicat (union) of physicians in the department of the Seine has recently studied the records of 100 foreign students and physicians during a period of four months and found that the majority of those who applied for naturalization and permission to practice were granted these demands by the government It would appear more necessary to subject such applications to a stricter control than to try to force retirement of older men. The latter, if the bill passes the legislature would not help young graduates born in France or its colonies as much as it would the recent influx of foreigners

Antidiphtheria Immunization of Medical Students

At the July 21 meeting of the Académie de médecine, Robert Clement made a plea for the routine examination of medical students by the Schick test and subsequent immunization with the Ramon anatoxin of all those showing a positive reaction. He quoted some statistics gathered by Azoulay in 1935 showing that, from 1923 to 1934, 224 cases of diphtheria had been treated in the nursing staff and personnel of four Paris public hospitals

In the School for Public Hospital Nurses, since 1926, every pupil nurse has been given the Schick test and immunized if this has been found positive This has so far not been applied to the nonnursing personnel, but it would seem advisable to subject them to the test. Up to the present time, no effort has been made to look for receptive individuals among medical students This is a loophole that ought to be given immediate attention, so far as diphtheria is concerned, just as all first year students are given tests to determine their receptivity to tuberculosis

Certain borderline Schick reactions present a difficult problem and negative results have been observed in cases of diphtheria. In certain of these individuals the percentage of antitoxin in the serum is inferior to the dose of one thirtieth antitoxic unit, which is considered adequate as protection against diphtheria. It has been shown recently by Meersseman and Renard that the limit of negativity of the Schick reaction does not correspond to this classic protective figure and can even be considerably lower. Now, if the test is carried out with a dilution of 1:300 instead of 1:600 as recommended by the Pasteur Institute, a positive reaction will be found in many who have a negative result with the more dilute solution. A person ought to have an antitoxic serum content which is superior to one thirtieth unit instead of below it. Another way of avoiding errors in the Schick test is to use syringes and needles sterilized by dry heat and to wait until the fourth or fifth day before attempting to observe the reaction. By this time the protein reaction has disappeared, whereas the toxin reaction is at its maximum. It is a good rule to consider all reactions as positive when they are not strictly negative. With these precautions the Schick intradermoreaction has a genuine value for receptive subjects. In young medical students it is positive in about half of the cases.

The excellent results of preventive immunization following two or three subcutaneous injections of the Ramon anatoxin at intervals of three weeks is proved by the increased antitoxin content of the blood serum, a negative Schick reaction and the diminution in morbidity of vaccinated students.

Serious accidents following immunization are very rare and are due to specific sensitization of the individual.

In the discussion, Surgeon General Rouvillois of the army maintained that medical students ought to be immunized not only against diphtheria but also against typhoid and tetanus. This form of triple vaccination is now obligatory in the French army.

In closing the discussion, Clement stated that such a triple vaccination has been given to every child in his service at the Trousseau Hospital for the past three years. Every medical student ought to be given similar treatment.

Treatment of Cancer in Women

Before the Medical Society of Freiburg-in-Breisgau, Professor Keller discussed the results obtained by the treatment used in carcinoma of the uterus at the Women's Clinic of Freiburg University from 1927 to 1933. Carcinoma of the cervix is treated almost exclusively by radium and roentgen irradiation. Although 62 per cent of the cases were operable surgical interventions were carried out in only 4 per cent, and in several instances only subsequent to radiotherapy. The treatment is generally a combination of irradiation with roentgen and radium rays, greater importance is attached to the latter. In addition the carcinoma must be locally eradicated, and the modern technic of dosage effects this without destruction of the adjacent tissue. This concept is opposed to that in vogue at this clinic during the administration of the late Professor Opitz. Opitz used relatively small doses in irradiation in order to protect the connective tissue and he considered this principle of great importance in combating cancer. The total radium dosage amounts to from 5,000 to 7,000 mg. element hours, two thirds of this amount representing intra-uterine and one third vaginal administrations. However the total dosage as well as the ratio of the intra-uterine to the vaginal dose is not inflexible but has been reckoned according to the conditions presented in individual cases. Thus if the situation warrants, only one third of the intra-uterine dosage

and two thirds of the vaginal dosage will be administered. The total dosage is estimated above all on the basis of the patient's age. For patients more than 60 years of age, the inferior limits of the total dosage are not overstepped. It is most favorable to apply the total dosage within three to four weeks. The best results are yielded by two irradiations with radium within a period of three weeks. If the dosage is administered in three or more stages, the danger of ascending infection will be increased. It is important that the entire tumor be submitted to thorough and uniform irradiation and that, to avoid injury, the rays be sufficiently filtered (secondary filtration with 2 mm., complete filtration with 3 mm. lead equivalence). Injuries to the rectum and bladder are carefully avoided since those organs are highly sensitive to the rays. The radium deposit is for the same reason kept at the greatest possible distance from the organs most endangered. Nine instances of damage were observable among 259 cases (four rectovaginal fistulas and five cystic ulcers). All the fistulas and four of the bladder injuries were presented in the years 1928 and 1929, at which time the secondary filtration was only 1 mm. of lead equivalence. Two radium irradiations according to the Seitz-Wintz method are administered and during the interval the right and left parametria are irradiated at two respective sessions with some 800 roentgens. During the latter procedure it is important that no overlapping of the ray cones should occur. On this account the cone of rays is directed toward the pelvic wall and a decrease in the incidence of recurrences in that region is thus obtained.

The primary mortality from radiotherapy amounted during the period under discussion to 3.5 per cent. If only the fatalities directly traceable to the treatment are considered, the figure is 2.3 per cent. Of the 259 observed cases the records of 142 cases of the years 1927-1930 are available for estimate as to permanence of cure. Of these 142 cases, 32.4 per cent are considered permanently cured. With improvement of the therapeutic technic the results become more satisfactory. The proportion of healed cases in 1927, 20 per cent, stands in contrast to the corresponding figure for 1930, 45 per cent. Radiotherapy is rejected in the treatment of carcinoma of the corpus uteri and operative treatment indicated as the method of choice. Whereas elsewhere six carcinomas of the corpus were observed among 100 cases of uterine cancer, the Freiburg material showed that in 30 per cent of all cases of uterine carcinoma the disease was located in the corpus. Of thirty-five cases of corpus carcinoma observed during the period 1927-1930, 91 per cent were operable and in 60 per cent permanent cure was achieved. Radiotherapy was employed in seventeen of these thirty-five cases (in part because of general inoperability). Of these seventeen patients, only five were still living at the end of five years, whereas, of the eighteen submitted to operative treatment, sixteen were still alive after five years. Apart from the local therapy, general restorative treatment was carried on simultaneously; this procedure is regarded as essential to the permanence of successful results.

New Regulations of Dentistry

According to a public announcement by the minister of the interior of the results of group examinations of persons of various ages, and the observations of the sick insurance societies, the health of the German people is being seriously imperiled by a formidable spread of dental diseases. Under these circumstances the care of the people's teeth by both dental physicians (zahnärzte) and so-called dentists (dentisten) has taken on a greater significance. As an initial step to eradicate professional deficiencies, the overcrowded state of the two groups, namely, the *zahnärzte* and the *dentisten*, is being combated. The *dentisten* are those persons who despite their lack of a regular university training, are engaged in the practice of dentistry. Members of this group are graduates of a 'dentist's

school' but their education is far from complete and they are not dental physicians (zahnärzte). For these reasons the admission of new students to the regular dental schools has been for the first time temporarily stopped. Since the educational requirements of the dentisten have not yet been legally regulated, only those persons shall henceforward be permitted to take the public examination for dentisten who are at present preparing themselves for admission to that professional group. So for the time being the admission to training schools for dentisten has also been stopped (The calling of dental mechanic [zahntechniker] is not affected by these measures, these technicians are only assistants to the dental physicians by whom they are employed to do the mechanical work.)

Attention had been called previously to the fact that the health of the German people may be seriously impaired by the spread of dental disorders. The prevalence of such disorders has been evidenced by the results of physical examinations in the defense forces. According to these observations 1486 of each hundred men examined were designated as "fit on condition" because of "bad teeth." On the basis of these examinations, together with the finding that of 558 apprentices in a South German industrial establishment only 7.5 per cent did not stand in need of dental care, Dr. Kientopf, director of the Berlin Municipal School Dental Clinic, a man who formerly occupied an influential position in the public health councils of National Socialism, has demanded that a program of compulsory treatment of dental, oral and maxillary disorders be instituted. The customary examinations by the school physician are distinctly inadequate, since they take place at too widely separated intervals and because the school doctor is in no position to carry out a comprehensive program of dental care among school children.

Attention is finally called to the great importance attributed to suitable bread nutriment. The newly founded cooperative association and the dental institute of the University of Berlin set forth as the objective that by means of an adequate nutrition accessible to the entire population the internal causes of dental caries be reduced to a minimum.

Professor Flössner called to mind in this connection that in Germany 40 per cent of the necessary nutrition was supplied by bread and flour. The controversial question "Should wheat bread or rye bread constitute the bread nutriment?" no longer exists, since no important physiologic-chemical differences between the two types can be distinguished. Science is today concerned with another problem, that of the degree of milling to which grain should be submitted, for it is assumed that a causal relationship between a certain group of diseases (including caries) and insufficiently milled flour can be established.

Dr. Kraft pointed out that whole grain bread because of its content of protein, vitamins, cellulose and mineral substances represents a food of the highest nutritive value. The dietetic physiologist Professor Scheunert of Leipzig spoke of the importance of the vitamin content of bread. That the population may be amply supplied with vitamin B₁, the largest possible supply of whole grain bread, or at least of a black bread in which 82 per cent of the grain has been utilized, is recommended. If the regimen is sufficiently varied and comprises vegetables, fruit, milk, eggs and so on, deficiency in vitamin B₁ could scarcely be present. According to Scheunert's most recent research, only bread that represents the greatest possible utilization of the grain, in quantities of from 300 to 400 Gm. daily, can supply the day to day need for vitamin B₁. If gray bread or white bread is eaten, a considerable part of the vitamin B₁ need must be supplied by other types of food.

Professor Euler, director of the dental institute of the University of Breslau furnished most illuminating communications on the interrelation of the nutrition of the mother and the teeth of the infant. Children were 95 per cent free from caries if

during pregnancy, their mothers had consumed generous quantities of fresh green vegetables, salads, fruits, tomatoes, carrots and raw sauerkraut.

The Admission of Children to Tuberculosis Sanatoriums

The National Antituberculosis Commission has issued suggestions with regard to the admission of child patients to the tuberculosis sanatoriums. The substance of these guiding principles was as follows. The initiation of therapeutic measures for child patients has heretofore for the most part not been carried on as conscientiously as the welfare of the state and of the individual child demand. The number of active cases of childhood tuberculosis, that is, those cases in need of treatment, is not so large as the number of children selected for treatment might lead one to believe. Unfortunately, even in medical circles, the idea has as yet not sufficiently been accepted that tuberculous infection in childhood, with the exception of the first four years of life, is not equivalent to the disease tuberculosis. An inaccurate diagnosis of "tuberculosis" may set a lifelong stigma on the child and, further, public funds are dissipated in unnecessary therapeutic procedures, funds that otherwise might be better used for the physical training of a greater number of healthy sound children on the one hand, and for the care of the truly sick on the other. It still happens today that certain constitutional phenomena are evaluated as the manifestations of tuberculosis and sanatorium care provided when actually contraindicated.

It happens repeatedly that a child termed "in danger of tuberculosis" is admitted to a sanatorium for treatment. But a child is imperiled only if he lives in the vicinity of an openly tuberculous person. Danger of this sort will not be removed from a child by confining him for two or three months in a sanatorium and then returning him to the same perilous surroundings. No good can come of such "precautionary measures." One thing alone will remove the peril in these cases and that is the exclusion of the source of infection, the child should be removed from the vicinity of the person capable of transmitting tuberculous infection, even if this means a permanent separation of the child from his normal surroundings.

ITALY

Aug. 31, 1936

Complications of Tonsillitis

Professor Chini of Rome, in a lecture before the Accademia Medica of Rome, made a study of the type of focal reactions that develop in patients suffering from several diseases, especially renal and articular complications of tonsillitis. Although the reactions can be nonspecific, they are of importance. They seem to be caused by superimposed diseases, which can explain the satisfactory results of tonsillectomy. In discussing Professor Chini's article, Professor Giudiceandrea said that probably the blood has a particular type of lability to the virus of pathologic tonsils, which lability seems to be proved by the fact that blood can present an agranulocytosis syndrome in the course of tonsillitis or act as a vehicle for the transportation of bacteria from the tonsils to the organs.

Professor Pontano emphasized the importance of the clinical and bacteriologic differentiation between rheumatic fever and articular localizations of streptococcal infections. The clinical criteria for a differentiation are based on the results of the administration of salicylates and on the presence of endocarditis. The speaker reported results of research that consisted in taking blood cultures in patients suffering from tonsillitis and from true rheumatism. In the latter cases the blood cultures are negative. The streptococcal infection of tonsillar origin causes

clinical symptoms of the organs and joints, especially the latter, and the kidney. The reason for a selective location of a tonsillar streptococcus is unknown. The occurrence of renal and articular complications of tonsillitis can be neither suspected nor prevented. The streptococcal infection can propagate itself through the blood to the meninges or the peritoneum, such as in the case in convalescents from scarlet fever, without any indications of predisposition of the involved organ. The speaker pointed out the advantages of the administration of salicylates in the course of tonsillitis for preventing the development of rheumatism as well as the value of repeated vaccinations in treating recurrent tonsillitis. Tonsillectomy should be complete in order to be satisfactory. Otherwise tonsillar stumps become the harbor of abundant bacteria. Professor Chini called attention to the fact that certain nonrheumatic pathologic conditions of tonsillar origin react favorably to salicylates, whereas certain cases of rheumatic fever do not. In his practice he found cardiac changes, shown by the electrocardiograms in some cases of simple tonsillitis without rheumatic complications. The indications of tonsillectomy are not general, he said, but depend on the relation between the pathologic condition in the tonsils and the disease at a distance from the tonsils.

Cancrocirrhosis of Lung

Professor Jona, in a recent lecture before the Società Medico-Chirurgica of Venice, reported a case of cancer of the upper lobe of the lung, in association with intense cirrhosis of the parenchyma of all the rest of the organ, and complete adhesive pleuritis. There were no metastases. The disease lasted for two years. It appeared in association with a mediastinal syndrome. The diagnosis of cancer of the lung was made early. It was proved that cancer developed before cirrhosis did. The speaker stated that this type of cancer of the lung is not rare and suggests giving it the name of cancrocirrhosis of the lung. The condition is not entirely analogous to cancer cirrhosis of the liver. The disease causes deformation and complete shrinkage of the lung, pachypleuritis, cirrhosis of all the lung parenchyma except at the small area of cancer, and intense histologic changes with the typical picture of lung sclerosis. The clinical signs and symptoms of the disease are retraction of the thorax on the side involved and general symptoms. There are signs of pleural thickening but no pleurisy. As a rule, the disease produces neither cachexia nor metastases. The knowledge of this new variety of cancer of the lung clarifies the subject of lung cancer and facilitates the making of an early diagnosis of the disease.

Surgery in Military Hospitals

According to statistics recently published by the Central Office of Sanitation of the Italian Army, 5,757 operations were performed in Italian military hospitals during 1935 on the cranium, thorax, abdomen and extremities. The operations most frequently performed were those on the abdominal wall, especially for hernia. The annual frequency of cases of hernia in soldiers is about 1,500 cases. In about 1,000 of the cases soldiers request an operation. Soldiers in the remaining groups prefer to be dismissed. The number of appendectomies performed during the year was 1,101, with twenty-two deaths. The number of operations in mastoiditis was 256, with fourteen deaths. The number of operations on the eyes, adnexa and orbital cavity was 388, including seventeen enucleations and three eviscerations of the eye. The operating rooms of military hospitals were remodeled. The training of military surgeons was given great attention. Postgraduate courses in surgery for military surgeons are given at the clinics of Italian universities. The best of the modern methods for examination and for medical and surgical treatment of patients is now in use at military hospitals.

Italian Medical Journals

The Sindacato Nazionale dei Medici is approaching the problem of improving the nature of Italian medical journals. A meeting was recently held, attended by representatives of the ministry of corporations, of the confederations of artists and professionals, and of journalists. A motion to organize a scientific society as a branch of the national syndicate of journalists was accepted. Members of the society will be editors of nonpolitical journals. The first task of the society will be to make a classification of all scientific journals. Those of lesser importance will be either discontinued or incorporated into others of greater value in the same field.

Aug. 5, 1936

Nonamebic Ulcerative Colitis

At the International Congress on Gastro-Enterology, held at Brussels, a thorough discussion of severe nonamebic colitis was presented by Messrs Gallart Mones of Barcelona, Snapper of Amsterdam, Vimtrup of Copenhagen and Donati of Milan. Donati advocated medical treatment for the majority of cases of severe nonamebic colitis. Surgical intervention is reserved for cases that are refractive to medical therapy. Interventions are of two kinds: indirect, for the treatment of "foci" presumed or established as the source of the colitis, and direct intervention in the diseased colon. The indirect surgery may concern the mouth and the teeth, the stomach and duodenum, the appendix, the colon proper, the rectum, the peritoneum, the gallbladder, the uterus and its appendages and the urinary organs. Direct surgical interventions that can be performed for a developing colitis are (1) enterostomies, among which appendicostomy occupies an important place, (2) intestinal anastomoses and exclusions, and (3) colonic resections (partial colectomies). Numerous complications and sequels of colitis lie within the scope of surgical intervention. The technique of intervention does not permit of special rules. The most important problem concerned is the selection of the proper operative procedure. The advisability of an operation in several stages should be considered, especially when it is a question of partial colectomies. Operation in multiple stages is the procedure of choice excepting in case of right colectomies, for which the one stage intervention should be selected whenever that method appears to be possible.

An Obscure Epidemic of Weil's Disease

Messrs P. Nélis and F. van den Branden have had published by the International Bureau of Public Hygiene a monograph on epidemic icterus catarrhalis (Weil's disease). While one of these men was performing antidiphtheritic inoculations with anatoxin among the educational centers maintained by the National Child Welfare Service, a dozen cases of Weil's disease broke out in one center. Nélis and van den Branden undertook to study the problem. A summary of the data elucidated by them and of the conclusions at which they arrived forms the substance of this note.

Weil's disease is rare in Belgium, but isolated cases were encountered at Ghent in 1920 and at Brussels in 1934. In 1932 Bessemans and Thiry examined eighty-four sewer rats and found 31 per cent of the animals to be hosts of *Spirochaeta icterohaemorrhagiae*. The incidence of the disease is greater in the Netherlands, where in 1932 207 cases were reported, sixteen of which were fatal. At that time, it should be noted, 60 per cent of the rats examined were found to be infected. At the educational center that was the scene of the Belgian outbreak, the authors were unable to capture a single rat. In fact, there appeared to be none in the vicinity. The drinking

water, on repeated chemical and bacteriologic analysis, was found to be excellent. The presence of the leptospira could not be detected even after several months of culturing with the Korthof medium. The authors at length concluded that neither the spirochetes of Inada and Ido nor a paratyphoid infection could cause Weil's disease.

The literature mentions two epidemics of icterus in which the patients, although free from leptospira, were found to be harboring paratyphoid bacilli. The one, reported by Cantacuzène, occurred in the Rumanian army, the other, reported by Angstein, took place in Poland.

G Dandi describes an epidemic at Novara, Italy, in May 1932 in which the disease was so mild that it was not necessary to hospitalize the patients. The negative character of the laboratory observations led the author to term the infection a benign icterus of unknown origin. The epidemic of Weils disease observed in Belgium must also be classed among that numerous family of obscure icteruses.

Mental Disturbances in Carbon Monoxide Poisoning

Vermeulen, discussing the psychic manifestations in the victims of carbon monoxide intoxication before the Belgian Society of Forensic Medicine, says that cases necessitating commitment are rare. The principal symptom in these cases is mental confusion, this may assume a simple form with disorientation in time and space or it may be complicated by hallucinations, anxiety and even symptoms resembling those of dementia paralytica. Another important symptom which, however, is not necessarily present, is amnesia—anterograde, retrograde or lacunar. The patient is frequently given to confabulation, conjuring up fictitious events to explain his predicament. Childish pathologic behavior is markedly present in a majority of the patients. In some instances a syndrome is observed analogous to that produced by lesions of the corpus striatum, and this may take the form of pseudoparkinsonism. Other conditions that may follow the intoxication are aphasia apraxia and in some instances even a definitive toxic dementia. Vermeulen analyzes a group of clinical cases, calling attention to the diverse peculiarities of the disturbances. He speaks of the complete mental murtias, of the diagnostic problem in cases that resemble senile dementia, of delayed cases in which the symptoms appear sometimes a month subsequent to severe intoxication.

BUDAPEST

(From Our Regular Correspondent)

Sept 1, 1936

The Spread of Echinococcus in Hungary

Dr N Czirer analyzed all the cases of echinococcus observed in the Hungarian surgical clinics from 1917 to 1927 and found that echinococic infection accounted for 0.2 per cent of the total. Among 13,087 persons examined post mortem at the Budapest St Stephan Hospital echinococic cysts were seen in only sixteen instances, whereas in 10,847 autopsies at the provincial hospitals, twenty-six cases were found. Moreover, some of those found at the Budapest hospitals were from the country. Surveying the echinococcus statistics of all Europe, Drs Lörmicz and Bodrogi of Budapest came to the conclusion that human infestation is not more prevalent in Hungary than in countries west of Hungary. Certainly conditions are better than in Yugoslavia, Dalmatia, Bulgaria, Greece or Turkey. Nevertheless, they think that it would be advisable to take strong measures against the echinococcus.

According to the statement of responsible Turkish authorities the rate of infection is considerably higher there than in any of the western countries. In Bulgaria Dikoff studied the conditions in Sofia and states that in 9770 postmortem examinations between 1900 and 1908 the echinococcus was the cause

of death in forty eight patients, or 0.49 per cent. In 1922 out of 780 autopsies, death in seven cases was found to be due to echinococcus. R. Peicic has collected the cases in Yugoslavia during the latter ten years and found 921 cases, including 241 from Bosnia and South Servia. Slavonia, northeastern Croatia and northwestern Bosnia appear to be immune, and this distribution Peicic associates with the distance from Greece, which he regards as one of the most infected of European countries. As to Rumania, no authentic data are at hand, but so much is sure that the disease is not rare, particularly in the old kingdom of Rumania, Moldova and the Dobrudja.

Graduate Teaching in Budapest

Graduate medical teaching is no longer a national affair in Hungary. In recent years about one third of those taking courses have been foreigners, the surgical obstetric and urologic clinics of Budapest having been a special attraction. To meet the requirements of our own physicians, in view of the difficult financial and economic conditions that have prevailed in Hungary, the Central Board of Postgraduate Teaching has resolved to arrange courses in the larger provincial centers, as well as in Budapest. Physicians who could not afford to take the courses in Budapest could attend courses at provincial centers near their homes. Those who could not afford to take the courses without help and could not get subsidies from their local authorities or other sources have been provided with free board in the Physicians' House in Budapest, while others got board at the same place at a much reduced rate. The central board also made daily allowances in certain cases and even paid the locum tenens fees. The board gave leave to those holding official positions for the duration of the courses, which have been entirely free for them, 5 pengo only (about a dollar and a half) being paid as the registration fee. The courses lasted, respectively, for a fortnight and a month. Some of the Budapest clinics gave tuition to graduate students during the whole of the academic year. This year new courses have been established in maternal and child welfare work. Another new feature was the course on the management of public health institutions for medical superintendents. The subjects dealt with included hospital construction and management, medical technic, institutional feeding and laundry work.

The Regulation of Dental Practice in Yugoslavia

A new law definitely settles the troublesome question of dental practice by declaring that dentistry can be carried on by duly qualified doctors or dental technicians who have specialized in stomatology. Those dental technicians who gained their right to practice before 1932 may continue their work without disturbance. Those whose license was not recognized by the revision in 1935, if over 42 years of age, will have to pass qualifying examinations in December 1936, while those under 42 will have to attend regular courses, lasting six months, in dental technic and pass the final examination. Only those technicians are justified in applying for admission to the courses who before 1932 had already five years of practice (two years as apprentices and three years as assistants in laboratories). Those who have passed a matriculation examination in a secondary school and attended some foreign high school for dentistry and obtained a diploma after four years of study may carry on dental practice in Yugoslavia without further notice. Dental technicians and also dental surgeons are not allowed more than one consulting room.

Diathermy machines, quartz-light lamps, therapeutic short-wave sets and x-ray apparatus may be owned and used by qualified physicians only. Likewise, electrolysis and electrocauterization should be applied by physicians, and this exclusively medical work must not be done by barbers, masseurs, manicurists, chiropodists or cosmetic institutes.

Marriages

WILLIAM HUME HOSKINS, Venice, Fla., to Miss Elizabeth Braxton Henry Watson of Richmond, Va., August 22

WILLIAM EARL OVERCASH, Southern Pines N. C., to Miss Marjorie Skinner of Elizabeth City, August 8

WILLIAM ANGLE YOUNG, Roanoke, Va., to Miss Margaret Maie Owens of Richmond, August 15

WASHINGTON C WINN, Keyesville, N. C., to Miss Harriet Irene Nance in Asheville, August 29

A LAFAYETTE STRATFORD to Miss Cary Valentine Cutchins, both of Richmond, Va., August 7

MUNFORD RADFORD YATES of Lynchburg, Va. to Miss Frances Jones of Petersburg, August 15

CHARLES WHITFIELD GASKINS to Miss Ruth Chunn, both of Asheville, N. C., in August

SAMUEL WEINSTEIN to Miss Hollis Hayward Young, both of Richmond, Va., August 2

ROBIN MILES OVERSTREET, Portland, Ore., to Miss Laura McGinty of Atlanta in July

HAROLD GIFFORD JR. to Miss Mary Elizabeth Jonas, both of Omaha, August 11

JOSEPH F GRIGGS to Miss Jeanette Speden, both of Tacoma, Wash., August 8

Deaths

J Leslie Davis of Philadelphia, Jefferson Medical College of Philadelphia, 1901, member of the American Academy of Ophthalmology and Oto-Laryngology, fellow of the American College of Surgeons, associate in laryngology at his alma mater from 1906 to 1909 and professor of laryngology at the University of Pennsylvania Graduate School of Medicine in 1919 and 1920 consulting otolaryngologist to the Pennsylvania Institution for the Deaf on the staffs of St. Mary's Hospital from 1903 to 1910, Philadelphia Lying-In Hospital from 1910 to 1925 and St. Agnes Hospital from 1915 to 1925, for many years trustee to the Philadelphia Free Library and the Philadelphia College of Pharmacy, made various contributions to the literature on otolaryngology, aged 63 died, August 1, in the Jefferson Hospital, of carcinoma of the sigmoid colon with metastasis to the ileum

James William Leech of Providence, R. I. University of Pennsylvania Department of Medicine, Philadelphia, 1904 for twenty years secretary of the Rhode Island Medical Society, member of the American Academy of Ophthalmology and Oto-Laryngology and the New England Ophthalmological Society fellow of the American College of Surgeons, past president of the Rhode Island Ophthalmological and Otolological Society surgeon, eye department, Rhode Island Hospital surgeon-in-chief eye department, Charles V. Chapin Hospital, consulting ophthalmologist to the Providence Lying-in Hospital Providence Memorial Hospital, Pawtucket, Westerly (R. I.) Hospital and consulting laryngologist to the Butler Hospital, aged 55, died suddenly, October 6, in the Jane Brown Memorial Hospital

George Oliver Sharrett of Cumberland, Md. Baltimore Medical College 1908, past president of the Medical and Chirurgical Faculty of Maryland and the Allegany-Garrett Counties Medical Society, member of the State Board of Medical Examiners member of the American Academy of Ophthalmology and Oto-Laryngology and the American Laryngological Rhinological and Otolological Society fellow of the American College of Surgeons member of the city board of health, served during the World War aged 49 consulting oculist and otolaryngologist to the Miners Hospital, Frostburg the Hazel McGilvery Hospital Meversdale Pa. the Allegany Hospital and the Memorial Hospital, Cumberland, where he died, August 27 of coronary occlusion

Hugh Poteet Muir, Columbia, Mo., Harvard University Medical School, Boston 1922 member of the Missouri State Medical Association, at one time lecturer in physical diagnosis and at various times instructor in the departments of pathology, anatomy and medicine at the University of Missouri School of Medicine first resident physician at the University Hospitals city health officer aged 41 died, August 14 in the Bell Memorial Hospital Kansas City Kan., of tuberculous peritonitis

Russell Dean Robinson of Chicago, College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1914, served during the World War, on the staffs of the Roseland Community Hospital and the Little Company of Mary Hospital, physician to the Morgan Park Military Academy, aged 46, died, August 5, of injuries received when he fell from the roof of his home while repairing a radio aerial

John Allen Douglass, McDonald, Pa., Hahnemann Medical College and Hospital of Philadelphia, 1896, member of the Medical Society of the State of Pennsylvania, served during the World War, for many years a member and at one time president of the borough council, on the staff of the Washington (Pa.) Hospital, aged 62, died, August 31, of carcinoma of the stomach and internal hemorrhage

William Lisenby Gray of Champaign, Ill., Keokuk (Iowa) Medical College, 1891, fellow of the American College of Surgeons, past president of the Champaign County Medical Society, for many years member and president of the board of education, formerly city health officer, aged 70, on the staff of the Burnham City Hospital, where he died, August 29 of a skull fracture received in a fall

John Schofield Eynon of Chester Pa., University of Pennsylvania Department of Medicine, Philadelphia, 1911 past president of the Delaware County Medical Society, fellow of the American College of Surgeons, surgeon to the Chester Hospital and consulting surgeon to the Taylor Hospital, Ridley Park, aged 47 was killed, August 15, in an airplane accident at Brant Beach, N. J.

Thomas M. Parkins, Staunton, Va., College of Physicians and Surgeons, Baltimore, 1894, member of the Medical Society of Virginia, city health officer and city coroner, formerly secretary and treasurer of the Augusta County Medical Society, on the staff of the King's Daughters Hospital, aged 70 died, August 10, following injuries received in an automobile accident

Richard Booker Easley, Huntington, W. Va., Medical College of Virginia, Richmond, 1926, member of the West Virginia State Medical Association, served during the World War, chairman of the staff of the Memorial Hospital and member of the staff of St. Mary's Hospital aged 41, died, August 13, near Bellehaven, Va., of coronary disease

Frank Keith Meade of Hays, Kan., Rush Medical College, Chicago, 1902, member of the Associated Anesthetists of the United States and Canada, formerly secretary of the Central Kansas Medical Society, served during the World War, for many years on the staff of St. Anthony's Hospital, aged 61, died, August 2, of angina pectoris

Theodore William Scholtes of Munising, Mich., College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1901, past president of the Marquette Alger Counties Medical Society, city health officer and county coroner, on the staff of the Munising Hospital, aged 58, died, August 25, of heart disease

William Capell Duckworth, Jackson, Tenn., Vanderbilt University School of Medicine, Nashville, 1900, member and past vice president of the Tennessee State Medical Association, past president of the Madison County Medical Society on the staff of the Memorial Hospital, aged 66, died, August 19, of coronary thrombosis

Wilbert Evans Fordyce, Sunnyside, Wash., Keokuk Medical College, College of Physicians and Surgeons, 1900, member of the Washington State Medical Association, served during the World War aged 61, died, August 12, in the Veterans Administration Facility, Portland, of carcinoma of the prostate and bladder

Robert Pattison Miller, Hopewell N. J. Hahnemann Medical College and Hospital of Philadelphia, 1906, member of the staff of McKinley Hospital Trenton and member of the board of managers of the New Jersey State Village for Epileptics at Skillman, aged 53, died, August 3, of coronary occlusion

John W. Scott, Gordonsville, Va., College of Physicians and Surgeons, Baltimore, 1878, member of the Medical Society of Virginia formerly health officer of Gordonsville for many years president of the town council aged 81, died August 23, in a hospital at Richmond of cardiorenal disease

William Thomas Henderson of Mobile, Ala., Detroit College of Medicine, 1896, fellow of the American College of Surgeons surgeon to the Providence Hospital and consulting surgeon to the City Hospital, aged 67 died, August 18, of arteriosclerosis and paralysis agitans

D. Edmund Cone, Coshocton Ohio College of Physicians and Surgeons of Chicago School of Medicine of the University

of Illinois, 1904, member of the Ohio State Medical Association on the staff of the Coshocton City Hospital, aged 67, died, August 28, of angina pectoris

Boyce Richardson Bolton ♂ Washington, D C, George Washington University School of Medicine, Washington, 1917 assistant professor of otorhinolaryngology at his alma mater served during the World War, aged 44, died, August 16, of carcinoma of the pancreas

Charles Wesley Rexroad, Harrisville, W Va, Starling Medical College, Columbus, 1886, member of the West Virginia State Medical Association, past president and secretary of the Ritchie County Medical Society, aged 78, died, August 4, of carcinoma of the bladder

Robert Joseph Boyle, Bristol Conn, Yale University School of Medicine, New Haven, 1908 member of the Connecticut State Medical Society, on the staff of the Bristol Hospital aged 50, died, August 6, in St Francis Hospital, Hartford, of pneumonia

John Earl Pulver, Chicago, John A Creighton Medical College, Omaha 1908, member of the Illinois State Medical Society, chief surgeon for the Chicago and North Western Railroad, aged 52, died, August 28, in Omaha, of arteriosclerotic heart disease.

Edward McGrath ♂ Baraboo, Wis, Rush Medical College, Chicago, 1909 past president of the Sauk County Medical Society, aged 62, on the staff of St Mary's Ringling Hospital, where he died, August 13, as a result of injuries resulting from an automobile accident.

Joseph T Graham, Booneville Tenn, Vanderbilt University School of Medicine, Nashville, 1883 member of the Tennessee State Medical Association, aged 82, died, August 27 of pneumonia which followed injuries received when he fell from his horse.

David A Morton, Boaz, Ala, Medical Department of Grant University, Chattanooga, Tenn., 1896, member of the Medical Association of the State of Alabama, formerly mayor of Boaz, aged 75, died, August 12, in Forrest General Hospital, Gadsden

Ranson S Gage, Dover, Ohio, College of Physicians and Surgeons, Keokuk, Iowa, 1890, member of the Ohio State Medical Association formerly on the staff of the Union Hospital aged 73, died, August 8, at the home of his son in Stockport.

John Wesley Chisholm, Natchez, Miss Memphis (Tenn) Hospital Medical College, 1907, member of the Mississippi State Medical Association, on the staff of the Natchez Hospital aged 63, died, August 15, of coronary thrombosis and arteriosclerosis

Warren Tecumseh Peters ♂ Burt, Iowa Rush Medical College, Chicago, 1894, past president of the Kossuth County Medical Society, bank president, and for many years president of the board of education, aged 66, died, August 3, of cardiac disease.

Edward Clarence Rumer, Flint, Mich, Detroit College of Medicine, 1902, member of the Michigan State Medical Society, veteran of the Spanish American and World wars, aged 60, died August 10, in Pleasant Lake, of a self-inflicted bullet wound

Duncan Alex Cameron, Alpena, Mich McGill University Faculty of Medicine, Montreal Que., Canada, 1885 member of the Michigan State Medical Society, formerly member of the state legislature, aged 73, died, August 3 of angina pectoris

Thomas D Cantrell, Bloomington, Ill Rush Medical College, Chicago, 1888, member of the Illinois State Medical Society served during the World War, aged 72, died August 18, of arteriosclerosis and cerebral hemorrhage

Benjamin W Bayless ♂ Shelbyville, Ky, University of Virginia Department of Medicine, Charlottesville, 1902 aged 55 formerly on the staff of the King's Daughters Hospital where he died, August 4 of heart disease.

John R Cason Jr, Delray Beach Fla University of Arkansas School of Medicine, Little Rock 1905, member of the Florida Medical Association aged 55 died, August 29 of nephritis and arterial hypertension

Amos Cornelius, Owensboro Ky Louisville National Medical College, Medical Department State University 1907 aged 55 died, August 29, in the Cook County Hospital Chicago of hypertensive heart disease.

Abraham William Chernoff, Cleveland, Tufts College Medical School Boston 1932 aged 26 on the staff of the City Hospital where he died, August 18 of a skull fracture received in an automobile accident

William C Dugan, Clark Ky University of Louisville (Ky) Medical Department, 1881, professor emeritus of surgery and clinical surgery at his alma mater, aged 77, died, August 1, of cerebral hemorrhage

Benjamin O. McCleary ♂ Baltimore, College of Physicians and Surgeons, Baltimore, 1910, for many years a member of the city health department, aged 54, died, August 23, at his summer home at Round Bay Md

Douglas Laten Potter, Chicago, Rush Medical College, Chicago, 1935, aged 27 on the staff of the U S Marine Hospital, where he died, August 25, of intestinal obstruction due to adhesions and acute peritonitis

Charles Frederick Lutz ♂ New York, Cornell University Medical College, New York, 1910, also a graduate in pharmacy, aged 48 died, August 20, at his home in Poundridge, of a self-inflicted bullet wound.

Jairus E Hileman, San Diego Calif, College of Physicians and Surgeons of Chicago 1886, member of the California Medical Association, aged 76, died August 4, of arteriosclerosis and heart disease.

George Henry Kuper ♂ St Louis, St Louis College of Physicians and Surgeons, 1896, Barnes Medical College, St Louis, 1911, aged 61, died, August 26, in the De Paul Hospital, of diabetes mellitus

Floyd Harold House ♂ Westville Ind, Baylor University College of Medicine Dallas, Texas, 1921 past president of the La Porte County Medical Society, aged 48, died, August 3, of coronary occlusion

Alfred Nelson Gordon, Fosterville, Tenn, University of Nashville Medical Department, 1905, member of the Tennessee State Medical Association, aged 56 died, August 2, of coronary thrombosis

Leander W Cape, Maplewood, Mo, St Louis Medical College, 1887, member of the Missouri State Medical Association, aged 76, died, August 28, of arteriosclerosis and hypertension

Virgil L Casto, Ripley, W Va University of Louisville (Ky) Medical Department, 1888 formerly member of the state legislature, aged 71, died August 6, of carcinoma of the esophagus

Robert Delroy Carl, Shenandoah, Pa., Jefferson Medical College, Philadelphia, 1930 aged 32, died, August 29, in a hospital at Ashland, as the result of an injury received in a fall

William E Driscoll, Craig, Colo, Medical College of Ohio, Cincinnati, 1886, aged 77, died, August 28, in the Ball Memorial Hospital, Muncie, Ind, of carcinoma of the pancreas

Joel C Chandler ♂ Columbiana, Ala, University of the South Medical Department, Sewanee, Tenn, 1908, aged 54 died August 9, in the Baptist Hospital, Birmingham of uremia

Palmer John Kress ♂ Allentown, Pa, Jefferson Medical College of Philadelphia, 1895, aged 64, died, August 3, in the Jefferson Hospital, Philadelphia, of aplastic anemia

Robert E Lyall, Los Angeles Willamette University Medical Department, Salem, Ore., 1882, aged 80 died, August 4 of ruptured aneurysm of the abdominal aorta

James T Ozanne, Oshkosh Wis, Hahnemann Medical College and Hospital, Chicago 1880, aged 83, died, August 13, in the Mercy Hospital, of a heart block.

Omer C Clark, Worthington, Pa, Western Pennsylvania Medical College, Pittsburgh, 1896, aged 67, died August 26, of chronic nephritis and myocarditis

Arthur L Churchill, Saratoga Springs N Y, Eclectic Medical College of the City of New York, 1880, aged 78, died, August 24, of cerebral hemorrhage

Alexander Craig, Toccoa, Ga., Jefferson Medical College of Philadelphia 1912 aged 53 died, August 12, from the effects of poison taken accidentally

William Edgar Cornett, Rush Hill Mo, St Louis College of Physicians and Surgeons 1890, aged 68, died suddenly, in August, of heart disease.

Richard Travis Edwards, Oklahoma City, Jefferson Medical College of Philadelphia 1889, aged 67, died, August 6 of coronary thrombosis

Herbert D Hill, Westfield Wis Rush Medical College, Chicago, 1880 aged 80, died, August 24, of cardiorenal disease

Edward Homer Griffis, Detroit Michigan College of Medicine and Surgery, Detroit, 1906, aged 58, died, August 29

Anna B Page, Louisville Ky Louisville National Medical College, 1902 aged 72 died July 15

Bureau of Investigation

VAPOR-GAS

"A New and Marvelous Discovery" for Piles Essentially a Mixture of Commercial Sodium Hydroxide and Commercial Gelatin

Inquiries coming to the Bureau of Investigation concerning "Vapor-Gas for Piles" an alleged "scientific remedy" put out by the Vapor-Gas Company of Vining, Minn., stimulate this report

According to a leaflet for Vapor-Gas Co., the product "was first put on the market in February 1935 and has been sold continually since in many states. It has never come in contact with a case it did not subdue with immediate relief the first treatment." The same leaflet claims that "These vapors and gasses penetrate every pore of the rectum. It also disinfects every exposed part and removes your troubles immediately. It's not a salve nor a pill—just gas." With the latter statement there can be no controversy.

One package of Vapor-Gas, purchased direct from the Vapor-Gas Company, Vining, Minn., was submitted by the Bureau of Investigation to the A M A Chemical Laboratory for analysis. The package contained a composition capped jar, the label of which is here reproduced in part.

VAPOR-GAS

FOR PILES

This jar contains 3 treatments
Immediate relief the first treatment
Seldom more than one treatment
necessary

THE VAPOR-GAS COMPANY
VINING, MINNESOTA

Pat. Appl. d For

The report of the A M A Chemical Laboratory follows

LABORATORY REPORT

"The Vapor-Gas jar contained three cork-stoppered vials of about 10 cc. capacity and directions as follows:

'Put about five inches of boiling water into Toilet Jar or tall bucket. Use Jar or Bucket tall enough so that body will be at least eight inches from water. Use towel on rim of jar or bucket so that vapor and gasses don't escape.

"Remove garments and sit down on jar or bucket then take one vial remove cork, and drop vial with contents into water. Remain seated ten minutes. If more treatments are necessary use them about three days apart. In the evening before retiring is the best time to take treatments. When you have been using salves and ointments the first treatments may not penetrate as effectively.

"Do not permit chemicals to come in contact with any part of your body. Keep jar away from children. Keep this jar tightly capped in dry cool place and remaining treatments will keep indefinitely.

"The antidotes listed are those used for alkalis.

VAPOR-GAS

FOR PILES

The latest and most successful
remedy for itching
bleeding and pro-
luding Piles. Its
not a salve nor
a pill - Just
GAS

The package does not give the common name of the caustic ingredient as directed by the Federal Caustic Poison Act, Sec. 2. Each vial contained approximately 205 Gm of material which consisted of a coarse mixture of crystals varying in size from powder to one centimeter in length and yellowish translucent plates varying greatly in size. One of the vials con-

tained no plate-like material. The crystals were odorless with a bitter taste and basic reaction to litmus. The plate-like material had an odor indicative of protein material and when boiled with water gave a gel.

"Qualitative tests indicated the presence of sodium, potassium, chlorides, gelatin, and traces of sulfate and phosphate. Bromides, iodides, heavy metals, nitrates, formaldehyde and agar were not found.

"Quantitative determinations yielded the following results:

Loss of weight (120 C)	3.33 per cent
Ash	99.81 "
Sulfated ash	174.97 "
Titrateable alkalinity (calculated as OH ⁻)	39.96 "
Titrateable carbonates (calculated as CO ₃ ²⁻)	3.51 "
Sodium	54.59 "
Potassium	1.15 "
Gelatin	approximately 1.25 "

"From the foregoing, it is calculated that the product contains essentially 90.32 per cent sodium hydroxide, 6.27 per cent sodium carbonate, 1.65 per cent potassium hydroxide, and 1.2 per cent gelatin. Commercial sodium hydroxide generally contains impurities (approximately 8 per cent sodium carbonate and 2 per cent potassium hydroxide). Therefore it is concluded that the product consists essentially of a coarse mixture of commercial sodium hydroxide (98.5 per cent) and commercial gelatin (approximately 1.2 per cent).

Thus a mixture consisting essentially of caustic soda and gelatin is hailed as a "new and marvelous discovery" and the "vapors" from such a combination are said to constitute a "scientific" treatment for hemorrhoids. The Food and Drugs Act of 1906 has never been adequate to meet this kind of exploitation.

Correspondence

A CRITICISM OF STYLE IN MEDICAL WRITING

To the Editor —As I peruse the periodicals of the day, I am struck by the fact that there is style in writing, and that, like all other styles, it is subject to change.

Certain words, new or old are brought before the public eye in some exceptionally good story and then begin to appear in 90 per cent of all stories that are published in the next twelve months. For instance, 99 per cent of all the heroes of today's short stories are 6 feet 2, have red curly hair and "gangling" legs, while some other member of the party is "meticulous" about this or that. Both of these words have been on the market more than a year and are quite shopworn, but no up-to-date story is complete without one or both.

Medical literature is probably the worst offender, it took twenty years to educate the physician to the fact that "phenol" meant carbolic acid, and the two little latin quips "per se" and "sine qua non" were bound to appear in the first column.

A more recent word that has broken all records is "evaluate", it certainly has filled a long felt want.

The Council on Pharmacy and Chemistry set the style years ago in renaming some old remedies by mentioning some of their more important ingredients. Immediately the chemist and the pharmaceutical houses went them one better and mentioned all (and sometimes more) of the ingredients that went into the formation of their new remedies. No longer is it proper to say Dr. Costa's Heart Stimulant or Kenyon's Hepatic. That puts them in the same category as Lydia Pinkham or Dr. Pierce's Favorite Prescription. Now we have backed out of the field and left the spoils to the victor. On reading our medical journals we find the name of some new headache remedy to contain thirty, forty or more letters. I sincerely hope this fad will stop right where it is.

A good old fashioned biscuit will become flouro sodio-lardo, while a pie should or would become a crisco-flouro-sugaro-apple—in oven at 350 for thirty minutes.

On that same basis mere man would become a musculo-torso mustachio basso profundo biped sans tailo while his fair

running mate could be described as faceo-smearo pigmento-voico soprano-exquisito, magno busto cum minimo hippo, cherrio, deario, sweetheart

If this little criticism strikes a responsive chord in your anatomy it is a sure sign that you are over 45 years of age. If so you will probably agree with me that no medical or medicolaboratory man should burst into print until after he had been graduated ten years

FAYETTE E. READ, M.D., Akron Ohio

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT HOWEVER REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS BUT THESE WILL BE OMITTED ON REQUEST

CONTAMINATION OF FOOTBALL PADS AND HARNESSSES

To the Editor—I have noticed that the skin of football men is often irritated and infected by contact with their shoulder harnesses. Is there any way in which the harness (pad) may be cleaned and disinfected to lessen this trouble? Any advice will be appreciated. Please omit name.

M.D. Wisconsin

ANSWER.—Most of the shoulder apparatus worn by football players on the large Eastern universities is made of a combination of leather and felt. The methods of sterilizing these pieces of apparatus are by dry heat, as for example baking them in some sort of oven. If this is done with care not to cause any burning, the effect on the leather and the felt is negligible. No method of sterilization has been found when rubber is incorporated in the material. The rubber used today in these appliances contains a certain amount of gas, and heat sterilization will cause shrinking of the rubber and it will become hard and useless. Of course, chemical sterilization of the sponge rubber also is impossible without changes occurring in the rubber itself. It is a common practice therefore, to remove the rubber and sterilize the remainder of the apparatus by dry heat, as in an oven, and then replace or renew the rubber. It might be added that dry cleaning by the usual method or zoric has proved unsatisfactory if not destructive to this apparatus

TOXICITY OF CYANIDE CHLORIDE

To the Editor—I would appreciate receiving information relative to cyanide-chloride 75 per cent which is a product in powder form sold for the purpose of hardening steel. A blacksmith has used this product for the past few years spreading it on hot steel which causes the powder to become liquid and then vaporize. No protection is taken from inhaling the fumes that arise. The steel covered with this product is then submerged in water. This whole process causes the fumes. The patient has experienced for the past two years a neuritis of the right leg and various indefinite gastric upsets unrelated to any other cause. Muriatic acid is handled in much the same manner. I would appreciate receiving any information regarding harmful effects

JOHN P. GALLAGHER, M.D. Oelwein Iowa

ANSWER.—Cyanide chloride is to be distinguished from cyanogen chloride (CNCl). The former is a mixture of about 75 per cent sodium cyanide (NaCN) with 25 per cent sodium chloride. This mixture is in wide use in the heat treatment of metal. One of the apparent anomalies of industrial toxicology is that in heat treating departments making use of cyanides no large numbers of poisonings take place even when the cyanide materials are handled with recklessness. Explanation appears to be found in the fact that cyanides at high temperatures such as prevail in heat treatment of metals are quickly changed over into carbonates. Thus sodium cyanide in contact with highly heated metal would be changed over into sodium carbonate and some free nitrogen would be produced. However, when temperatures are fairly low, decomposition of cyanides liberates hydrocyanic acid gas with its deadly properties. Because of the chemical changes mentioned, the occurrence of dangerous vapors or gases in case hardening by a blacksmith is minimized. The advent of a neuritis is suggestive of cyanide action. Collins and Martland have been able to produce a peripheral neuritis in animals by cyanides. This neuritis

was accompanied by degenerative changes of the spinal cord. Any chronic involvement from cyanides as the cause is open to some question. Sponsors of the belief that chronic poisoning may take place point out the following manifestations as characteristic

"In chronic cases muscular weakness, lassitude, pulmonary congestion, irritation of the skin, huskiness, conjunctivitis, edema of the eyelids, irregularity of the pulse varying with the extent of the exposure to the poison, diminution of the appetite with abrupt crises of abnormal and unnatural hunger, loss of weight."

BONE PAINS IN AGRANULOCYTOSIS

To the Editor—A woman aged 51 suffered from an attack of agranulocytosis two years ago. At that time she was desperately ill with a white count of 250. She became moribund but was given pentnucleotide and a series of transfusions. Although recovery was despaired of she recovered. She did however retain the effects of sloughing of her soft and hard palates with speech impairment. Her past history is negative except for typhoid at 15 years of age. About two months ago she began to complain of pains in her bones particularly in her arms and about her neck. These pains have gradually spread until she has become bedridden. While she says the pain is like a crushing process inside the bones I am not convinced that a great deal of it exists in the muscles. The pains are constant day and night and are aggravated by any movement. Examination reveals nothing significant. The long bones are tender to touch however. The temperature does not range above normal but tends to be subnormal. X-ray studies of the long and flat bones are negative. The basal metabolism is minus 11. Blood studies reveal no anemia. The white blood count has ranged around 7,000 with 75 per cent polymorphonuclears. The blood sugar is 95 mg. fasting nonprotein nitrogen 52. Wassermann reaction negative. The urine shows a trace of albumin no sugar one plus fine granular casts and one plus pus cells. The phenolsulfonphthalein test was poor with only 30 per cent regained in two hours. I should like to ask whether you think her present condition bears any relationship to the previous attack of agranulocytosis and what form of treatment you would suggest. So far she has had various sedatives but little opiates, sulfur intravenously, liver extract intramuscularly and a high vitamin high protein diet. Please do not publish name.

M.D. Georgia

ANSWER.—There is no evidence in recorded cases to indicate that bone pains are a part of the picture of a present attack or past attack of agranulocytosis. In many cases of leukemia however, including the aleukemic types, bone pains are a part of the clinical picture. Agranulocytosis and aleukemic leukemia are often difficult to differentiate. It appears unlikely that this patient has aleukemic leukemia, because the duration of the disease since the acute attack and the present blood picture does not indicate it. For that matter, the present blood picture does not indicate the presence of any blood dyscrasia.

Treatment would be purely empirical because of a lack of diagnosis. There would seem to be no reason for employing liver extract or sulfur when the blood appears normal. The use of aminopyrine drugs should be avoided in view of a past attack of agranulocytosis. In view of negative X-ray studies, the probability of these pains arising in muscles would have to be strongly considered. Blood calcium studies may be of value. In view of kidney damage, an obscure infectious process may be likely. Perhaps the Wassermann test should be repeated, in view of the bone pains and past sloughing of the hard palate

FATE OF ASEPTIC SPONGE LEFT IN ABDOMINAL CAVITY

To the Editor—Assuming that an aseptic sponge should be left in the abdomen after a laparotomy what would happen to the sponge? How long would it take for the gauze to deteriorate? What would be its condition say after a period of five years? What effect would it have on the patient? I would appreciate having data bearing on these questions

ARCHIE A. SKEMP, M.D. LaCrosse Wis

ANSWER.—The fate of an aseptic sponge left in the abdominal cavity after laparotomy varies with the size and location of the sponge. A sponge of normal size or smaller may become adherent by connective tissue to a viscus usually a loop of intestine or the peritoneal wall, and undergo encapsulation. The omentum is helpful in the walling-off process. Partial or complete absorption of the sponge is uncommon. Abscess formation may be provoked. More usually the sponge is retained more or less intact for perhaps many years. R. D. Forbes reported the removal of a whole sponge after eighteen years (*S. Clin. North America* 13:1353 [Dec.] 1933). A not uncommon result is ulceration from without of the intestine, vagina or urinary bladder into the lumen or cavity of which the sponge may emerge but expulsion through any of these routes is seldom complete, and obstructive and other symptoms will demand surgical intervention. Symptoms may develop

early, be delayed for years, or be absent entirely. After a few days or weeks severe pain may arise in the abdomen followed by signs and symptoms of ileus, bladder disturbances or rectal tenesmus. According to J. P. Greenhill (*Am J Obst & Gynec* 25:231 [Feb.] 1933) the death rate of patients operated on for removal of a foreign body in the abdominal cavity is 17.6 per cent.

CONTROL OF PHLEBITIS

To the Editor—An unmarried girl aged 26 a bank clerk suffered from phlebitis of the left femoral vein and its tributaries two years ago following a simple appendectomy. The left hip had been painful many times previous to the operation and would snap partially out of joint at times. She attributes this to a fall on the hip during childhood. The left thigh measures $1\frac{1}{4}$ inches larger in circumference than the right hip. The left thigh and leg remain swollen continuously. There is slight tenderness over the left femoral vein below the inguinal ligament and over the left popliteal space. Is it probable that the chronic hip ailment caused or aggravated the phlebitis? What is the best treatment for the late effects of the phlebitis? Would an operation in an attempt to remove the venous obstruction be advisable? What is the prognosis if left untreated? Please omit name.

M D Kansas

ANSWER—It is highly improbable that the chronic hip ailment had anything to do with the development of the phlebitis or with the secondary consequences of the phlebitis, provided, of course, it is not a lesion that produces obstruction of the iliac or femoral vein. There is no logic to resection of a vein to overcome venous obstruction and this procedure is not recommended. The results of thrombophlebitis depend on the extensiveness of the thrombosis. They vary from simple edema to varicose veins, stasis dermatitis and varicose ulcers. In order to prevent these complications it is extremely important to treat the condition adequately. The patient should go to bed and have the affected limb elevated until there is no further reduction in the swelling, this usually requires about three days. Then adequate support should be applied to the limb to prevent swelling when the patient again becomes active. Ordinarily a cloth elastic bandage is not adequate. In some cases a well fitted heavy elastic stocking prevents edema. However, in many instances a pure rubber bandage is required. These bandages come in different weights and are 3 inches wide and 15 feet long. The bandage is applied like a puttee over a lisle stocking after preliminary figure-of-eight turns around the foot and ankle and should extend to just below the knee. A support is adequate when it prevents edema when the patient is active and should be worn only during this period. In most instances swelling of the thigh will disappear if swelling below the knee is satisfactorily controlled. In other instances it is necessary to apply an elastoplast or trichoplast type of bandage, since cloth or rubber bandages do not stay in place well. The patient should be instructed to try one day about every month without the bandages or stockings. If edema recurs the support should be worn for an additional month. It can be dispensed with only when there is no further edema when the patient is active. This period varies greatly from a few months to many years. If edema of the limb is prevented by adequate support varicose veins, ulcers and dermatitis will not occur.

TREATMENT OF SYPHILIS

To the Editor—A white woman aged 33 has 3 plus Wassermann and Kahn tests. She states that there never was a primary lesion or a secondary eruption and she presents no evidences of a congenital or a cerebral syphilis. On physical examination she has an enlarged liver and spleen each having a smooth edge and projecting about three finger breadths below the costal margin. Recently she was hospitalized for a period of three weeks and because of failure (through blood urine and roentgenologic studies) to attribute the hepatomegaly and splenomegaly to any other disease entity but syphilis she was referred to me for anti-syphilitic treatment. Would the arsenphenamines be contraindicated in treatment of this case in view of the hepatomegaly? If so will you kindly outline an antisyphilitic course for treatments? May arsenphenamine be used in antisyphilitic treatment if there is liver enlargement due to cirrhosis chronic passive congestion or chronic alcoholism? Please omit name.

M D New Jersey

ANSWER—Apparently this patient has a symptomless type of syphilitic infection. It would probably be well to do lumbar puncture for sometimes there may be an involvement and yet nothing will show on physical examination. Naturally if she is married the husband and children should also be checked up.

In a case of this type it is correct to surmise that the arsenicals for the present at least should not be employed. It would be preferable to put the patient on potassium iodide internally and give a course of twelve intramuscular injections of bismuth salicylate giving the injections once a week, and of course watching the patient for any manifestations of

toxic phenomena. Following this therapy a course of from fifty to sixty applications of mercurial ointment may be given, the patient rubbing the ointment in for thirty minutes by the clock. Following this course of treatment, if the patient has responded well and there have been no unusual disturbance and no toxic manifestations, and if the liver volume has decreased in size without the production of too much scar formation, neoarsphenamine may be tried cautiously, starting with an injection of 0.2 Gm and gradually working it up to a maximum of 0.3 Gm, the injections being given one week apart for a series of twelve treatments. If there is no disturbance from this treatment, there would then be no objection to alternating courses of neoarsphenamine and of bismuth salicylate until the patient has received at least thirty or forty injections of the bismuth and possibly from twenty to thirty of the neoarsphenamine.

Naturally, it is difficult to outline a complete course of treatment for a patient of this sort complications may arise. It would be well to follow the patient's icteric index in connection with the treatment, especially the arsenical therapy.

Naturally, a Wassermann test should be made at the end of each course of treatment, and if there is involvement of the central nervous system this would likewise require further changes in therapy.

In cirrhosis of the liver the arsenicals should be used with great care, and in chronic passive congestion with liver enlargement much would depend on the causation. It probably would be preferable to get along with other therapy.

Chronic alcoholism of itself is no contraindication to therapy if the alcohol is stopped after the treatment is instituted.

TREATMENT OF OBESITY

To the Editor—I have under my observation a man aged 32 height 5 feet 11 inches (180 cm) who is gaining weight constantly in spite of rigid dietary restrictions. His present weight is 307 pounds (139 Kg). About a year ago he was treated with alpha-dinitrophenol sodium of which he took approximately 8 to 10 grains (from 0.5 to 0.65 Gm) daily for ten weeks. There was a reduction in weight to about 275 pounds (125 Kg). He was greatly pleased with the results but following the numerous reported cases of undesirable effects of dinitrophenol I discouraged the further use of the drug. There is a family tendency toward obesity although not as marked as in this case. The basal metabolic rate was taken on several occasions the results being plus 13 and minus 8. He has a persistent tachycardia and is quite dyspneic on exertion. The pulse rate is usually between 96 and 104. The blood pressure is 160 systolic, 110 diastolic. In other respects his health seems quite normal. Thyroid therapy when pushed to tolerance only accentuates the tachycardia. Is there any possibility of any pituitary dysfunction? What suggestions can you give me as to handling this case? Kindly omit name and address.

M.D. Ohio

ANSWER—It is impossible, from the description of the case to rule out the possibility of a pituitary dysfunction. Nevertheless to consider such a dysfunction, if present, as the chief etiologic agent in this case of obesity would be incompatible with the increased blood pressure and pulse rate and with the normal basal metabolic rates.

It is apparent that the patient is not exhibiting a subnormal expenditure of energy. The only alternative explanation of the obesity, regardless of endocrine or hereditary factors, is therefore an excessive caloric intake. In other words, he eats too much. If the dietary prescription really represents a "rigid restriction" of calories, the patient is either mistaken or is lying about his adherence to it. A useful procedure in such cases when economically and socially possible, is the administration of the prescribed diet under supervision in a hospital for a week or two.

The resumption of gain in weight after cessation of dinitrophenol illustrates the common fallacy of attempting to treat obesity by temporarily increasing the energy expenditure with drugs. It is obvious that, unless the patient learns to eat less he must regain his excess weight as soon as the artificial stimulus to his metabolic processes is removed. Thus except in a case of frank hypothyroidism it is not logical to use such drugs, since they cannot be justifiably continued for an indefinite period.

The use of either dinitrophenol or thyroid extract in this case is also inadvisable from another standpoint. Aside from the many toxic effects of the former, both these substances increase the work of the cardiovascular system. Since this is the system which seems to be showing the most deleterious results of the obesity it is hardly reasonable to burden it still further by the method of treatment that has been given.

It is suggested that every effort be made to see that the patient really follows a proper dietary regimen.

IMPOTENCE IN DIABETES

To the Editor—About a month ago a white man aged 36 came to me complaining of impotence. The libido was present but he could not get an erection. I elicited a history of diabetes in the family with a history that caused me to suspect it in the patient. The impotence had been present for three weeks. An examination revealed that he was obese with the pituitary distribution of fat. He weighed 182 pounds (83 Kg) and was 5 feet 5¼ inches (165 cm) in his shoes in height. The penis was small, the testicles were small and hard. A prostatic examination revealed uncountable white blood cells in the secretion. A urinalysis was positive for sugar, the remainder of the analysis being negative. A fasting blood sugar showed 222 mg per hundred cubic centimeters of blood. The patient was placed on a diabetic diet and his blood sugar tested at intervals. He has dropped to 164½ pounds (75 Kg) after about two months of dieting and the sugar dropped to 124 mg per hundred cubic centimeters after six weeks of dieting. However, he was not experiencing any return of potency and his anxiety induced me to put him on endocrine (Phenglandular tablets Anglo-French) medication but I was shocked to find that the blood sugar had increased markedly after about three weeks. I would appreciate advice as to further treatment. Would antutrin S increase the blood sugar? If not how would you administer it? I hope you can give me an early answer as I am in a quandary. Please omit name.

M D Pennsylvania

ANSWER—It is not unusual that patients with diabetes have impotence. It seems extremely important that the diabetes should be adequately controlled. To this end the patient should be taught how to test his urine for sugar and a program of treatment should be outlined which keeps the urine free from significant amounts of sugar all the time. Insulin should be used if the diabetes cannot be adequately controlled without it. It is generally agreed by most students of diabetes that it is adequately controlled when significant amounts of sugar are not found in the urine, regardless of the amount of sugar in the blood. It is almost certain that the tablets which the correspondent has prescribed for the patient are without medicinal value. Antutrin S would not increase the blood sugar and it does not seem indicated for this particular patient. It is quite probable that the impotence will disappear gradually after the diabetes has been adequately controlled for a time. It is advisable to treat the chronic prostatitis, and a good deal of encouragement will probably be needed from time to time to overcome the psychic factor, which constitutes part of the cause for the impotence.

BENEDICT TEST FOR SUGAR

To the Editor—In response to a query concerning the use of Benedict's solution for the determination of sugar in urine (*THE JOURNAL* March 14) you advise the use of 5 drops of urine. Why do you advocate only 5 drops of urine? Benedict's original article you know specifies 8 drops of urine. Students are instructed to follow an 8-5-22 procedure (Wylie, H. B. *Laboratory Manual of Biochemistry* University of Maryland School of Medicine ed. 9 1935) wherein 8 drops of urine is added to 5 cc. of Benedict's solution and shaken. The mixture is boiled for two minutes and then set aside to cool for two minutes. Any deviation from this procedure is supposed to yield misleading results. Please omit name.

M S Maryland

ANSWER—As drops vary in size with the kind of dropper used it would be better to specify the amount of urine to be used for a qualitative test for sugar in terms of cubic centimeters. Five drops (0.25 cc) was recommended to avoid errors due to turbidity caused by urates and phosphates. Nicholson's *Laboratory Medicine* advises the use of 0.25 cc, Osgood and Haskins advises 0.3 cc, or about 6 drops, Kolmer and Boerner use 0.5 cc, Gradwohl's new book recommends from 8 to 10 drops, and Gershenfeld advises 8 drops. The important conclusion to be drawn is that an excess of urine should be avoided. The amount added to 5 cc. of Benedict's solution should not exceed 0.5 cc. of urine.

SERUM TREATMENT OF POLIOMYELITIS

To the Editor—In reference to the editorial on the serum treatment of acute poliomyelitis it is not quite clear to me whether or not normal adult serum is of equal value to convalescent serum. Would it be necessary to cross agglutinate convalescent or normal adult serum before it is given intravenously?

L CHARLES ROSENBERG M D Newark N J

ANSWER—All the studies that have been made so far indicate that pooled normal human serum contains as great a quantity of neutralizing substances as does convalescent serum or greater. Therefore it would be anticipated that pooled normal adult serum would be effective in treatment. Such a hypothesis is borne out by the few reports already published (Zingher in 1916, Levinson, McDougall and Thalheimer in 1931 and Brodie in 1932). It is not necessary to cross agglutinate either convalescent or pooled adult human serum before using

either intravenously. This and other questions in regard to poliomyelitis serum are reviewed thoroughly in an article by Paul H. Harmon (*Poliomyelitis. I. Experimental and Theoretical Basis for Serum Therapy, II. Results of Treatment in the Acute Disease, Analysis of Reports of 4,400 Patients Treated with Serum, Observations on 2,660 Untreated Patients, Am J Dis Child* 47 1179, 1216 [June] 1934).

PLASTIC SURGERY FOR COLLAPSING ALAE NASI

To the Editor—Please let me know if plastic surgeons can correct collapsing alae nasi and how they do it. The inside of the nose is sufficiently open and there is no nasal obstruction.

JACOB SEIBERTH M D, Pixley Calif

ANSWER—Since, depending on its location, collapse of the ala is to be attributed to failure of the upper or the lower lateral cartilage to maintain the natural external convexity, and since that failure is due to attenuation of the cartilage, attention should first be directed to locating and determining the degree of this attenuation. This done, the choice is between alternative methods. In the case mentioned, the passage being "sufficiently open," the external concavity might be corrected by means of wedge shaped excisions within the nose, parallel to the nostril rim, with the apex in the direction of the external surface. When the edges are approximated, within, the inner surface being thus reduced, the effect is toward producing concavity within and consequently convexity on the outside.

The other recourse, based on inadequate support by the cartilage, is to excise a rhomboid of the cartilage, with the long diagonal in the vertical direction, and transfer it with the long diagonal horizontal. This tends to establish exterior convexity. It involves lifting the alar eminences, for freedom of access and when these are returned they can be shifted a little inward on the nose floor, thus still further establishing the convex line. Slight advancement of the skin will cover the small surface defect.

USE OF TETANUS ANTITOXIN

To the Editor—Nov. 23, 1934. I wrote you regarding tetanus antitoxin. My letter and answer appeared in *THE JOURNAL* Aug. 22, 1936. I should like to have you consider in relation to the answer to my query the point of view expressed in a recent issue of *THE JOURNAL* replying to a question on the use of tetanus antitoxin (puncture wounds received from needles while sewing mattresses). The answer states that unless tetanus is present in the community or unless cases of tetanus have been reported from wounds produced in connection with unprocessed cotton there is no need of giving tetanus antitoxin. I should like to know how one can correlate the two divergent points of view expressed in these two answers. I realize that these answers come from outside sources and that you cannot agree with both of them but I know you will agree that so far as possible consistency should govern the policy that shapes the answers to these letters.

ELMER S. BAGNALL, M D Groveland Mass

ANSWER—It is natural that the judgment of physicians will vary with respect to the danger of tetanus from wounds of various kinds. There can be no question, however, about the deadliness of tetanus once established, even if antitoxin is used for curative purposes. Nor is there any question about the value of antitoxin for preventive purposes. Hence it is clear that the general principle governing the use of tetanus antitoxin for the prevention of possible posttraumatic tetanus must be take no chances—safety first.

X-RAY TREATMENT OF ACTINOMYCOSIS

To the Editor—Has the x-ray proved a valuable aid in the treatment of actinomycosis? I have in mind a case of this kind in the scapular region (confined to the subscapular muscle area) with a duration of two months.

ALEXANDER KREMER M D Mercer Wis

ANSWER—The treatment of actinomycosis by large doses of x-rays can be considered the most successful treatment. In contrast to x-ray treatment of every other inflammatory process actinomycosis requires the largest doses that can be applied without damaging the skin. The more localized the actinomycotic foci are and the earlier they are treated the more favorable is the prognosis. Therefore the prognosis of subcutaneous involvement is obviously better than that of abdominal or pulmonary involvement. The radiation should be applied from more than one field. The simple reason for this is that it gives opportunity of repeating the treatment when the first application has not been completely satisfactory. In this particular case in which the subscapular region is involved the irradiation should be attempted from two fields.

The x-ray treatment is usually combined with the administration of potassium iodide in daily doses of from 1 to 2 Gm for one week, followed by a week of rest. The x-rays usually employed are of 180 to 200 kilovolt peak and 5 milliamperes, and are filtered through 0.5 mm of copper and 0.25 mm of aluminum.

After a period of from six to ten weeks the average case of actinomycosis should be cured by this treatment.

GLYCOSURIA IN DIABETES INNOCENS

To the Editor—A man aged 55 in good health has had a mild glycosuria for the past twelve years. The urine which is frequently normal contains from 0.1 to 0.3 per cent of sugar in a twenty-four hour collection. He has absolutely none of the recognized symptoms of diabetes. He is not restricted as to his diet except as to the prohibition of sugar in his tea or coffee. A number of sugar tolerance tests were essentially alike and showed up about as follows. Before breakfast the urine is negative and the blood contains 71 mg per hundred cubic centimeters after ingestion of 100 Gm of dextrose.

Time	Urine	Blood
10 20 a m	0.15%	117
10 50 a m	0.9%	87
11 50 a m	0.3%	80
12 50 p m	0.15%	64

Is this man diabetic? Is he potentially diabetic? In view of the low blood sugar three hours after the ingestion of the dextrose would it be rational to advise the use of some carbohydrate before retiring at night? Kindly omit name.

M D New York

ANSWER—The description is that of a mild renal glycosuria or diabetes innocens. It is not characteristic of a potential or true diabetes mellitus.

No treatment is necessary or advisable in such cases unless the loss of sugar in the urine is sufficient to cause undernutrition. Under these circumstances the treatment consists in simply adding sufficient carbohydrate to the diet to offset the loss by excretion. It is not necessary to give carbohydrate before retiring at night, unless the low blood sugar at this time is accompanied by symptoms of hypoglycemia.

INFERENCES FROM SUGAR TOLERANCE TEST

To the Editor—A patient had a fasting blood sugar of 160 mg with no urinary sugar. One hour after administration of 100 Gm of dextrose it was 275 mg with 2 plus urinary sugar. Two hours after it was 187 mg with 1 plus urinary sugar. Three hours after it was 110 mg with no urinary sugar. The question is whether this sugar tolerance curve indicates a diabetic state or is more probably an endocrine disturbance or infectious process. Please omit name.

M D Missouri

ANSWER—The dextrose tolerance curve which the correspondent has described is not typical of a diabetic state. In the absence of further information regarding the history and clinical status of this patient it is impossible to arrive at any specific conclusions. However, the curve is suggestive of either a moderate toxic liver damage (Soskin, Samuel, and Mirsky, I A, Influence of Progressive Toxic Liver Damage upon the Dextrose Tolerance Curve, *Am J Physiol* 112:649 [Aug] 1935) or a hyperactivity of the anterior pituitary gland (Soskin, Samuel, Mirsky, I A, Zimmerman, L M, and Heller, R C, Normal Dextrose Tolerance Curves, in the Absence of Insulin, in Hypophysectomized-Depancreatized Dogs, *Am J Physiol* 114:648 [Feb] 1936).

BLOOD TESTS FOR PATERNITY

To the Editor—The question has been raised as to the efficiency of the blood typing method of determining parentage together with the dependability and reliability of this method. Can you tell me the weaknesses of the method and the situations in which it is scientifically dependable and reliable? Please omit name.

M D Pittsburgh

ANSWER—Blood typing can show only that a given man may be the father of a given child or that he could not possibly be its father. It cannot show that a given man is the father of a given child. If the blood of a child contains an agglutino-gen that is not present in at least one of its purported parents the child cannot be the offspring of the pair. There is no known test by which it can be determined that the unknown father of a given child belongs to any given race. Racial affiliations cannot be determined by any known blood test. Admissibility of evidence as to blood grouping was ably discussed by the Supreme Court of South Dakota in *State v. Damm* 266 N W 667 decided April 16, 1936 in which the court held that such evidence had been properly excluded in the case before it, because of the status of the art of blood grouping when the

case came to trial, but indicated, without actually deciding, that when the Supreme Court rendered its decision about four and one half years after the trial, the state of the art had advanced sufficiently to make it not improper for a trial court to hear such evidence.

ALCOHOL IN DIABETES

To the Editor—May I ask you do you know and is it recorded that diabetes is caused by drinking beer and whisky? Also is it detrimental for a diabetic patient to drink beer or alcohol in moderate amounts? I cannot find recorded in Allen's book regarding alcohol—I have had it inferred—that alcohol may be a benefit.

R B HOPKINS M D Milton, Del.

ANSWER—The only way in which it seems reasonable that alcoholic drinks could lead to diabetes would be through the causation of obesity. Few today consider that carbohydrates taken in excess will lead to diabetes, except through obesity in the hereditarily predisposed. Indeed, Himsworth is of the opinion that a high fat and low carbohydrate ration is more common among nations in which the diabetic incidence is high.

It would appear reasonable to conclude that it is as detrimental for a diabetic as for a normal person to drink beer or alcohol in moderate amounts, but with this difference that if a diabetic person taking insulin should have a reaction and the remotest suspicion of an alcoholic breath should be noted he might lose his life. Indeed repeatedly persons with diabetes have been sent to jail for drunkenness when they were simply having an insulin reaction. Furthermore, the diabetic patient is especially susceptible to toxic amblyopia produced by the use of alcohol and tobacco. For practical purposes a diabetic patient would best leave alcohol alone. This opinion is not shared by some physicians, who allow a certain amount of alcohol.

EARLY CLOSURE OF FONTANELS

To the Editor—I have under my care a child aged 3 months whom I examined the first time two weeks ago. I found at that time the fontanels completely closed. The head is slightly flat on top and is 15 1/4 inches in circumference. Aside from the premature closure of the fontanels the child is normal physically and mentally. Is there any possibility as the child grows that this premature closure may interfere with further growth of the head and normal development of the brain? Can anything be done? Please omit name.

M D Illinois

ANSWER—Under normal conditions the posterior fontanel of an infant is usually closed by the end of the second month, and the closure of the anterior fontanel varies between fourteen and twenty-two months. The average circumference of the head for a 3 months old infant varies from 15 1/8 to 15 1/2 inches. The circumference of the head of the infant mentioned in the question is, therefore, within the normal limit.

Ordinarily the occurrence of premature closure of the fontanels indicates a disturbance in the growth of the brain. The common example is microcephaly. It would be interesting to compare the circumference of this infant's head with the chest circumference. Normally at birth the head circumference is greater than the chest circumference and remains so until about the twelfth month, when the circumference of the chest and of the head are about equal. Thereafter the circumference of the chest surpasses that of the head in measurement.

As the question states that the infant is otherwise normal, both physically and mentally, and as the circumference of the head is within normal limits, one would infer that the early closure of the fontanels in this case is simply a normal developmental deviation and not related to any organic defect of the brain.

EFFECTS OF COLD ON ERYTHROCYTES

To the Editor—What effect has been noted on erythrocytes after passing through cold extremities? Please omit name.

M D Minnesota

ANSWER—There is some stasis or slowing of the blood flow in the skin subjected to such a degree of cold that the normal tone of the blood capillaries and the musculature of the arterioles are paralyzed by the local lowering of the temperature. There is also some evidence that in normal animals very prolonged stasis (from thirty minutes to several hours) renders the erythrocytes more susceptible to hemolysis by hypertonic solutions. But this stasis probably exceeds that induced by cooling of the body surface of man except in cases of extreme exposure. In susceptible individuals (paroxysmal hemoglobinuria) intravascular hemolysis occurs in the blood vessels of the skin, even on moderate exposure to cold. This seems to

be due to the presence in the blood plasma of these people of an isohemolysin which becomes absorbed on the cooled corpuscles, and the laking takes place when the blood again approaches the normal body temperature. Ninety per cent of the people showing this reaction to moderate surface cooling have chronic syphilis or show symptoms of Raynaud's disease. The origin and nature of the isohemolysin are not known.

USE OF X-RAYS IN ACUTE LEUKOSIS

To the Editor—A white woman aged 53 weighing about 160 pounds (73 Kg) a loss of about 50 pounds (23 Kg) in the last six months has occasional hemorrhagic areas over the body and circumscribed lesions on the tongue. The red cell count is 1 800 000 hemoglobin 40 per cent, total white cell count from 20 000 to 26 000 differential count as reported by a professor of pathology myeloblasts 22 per cent premyelocytes 4 per cent myelocytes 1 per cent juveniles 3 per cent band forms 17 per cent segmented forms 42 per cent, lymphocytes 10 per cent basophils 1 per cent. There is no splenic enlargement. I am now giving repeated blood transfusions and should like to know whether the use of x-rays is indicated in relatively low leukocyte count and no splenic enlargement. Please omit name.

M D Georgia.

ANSWER—The use of x-rays or radium is ordinarily contraindicated in acute leukosis (lymphadenosis and myelosis) whether it is leukemic or subleukemic. While no form of treatment has any appreciable effect on the course of the disease, repeated blood transfusions have a temporary value since two of the symptoms of acute myelosis are severe anemia and hemorrhage.

LEUKOPENIC INDEX

To the Editor—What is the technic for determining the leukopenic index? Please omit name.

Tennessee

ANSWER—The leukopenic index was described by Vaughan in the *Journal of Allergy* for September and November 1934. According to the test an allergic hypersensitivity to a food exists if ingestion of the food is followed by a fall in the total leukocyte count of more than 1 000. Gay in 1936 also stated that the test was of value in determining the allergic state and the allergen at fault.

The test cannot be accepted as of established value in determining hypersensitivity because the normal fluctuations in the white blood count of normal persons in a fasting state are greater than 1 000. Sabin Simpson and many others have demonstrated fluctuations of several thousand in a few minutes. There is a difference of from 3 000 to 6 000 in the white blood count of many normal persons at different times of the day. An editorial in *THE JOURNAL* June 6 discusses the leukopenic index and gives references to the literature.

ROENTGENOGRAPHY OF THE EYE

To the Editor—Is it safe to take an x-ray picture of the eye when trying to locate some foreign object, that is will the optic nerve be injured by the x-rays? Can you supply references or information on the frequency and severity of eye injuries due to x-ray pictures?

C ENITH KERBY Statistician New York

ANSWER—It is perfectly safe to make a roentgenogram of the eye and orbit. If a number of roentgenograms are made at the same time, however, there might be danger from excessive total exposure. This depends on the number of exposures made. The optic nerve is one of the least sensitive of the ocular structures. The structures most likely to be affected by excessive exposure are the conjunctiva and the crystalline lens. References on the frequency and severity of eye injuries in relation to roentgenography are not available.

EFFECT ON SPERMATOZOA OF HEAT APPLIED TO SCROTUM

To the Editor—I have read that the health of spermatozoa is conserved by being kept in the refrigerator like scrotum and that on reaching a warm vagina they soon begin to lose their vitality. As a practical proceeding in birth control, what is the effect on spermatozoa of immersing the scrotal sac in hot water for a length of time? Please omit name.

M D Minnesota.

ANSWER—Whereas it is well established that spermatozoa are susceptible to and injured by ordinary body temperatures (extrascrotal temperatures) and that numerous experiments on the application of hot water to the scrotum of the lower mammals causes loss of the sperm producing elements, it is not yet known what degree of hot water applied to the scrotum of man is effective. There is little doubt that the method could be made a practical birth control procedure but the temperature and time of application and the frequency of application to be effective in man have not yet been worked out.

LOCATING BRAIN TUMORS BY OLFACTORY TESTS

To the Editor—I am interested in obtaining information concerning the location and diagnosis of brain tumors by olfactory tests also the method of conducting these tests. I should like reprints of articles or references on this subject. I understand that Dr Charles A. Elsberg of Columbia University is to lecture on this subject at Buffalo University on April 18 and thought it might be possible to obtain a copy of his lecture.

ALFRED C KINGSLEY M D Phoenix, Ariz.

ANSWER—A series of papers on the new methods for testing the sense of smell were published in the *Bulletin of the Neurological Institute of New York* in 1935 and 1936. A preliminary report on the value of the new tests for the localization of supratentorial tumors of the brain appeared in the December 1935 issue of that journal. A report on the value of the tests for the localization of frontal lobe tumors appeared in the April 1936 issue. The test is based on a new principle and is a simple one. Reprints of the papers can be obtained by addressing the editor of the *Bulletin*, care of the Neurological Institute, Fort Washington Avenue and 168th Street, New York City.

FATAL DOSE OF STRICHNINE

To the Editor—Is it likely that an adult dose of strychnine sulfate given subcutaneously by a nurse by mistake to a young child would be a fatal dose? Are infants relatively insensitive to strychnine? Please omit name and initials.

M D Pennsylvania

ANSWER—Children are not generally considered more sensitive to strychnine than adults, but there is a fatal case on record (Willführ) after a dose of 4 mg in a 2½ year old girl. As the minimum lethal dose for the adult is generally assumed to be 30 mg this might—considering the probable weights—suggest a relatively greater sensitiveness in the child.

DUSTING POWDER FOR SHOES IN RINGWORM INFECTION

To the Editor—I should like a formula for a dusting powder that would be suitable for use in the shoes of persons who are suffering from ringworm infection of the feet.

R B KROUSE M D Lima Ohio

ANSWER—A dusting powder suitable for use in the shoes of persons suffering from ringworm of the feet may be compounded as follows:

Sodium thiosulfate	6 Gm
Boric acid	to make 30 Gm

From 5 to 10 per cent of sodium or potassium iodide is sometimes added to this formula.

COMPATIBILITY BETWEEN PROCAINE AND ARSENICALS

To the Editor—Will you please inform me as to any possible incompatibility between novocain and arsenicals?

M D Mich

ANSWER—While procaine (novocain) hydrochloride is compatible with arsenic trioxide or acid solutions of arsenic trioxide it is incompatible with solution of potassium arsenite (Fowler's solution) because of the alkalinity of the latter.

COMPLEMENT FIXATION TEST IN GONORRHEA

To the Editor—In the reply to M D Ohio (*THE JOURNAL* September 26 p 1071) concerning the significance of a strongly positive complement fixation test in gonorrhea it is stated that, since such specific antibodies are found only when gonococci are present in the body and disappear within several weeks after the disappearance of the gonococci a careful search for the residual infection must be made. It is stated in the query that a gonococcus filtrate was injected intradermally. It has been my experience and it is fairly generally accepted in the literature that injection of a gonococcus vaccine or filtrate stimulates the production of complement fixing antibodies. I believe that in the case in question the positive complement fixation test may have been due to the injection of the filtrate and not to the residual infection.

ISRAEL DAVIDSON M D Chicago

ADMINISTRATION OF ANTITOXIN TO SENSITIVE PATIENT

To the Editor—An additional procedure to that mentioned in your reply on the Administration of Antitoxin to Sensitive Patient" is advisable (*THE JOURNAL*, October 10 p 1243). It is well to administer epinephrine with the antitoxin but the transient effect of the epinephrine would leave the patient exposed within a few hours to the later serum reactions in the sensitive case. I advise in addition to the epinephrine injection the oral use of ephedrine every four hours for a period of ten days and so obviate or minimize the untoward serum reactions that are not immediate.

Book Notices

Synopsis of Diseases of the Heart and Arteries By George R. Herrmann M.D. Ph.D. Professor of Clinical Medicine University of Texas. Cloth Price \$4 Pp 344 with 91 illustrations St. Louis C. V. Mosby Company 1936

George Herrmann has written a synopsis of diseases of the heart and arteries dedicated to Henry Christian and intended primarily for the plodding student and the assiduous conscientious practitioner. It is well arranged and full of information which should prove to be of great value to the medical student beginning his study of heart disease. Its brevity on certain clinical subjects makes it somewhat less useful for the physician in practice. It is difficult or impossible to construct a small volume that is equally suitable for the beginning medical student and for the more or less experienced practitioner.

The book is replete with wise observations, an example of which is found at the top of page 19. "The early recognition of a heart affection is a great boon for the patient, provided it is made by a wise physician who is not an alarmist and who knows his patient and quietly arranges his life along conservative lines. Every patient must be spared the ravages of worry, for it may cause more distress than the actual heart disease itself." As in any volume of the sort, inaccuracies have crept in, but they are surprisingly few. One of these on page 51 states that "in pneumonia a diagnosis of heart failure should be made only when the venous pressure has been determined and found elevated, regardless of the amount of dyspnea and cyanosis", this statement holds true for failure of the right ventricle but not when the strain and failure are wholly on the left side, when for example the toxic effect and other strain incident to any severe infection may prove too much for a left ventricle already severely damaged or strained by hypertension, coronary thrombosis or aortic valve disease. On page 54 the statement that teleroentgenograms made at a distance of two meters or six or seven feet "can be measured for exact cardiac and aortic transverse diameters" is not strictly true, for even at that distance there is an appreciable magnification obviated only by orthodiagraphy. On page 277 the statement that aortic stenosis is the rarest of (valve) lesions is probably a slip of the pen for later statements belie this and moreover in some parts of the country north of Texas aortic stenosis is fairly common. The chapter on congenital heart lesions is as in the great majority of books on the heart, disappointing. Also little is said of the clinical recognition of dissecting aneurysm of the aorta. These few errors and omissions detract, however, but little from the general excellence of the book.

The volume is well printed and the illustrations are clearly reproduced. It is a pleasure to recommend the book to the student beginning his study of cardiovascular disease and to the physician who wishes to review some of the fundamental facts of the subject.

Die einheimische Sprue und ihre Folgekrankheiten (sekundäre Avitaminosen) Von Professor Dr. K. Hansen und Dr. H. v. Stan. Boardest. Price 1.80 marks. Pp 113 with 45 illustrations Leipzig Georg Thieme 1936

This is primarily a discussion based on five cases of endemic sprue of long duration observed in Germany. Study of the symptomatology led the authors to the conclusion that there are four principal stages of endemic sprue. First is the prodromal stage, which lasts from a few to many years and during which period correct diagnosis is frequently overlooked. It is characterized by either painful or painless disturbances of the gastro-intestinal tract without any definite objective changes. In the second stage objective signs appear most common of

which are aphthous stomatitis, meteorism, often large gray heavily fat containing stools loss of appetite, pigmentation of the skin, and beginning psychic changes. Anemia of the pernicious type is often present. In the third stage complications frequently appear. The pigmentation, the anemia, the cachexia, copious fat stools and severe psychic changes are the most marked signs during this stage. True tetany and osteoporosis of the skeletal system and the characteristic changes of the skin (mummy skin), the nails and the hair become exaggerated. Finally, the fourth stage leads toward rapid death accompanied by one or all of the following symptoms. The thorax of the patient is pushed together like that of a mummy, the transverse colon, filled with fecal masses, is easily visible through the paper thin skin, and the skin of the extremities is edematous. Decalcification of the bones makes every motion virtually impossible. The most important three theories concerning the etiology are the infection theory, the primary disturbance of internal secretion, and the vitamin deficiency theory. At present it is impossible to determine the primary importance of any of these explanations. Therapy involves primarily an early recognition of the true condition and the administration of a fat free high protein, high carbohydrate, high calory diet and the oral administration of calcium salts. Vitamins C and D and the "antipernicious factor" should also be given. This short monograph on endemic sprue is readable and furnishes a creditable addition to the understanding of sprue in nontropical countries. It seems probable that, if endemic sprue is as common in this country as it appears to be on the continent of Europe, wider recognition of the symptomatology and treatment is highly desirable.

Training of the Neurologist and the Psychiatrist. By various authors. Reprinted from the Archives of Neurology and Psychiatry Vols. XXIX and XXX 1933 and Vols. XXXI and XXXII 1934. Paper Pp 102 Chicago American Medical Association [n. d.]

This series of papers, now bound together with a paper cover, appeared in the *Archives of Neurology and Psychiatry* during 1933 and 1934. Five deal specifically with the training of a neurologist, all written by representative men from England, the Netherlands, France, Canada and America. Two other papers concern more definitely the training of a psychiatrist, both written by men in this country. As might be expected nearly all the authors make a plea for a broad foundation on which to build a knowledge of the complicated structure of neuropsychiatry. Like any of the other branches of medicine, anatomy, physiology and pathology must form the base and to these the neuropsychiatrist adds psychology. The form and function of the normal nervous system must be thoroughly mastered, the pathology of structural disease fully visualized and psychologic reactions widely appreciated before clinical study can be profitable. The trends expressed in this series of papers have recently been embodied in the work of the American Board of Psychiatry and Neurology. All teachers of neuropsychiatry will find much of interest in these selected papers.

Physiopathologie du système nerveux du mécanisme au diagnostic. Par Paul Cossa. Préface de Cloris Vincent. Cloth. Price 75 francs. Pp 690 with 193 illustrations. Paris Masson & Cie 1936

Nervous activity is treated in this work as a complex of reflexes, the conditioned reflex being given prominent attention with regard to its bearing on psychic activity. The book consists of four parts, the first being a treatment of histology from a functional point of view, including a discussion of the cerebro-spinal fluid its formation, its pressure and its observation. The second part consists in a treatment of the normal and pathologic physiology of the nervous system. In this the sensations are discussed first and next the elementary reflexes, including those of posture and movement. Then the regulation of movement receives attention and is illustrated by alterations in pathologic states. In the third part the so-called vegetative functions are taken up. The regulation of the circulatory system and heat regulation, including the sweating mechanism, receive attention. The fourth portion of the book treats of the nervous system and the psychic phenomena. In this portion it becomes difficult to present much physiology outside of the discussion of conditioned reflexes, although the aphasias are described in this section. The book lacks a comprehensive index and the table of contents is on the last page. It is profusely illustrated and well printed.

This volume is more complete with regard to the anatomic aspects of neurology than regarding the physiologic. The functional ideas are largely descriptive and consist in the enumeration of functions of nervous structures, along with attempts at psychologic interpretation. In this type of work it is difficult to do more than describe, define and classify, which the author has done well. The attempt to combine in one treatment pathologic physiology and anatomy of the nervous system is in itself a considerable undertaking, and the emphasis placed on physiology in the whole treatment is indicative more of the importance the author expects it to play in the future in applied neurology than of its present importance.

The Diabetic Life. Its Control by Diet and Insulin. A Concise Practical Manual for Practitioners and Patients. By R. D. Lawrence. M.A. M.D. F.R.C.P. Physician in Charge Diabetic Department King's College Hospital Ninth edition. Cloth. Price \$3. Pp. 231 with 15 illustrations. Philadelphia: P. Blakiston a Son & Co. Inc. 1936.

The fact that this manual has reached its ninth edition speaks for its popularity. It is written for the physician and the patient, but there is entirely too much technical material in it for the layman and it is more adapted to the needs of the general practitioner. The chapters on blood sugar and dextrose tolerance are especially well written and show the author's thorough grasp of the subject. The book is written in a light and clear style. The chapter on the treatment is of a practical nature for the man outside the hospital atmosphere, one who does not have the technical facilities at his disposal. The problem of coma is clearly discussed and ought to serve as a guide to the doctor. The author uses a method of calculating the diets not used in this country, namely, the "line treatment" which is intended to simplify the dietary routine. The latter part of the book deals with diets and recipes common to all manuals. The chapter on technic could stand some more modern changes. On the whole this little volume presents ideas of the general routine work in the field of diabetes in a clear and adequate manner.

De l'utilisation des courbes glycémiques après injection veineuse en pathologie viscérale. Par A. Biron. Paper. Pp. 172 with illustrations. Paris: Librairie E. Le François. 1936.

Following a formidable array of personal dedications, which include parents, professors, associates and layman friends and which occupy sixteen pages of this monograph, the author describes an intravenous method of determining sugar tolerance. He uses 100 cc. of a 30 per cent dextrose solution administered as a drip, taking about thirty minutes to complete the injection. Samples of blood are taken from the finger and analyzed by a modification of MacLean's micro method. The normal controls are few and poorly selected. In cirrhosis of the liver and in kidney lesions the curves are elevated. A few animal experiments are included demonstrating tolerance curves in dogs with an Eck fistula and phosphoric necrosis of the liver. This book offers no help or stimulation to the general practitioner. To the investigator it appears as a superficial and unconvincing presentation of well known facts, with an incomplete and overwhelming Gallic bibliography.

Disinfection and Sterilization. By Ernest C. McCulloch. M.A. D.V.M. Ph.D. Cloth. Price \$5.50. Pp. 525 with 53 illustrations. Philadelphia: Lea & Febiger. 1936.

The early chapters of this book are taken up with such general subjects as the history of disinfectants, the action of sunlight and other physical agents on bacteria, the germicidal properties of body fluids and similar subjects. In the discussion of testing of disinfectants, the author's method of choice is that of the Food and Drug Administration, but adequate descriptions are given of other methods. Special chapters are devoted to sterilization by steam and otherwise, and to milk pasteurization, water purification and sewage treatment. The half dozen chapters given to the disinfectant properties of various chemicals, dyes and gases are well written and elucidating. For the most part the author has presented the subject from an impartial standpoint but he has stated his views clearly on occasion as when he says concerning tooth pastes and tooth powders "some of the claims for germicidal efficiency and ability to dissolve mucus have been greater tributes to the romantic tendencies of the writers of advertising copy than to the veracity of the manufacturers."

The book is written in simple language and the subject matter is brought down to date. It should be in large demand,

for many years have passed since a similar publication appeared. Hundreds of references are given to articles appearing in the scientific literature.

Arbeitsphysiologie der Schwangerschaft. Wehenarbeit—Wehenatmung—Schwangerschaft u. Muskelarbeit. Von Dr. med. habil. Fritz Stähler. Oberarzt an der Universitätsfrauenklinik Frankfurt a. M. Heft 1, Abhandlungen aus der Geburtshilfe und Gynäkologie und ihren Grenzgebieten. Beihefte zur Monatsschrift für Geburtshilfe und Gynäkologie. Herausgegeben von E. Anderes et al. Paper. Price 9.20 marks. Pp. 103 with 33 illustrations. Berlin: S. Karger. 1936.

This small monograph is divided into three parts. The first deals with the work performed by the uterus during labor. The author demonstrated for the first time that a uterine contraction produces 4 calories of energy. During each hour of labor the output is about 42 calories, but when the patient bears down this is increased to 56 calories. An entire labor in a primipara is equivalent to the energy expended during two hours of strenuous work performed by a stone mason or a sawer of wood. In the second part of the monograph is a discussion of respiration during labor pains. The author maintains that during labor there is an increase in pulmonary aeration from 7 to 8 liters to 13 to 20 liters a minute. The third section of the book is devoted to the relationship of pregnancy to muscular activity. It is shown that light work does not affect a normal pregnant woman any more than it does a non-pregnant woman, but that prolonged, heavy work produces serious disturbances. The latter affects the lungs, the heart and the vascular system. Even strenuous housework may produce deleterious effects. The author offers practical suggestions as to how women may avoid unnecessary and strenuous exertion during pregnancy.

Regional Anatomy Adapted to Dissection. By J. C. Hayner. B.S. M.D. Associate Professor of Anatomy Flower Hospital, New York. Cloth. Price \$6. Pp. 687. Baltimore: William Wood & Company. 1935.

This book is a descriptive account of each of fifty-one regions of the body. It contains no illustrations. It is intended for students and practitioners who, having completed the dissection, wish to review conveniently the anatomy of a particular region. In each region the description is arranged systematically, that is the arteries, veins, lymphatics, nerves and so on, are described one after another. The descriptions are brief, clear and accurate. They do not attempt to furnish a storehouse of information, but only such major facts as are likely to be sought by students preparing for examination or by surgeons preparing to operate in the region. The Basle anatomic nomenclature is used throughout. An extensive index is furnished. The value of the book lies in its arrangement and in the clarity of the text.

Die Grundlagen der unspezifischen Therapie. Von Professor Dr. Wolfgang Weichardt. Paper. Price 8.70 marks. Pp. 83 with 8 illustrations. Berlin: Julius Springer. 1936.

German investigators are still much interested in the physiology and chemistry of foreign protein therapy. In this monograph Weichardt concerns himself chiefly with a summary of his own investigations and a critical review of the contributions of other workers to the subject. The bibliography is chiefly German, but it must be admitted that most of the fundamental studies in this field have been made by German investigators. In the introduction the author says he often hears the remark "Concerning nonspecific therapy, one knows nothing" whereas the speaker would have been more accurate if he had said "Concerning nonspecific therapy, I know nothing." Certainly no one can read this erudite treatise on nonspecific treatment without realizing the great amount of information which has been obtained concerning this problem during the last few years. The author's conception of the biologic principles underlying foreign protein reactions is briefly as follows. He conceives of cell function as activated by secondary products inherent in the body (protoplasmic activation). He points out that most of the split products found in the body stimulate function when experimentally injected in optimal dilution. Such effects are in no way specific. He stresses particularly the nonspecific stimulating effect of various split products on the normal and on the exhausted heart.

The author does not go into the practical application of foreign protein therapy in the treatment of disease. However, there is a brief discussion of the various forms of nonspecific therapy as induced by albumin, histamine and malaria.

The Course of the Oesophagus in Health and in Disease of the Heart and Great Vessels By William Evans Medical Research Council Special Report Series No 208 Paper Price 2s 6d Pp 93 with 66 illustrations. London His Majesty's Stationery Office 1936

This is a brief but excellent description of the roentgenologic anatomy of the course of the esophagus in health and in disease of the heart and great vessels. The observations are the result of an investigation of the course of the esophagus in healthy subjects and in patients from the cardiac department of the London Hospital in whom cardiovascular disease was suspected or known to be present. The relationship of the esophagus to the aortic arch, trachea and bronchus and the pulmonary artery and its branches was determined by the dissection of three cadavers. In one dissected specimen these structures were impregnated with barium and roentgenographed. Radioscopy of all subjects was carried out in the three conventional positions: anterior (postero-anterior), right oblique (oblique I), and left oblique (oblique II). The four esophageal curves or impressions observed in a healthy subject and according to the viscus producing them are designated the aortic arch impression, left bronchus impression, left auricle impression and descending aorta impression. Changes in each of these impressions produced by pathologic conditions are discussed in detail. The author emphasizes the uncertainty of the element forming the left border of the aortic shadow, which calls for caution before the measurement from the aortic arch impression to the left border of the aortic shadow in the anterior position is accepted as the diameter of the aortic arch. The book is well illustrated by excellent roentgenograms and numerous black and white drawings. While much of the data is familiar to experienced radiologists, this work will be of value to less experienced individuals and particularly students.

A Textbook of Histology By Joseph Krefka Jr. Ph.D. M.D. Professor of Microscopic Anatomy University of Georgia School of Medicine Augusta. Cloth. Price \$2.50 Pp 246 with 95 illustrations. Baltimore: Williams & Wilkins Company 1936

This little book is an elementary histology intended to encourage the study of this subject early in college courses with the belief that some understanding of histology is a valuable and necessary part of general education and that it has not been sufficiently studied by students looking forward to the social sciences. The author believes also that it is advisable to offer to those with special aptitudes for histologic study an early opportunity to become acquainted with histologic methods and ideas. The text is brief, simple and clear, as might be expected in an introductory book. It mentions only the larger elements of structure omitting finer details and controversial questions. It regards these structures as parts of the living body and gives due consideration to the physiologic processes in which they are involved and of which they are an expression. The illustrations are simple and for the most part are diagrammatic representations made from preparations in the laboratory where the author's course in histology is given. The use of terms and the spelling are sometimes startling, for example, "mote" for the moats around the circumvallate papilla. "Fascia" is used always as a plural. Apart from these peculiarities the volume can be recommended as a good brief introductory textbook.

Handbuch der mikroskopischen Anatomie des Menschen Herausgegeben von Wilhelm v. Möllendorff Band III Haut und Sinnesorgane Teil 2. Auge Bearbeitet von W. Kolmer und H. Lauber. Paper. Price 150 marks. Pp 782 with 475 illustrations. Berlin: Julius Springer 1936

This constitutes one of the most reliable storehouses of information concerning microscopic anatomy available to students and research workers. It is an exhaustive presentation of the work in this field up to the present time. The whole book is organized in seven volumes, on living matter, the tissues of the skin and sense organs, the nervous system, the digestive apparatus, the blood and lymph systems, respiratory system and endocrine glands and the urogenital organs. Each of these volumes is subdivided into two or three parts making in all eighteen parts of which thirteen have appeared between 1927 and the present time. The present book constitutes part 2 of volume III and deals with the eye and associated structures. It was written by Kolmer of Vienna and Lauber of Warsaw. Kolmer has written the part dealing with the retina (172 pages), including an extensive account (fifty-two pages) of its comparative anatomy and a review of the literature (fifty-four pages).

Lauber has written the larger part of the book (504 pages). In addition to the eyeball, the book deals with the eyelids, the lacrimal apparatus, the connective tissue and blood vessels of the orbit, and the eye muscles. It will be indispensable to anatomists and ophthalmologists. It will also be a source of much pleasure and satisfaction to them.

Slim and Supple: A New System of Swedish Exercises for Young and Old By Barbro Leffler Egnell. Translated from the Swedish by Greta Olsson. M.R.C.S. L.R.C.P. Cloth. Price \$2 Pp 209 with 274 illustrations. New York & London: D. Appleton Century Company Incorporated [n.d.]

In this book there are outlined a number of exercises which have been planned to aid in keeping the body supple. It is also stated that they will be useful in preventing obesity. The material is clearly and simply presented, with a number of well taken photographs. Unfortunately, it is difficult for individuals to get into the habit of doing such exercises in a routine way. Furthermore, any exercises tend to increase appetite and produce overeating, with the result in gain rather than loss in weight. However, for those who wish a detailed outline of exercises for the various muscles of the body, this book will be found useful.

Ideal Birth: How to Get the Finest Children By Th. H. Van de Velde. M.D. Cloth. Price 10s 6d Pp 296. London: William Heinemann Ltd. 1935

This book is a preposterous conglomeration of established facts with unsupported and discredited theories. One need search no further than the last paragraph of the introduction to find an adequate condemnation in the author's own words, to wit: "I have even laid stress intentionally on theories and possibilities which have not yet obtained scientific support, because these views, even in the absence of cogent proof of their scientific rightness, seem to me of such great value regarded from the didactic standpoint that they may in any case hold good as 'working hypotheses' in life."

Among these theories and possibilities the author includes osteopathy, Christian science, hypnotism, physical culture and a large list of discredited theories about predetermination of sex, including the Unterberger theory of lactic acid douches or sodium bicarbonate douches and the idea that a suitable selection of climate for purposes of procreation is an important element in assuring ideal birth. There are so many good books for the expectant mother that this book, which is neither scientific nor popular but embodies the worst features of both kinds of writing, should have no place in any physician's recommendations to his patients.

Pathologie dentaire Par les Docteurs Bercher, Fargin, Fayolle, Fleury et Lacaille. Tome II. La pratique stomatologique. Publiée sous la direction du Dr. Chompret. Cloth. Price 85 francs. Pp 562 with 280 illustrations. Paris: Masson & Cie 1935

This is the second volume of a nine volume series of textbooks dealing with the whole field of dentistry. Volume I covers all the pathologic changes in the oral cavity except those concerning the teeth, their investing tissues and such tumors as arise from the tooth-forming structures. The latter comprise the subject matter of this book. The subject matter is typically French, that is, the classifications are elaborate, the theoretical considerations are given undue emphasis, and the illustrations are for the most part made from drawings. The references to the literature are predominantly of French origin, and the bacteriologic nomenclature does not conform to current American practice. There are no serious omissions of subject matter. The two sections that are least satisfactory are those treating of caries and pyorrhea. Relatively little attention has been given to recent research in these two important subjects, except for the dietary studies in connection with dental caries, and the point of view is that of two decades ago.

The Study of Anatomy Written for the Medical Student By S. E. Whitnall. M.A. M.D. B.Ch. Third edition. Cloth. Price \$1.75 Pp 113. Baltimore: William Wood & Company 1936

The fact that a third edition of this little book is called for indicates that it has been useful and popular. It gives the student of anatomy and of medicine a good point of view and good ideas of the nature of the subject. It suggests practical considerations for dissection and for study of the relation of gross anatomy to function and disease, and it suggests also interesting books and articles in this field. Like most similar books published in England it devotes a relatively large amount

of space to consideration of examinations. This edition has been slightly modified to express more fully the recommendations of the Curriculum Committee of the General Medical Council of Great Britain, although the book in its earlier editions was thoroughly in accord with the principles expressed by that body. It can be highly recommended as a pleasing and valuable aid to students and teachers of anatomy.

Hauttemperaturen Von Johannes Ipsen. Dr. Chirurg. Dr. Med. Statshospitalet Sønderborg Dänemark. Paper. Price 18 Danish kroner. Pp. 375 with 88 illustrations. Copenhagen. Levin & Munksgaard. Leipzig. Georg Thieme 1936.

As Dr Ipsen states in his foreword, this book is not a monograph in which the whole subject of skin temperature is considered but rather a record of his own studies and observations based on a quarter of a million observations made on various parts of the body in many different pathologic conditions. Most of the measurements of the "skin temperature" were made with a mercury thermometer held in place and covered with a thin layer of gauze, a smaller number of determinations were made by a specially designed thermocouple, no observations were made by a radiometer such as that used by Du Bois and Hardy.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Workmen's Compensation Acts. Compensability of Sunstroke or Heatstroke.—The claimant, during the course of his employment as a carpenter, collapsed from sunstroke or heatstroke. The temperature was 106 F. The state industrial commission awarded compensation for temporary total disability and the employer and his insurance carrier brought suit in the Supreme Court of Oklahoma to review the award.

The circumstances under which sunstroke may constitute a compensable injury, said the court, were set forth in *Stanolind Pipe Line Co. v. Davis* (Okla.), 47 P. (2d) 163. In that case it was held that an injury caused by sunstroke arises out of employment when the employee is placed by the nature of his work, in a position or under circumstances subjecting him to a greater hazard of injury by sunstroke than other people in the same vicinity who are not engaged in such work. In other words, the employment must increase the danger of being injured by sunstroke. In the present case, the conditions under which the claimant worked were, in the opinion of the court, such as to accentuate the heat and subjected him to a risk greater than that to which other persons not similarly employed were exposed. The injury was therefore compensable.

The claimant, however, was awarded compensation for temporary disability for a longer period than he had actually proved. The cause was remanded to the commission, therefore, for further hearing as to the actual duration of the claimant's disability.—*Smith v. Zweifel* (Okla.) 54 P. (2d) 649.

Workmen's Compensation Acts. Coronary Thrombosis and Strain.—The claimant, an automobile mechanic experienced, in the course of his employment, a burning pain in the center of his chest. After resting a few minutes he resumed work. The following day, while attempting to loosen a nut under an automobile, and bracing his feet and exerting a steady, hard pull on the wrench he was stricken with excruciating pain about the center of his sternum. A physician to whom fellow workmen took the claimant observed all the signs of acute shock and made a diagnosis of coronary thrombosis. When it appeared that the claimant would never again be able to perform manual work, he instituted proceedings under the Kansas workmen's compensation act, attributing his condition to the strain or effort exerted in attempting to loosen the nut.

The reported case does not clearly indicate the claimant's condition prior to the onset of the attack of coronary thrombosis. Apparently, however, the claimant, even though he testified that he was "in good physical condition" before the alleged industrial accident in the words of the court, had an

affliction of his heart or circulatory system that eventually might cause his death or render him incapable of manual labor," of which he probably was not aware. The physician in testifying in the compensation proceedings, stated that he diagnosed the claimant's condition as coronary thrombosis, and after defining that term he stated that "the heart muscle becomes weaker on account of lack of blood supply until eventually, either due to some effort or emotion, the safe limit is passed where the excess force of the heart is not sufficient to carry on the normal function, and heart failure, either immediate or delayed in its effects, occurs." He further stated that the sudden pulling and effort the claimant had put on the wrench "aggravated, activated or hastened the condition of coronary thrombosis" and that the claimant was not now able and would never be able again to perform manual work. On cross examination he admitted that "there are many cases in which no physical effort is made at all and it (probably attack of coronary thrombosis) will occur" but that, in his opinion, "it is the last physical effort (the attempt to loosen the nut) that brought it on." The employer offered no testimony. The compensation commissioner awarded compensation and the district court, Sedgwick County, division 3, affirmed that award. The employer and his insurance carrier appealed to the Supreme Court of Kansas.

The appellants argued that what happened to the claimant happened while he was doing his regular work in the manner in which it was ordinarily done, that there was no slipping, falling or other unexpected occurrence, and that there was no accident, in other words that the "heart attack" under the circumstances was not an accident for which the employer and his insurance carrier were liable. In our judgment, answered the Supreme Court, the evidence before the compensation commissioner and later before the district court warranted the conclusion that, even though the claimant unknown to himself "had an affliction of his heart or circulatory system that eventually might cause his death or render him incapable of manual labor," the hard pull on the wrench aggravated his condition and caused a speeding up of a result that might or might not have occurred in the future. Certainly as to the claimant it cannot be said he intended by the pull on the wrench to cause a thrombosis that might cause his death or render him an invalid. When he braced his feet and exerted a strong pull on the wrench, so far as he or any one else was concerned, what then happened to him was undesigned, sudden, unexpected and of an afflictive character—or, in shorter form, it was an accident. It arose out of and in the course of his employment and he is entitled properly to compensation.

The judgment of the district court in favor of the claimant was accordingly affirmed.—*Hill v. Etchen Motor Co.* (Kan.) 56 P. (2d) 103.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1926 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

Racial Differences in Incidence of Coronary Sclerosis
—A study of the necropsy records of 400 patients above the age of 39 years revealed to Johnston that the incidence of marked coronary sclerosis is 24 per cent for white males, 9 per cent for Negro males, 10 per cent for white females and 4 per cent for Negro females. Coronary occlusion with myocardial infarction, either recent or old, was found in 9 per cent of the white males, 4 per cent of the Negro males, 4 per cent of the white females and 2 per cent of the Negro females. The evidence suggests that members of the white race are much more susceptible to coronary sclerosis than are Negroes.

Relation of Renal Adenomas to Hypernephroma
—Trinkle made a study of the origin and development of renal adenomas. His material consisted of numerous examples of dilatation of tubules in subcapsular wedge-shaped areas of atrophy (believed to represent the starting point of cysts and adenomas), six simple cortical cysts, five small papillary cysts, thirty seven cystadenomas, three alveolar adenomas, four tubular adenomas and four small but typical hypernephromas that had not metastasized. This material was studied microscopically in an effort to work out the origin and development of the adenomas and to determine whether there is any evidence

that adenomas may develop into hypernephromas. He found that adenomas of the kidney occur most frequently in kidneys which are the seat of vascular disease. They also occur with the greatest frequency in the advanced years of life. These facts suggest that adenomas are the result of a proliferative reaction on the part of the tubules, which have been cut off from their primary blood supply. In papillary cystadenomas, after occlusion of the afferent arteriole, the glomerular tuft becomes avascular. In the majority of instances the corresponding tubule undergoes atrophy, but occasionally it continues to grow and becomes hyperplastic. This change is dependent on a renewed blood supply. As a result of hyperplasia, epithelial folds are produced which project into the lumen, converting the cystic tubule into a papillary cyst. Connective tissue of the renal stroma grows into the epithelial invaginations, forming a supportive stalk. Growth which is of the central expansive type, converts the tumor into a solid structure. As the tumor compresses the adjacent renal tissue, a fibrous capsule develops. The connective tissue of the papillary processes may fail to be carried along with the proliferating epithelium, leaving the cells lying in long cords. Occasionally masses of budded-off epithelium differentiate into tubules. These processes account for the variations in structure observed in the larger adenomas. Adenomas suggest that deficient oxygen may be a factor, but not the only factor. Large adenomas of the papillary type may show areas in which the structure is indistinguishable from that of hypernephroma. This type of adenoma represents a true transition stage. The similarity in structure between certain early hypernephromas and large papillary adenomas supports the theory that hypernephromas develop from adenomas.

Clinical Features of Carcinoma of Stomach.—Minnes and Geschickter believe that, regardless of the clinical features, all cases of carcinoma of the stomach are unfavorable from the standpoint of curability. In 370 cases followed more than five years or until death there were but 35 per cent of five year cures. Of 541 cases, slightly more than 75 per cent occurred in men and an equal percentage occurred between the ages of 44 and 66 years. Fifty per cent of the tumors occurred in the pyloric region, 20 per cent on the lesser curvature and the remainder elsewhere in the stomach. The duration of symptoms varied between six months and one year. In the dyspeptic group of cases the symptoms varied from gastric discomfort to acute pain accompanied by nausea and vomiting with occasional hematemesis. In the cachectic group there was progressive weakness, fatigue and loss of energy. In the third ulcerative group there was a typical history of gastric ulcer with symptoms changing in character and severity after a period of six or more months. The most conspicuous clinical change (91 per cent) was marked and rapid loss of weight, averaging 30½ pounds. A palpable mass in the epigastrium was found in 236 of the 541 cases. Occult blood was found in the stool in 58 per cent of 193 cases in which the test was performed. Analysis of the gastric contents in 339 cases showed achlorhydria in 64.6, hypochlorhydria in 25.9, normal values in 6.7, and hyperchlorhydria in 2.6 per cent. In 197 cases in which roentgen examinations were recorded, organic lesions were revealed in 157 cases. In thirty-four cases neither an organic lesion nor disturbance in the function of the stomach was disclosed and in six cases disturbances in motility only were observed. Laparotomy should be performed in cases that are clinically doubtful.

Passage of Particles Through Walls of Blood Capillaries—Experiments carried out by Field and Drinker show that visible particles of many different sizes and physical characteristics pass through the uninjured walls of blood capillaries and frequently into lymphatics. Graphite with a particle size of 1 micron has been observed to leave blood capillaries in the tongue and web of the frog. Calcite with a particle size of from 1 to 2 microns behaved similarly in the mesenteric capillaries. The material could easily be found in lymph from the foot of the frog and also in lymph from the foot of unanesthetized dogs. Pneumococci injected intravenously in the rabbit appear rapidly in thoracic duct, cervical and foot lymph. Erythrocytes readily become extravascular and are found in the lymph if the part is exercised or if the venous pressure is increased. No extra leakage of blood proteins accompanies this escape of red cells. Microfilariae 40 microns in length and 5 in breadth readily leave blood capillaries and enter lymphatics. These organisms are large and highly motile. Their escape from blood capillaries is accomplished without injury to the vessels involved. There is no evidence as to favored points of particle egress, and the final nature of the passage is not known.

Alzheimer's Disease—Jervis and Soltz think that Alzheimer's disease is to be considered a definite clinicopathologic entity. Of ten cases reported in the literature occurring at

an age prior to the presenile stage, seven presented either insufficient pathologic and clinical elements or typical pathologic changes but noncharacteristic clinical symptoms. Their inclusion in the group of Alzheimer's disease cannot therefore be made without unduly stretching the original conception of the malady. In addition to the case described in this presentation, three others have been reported in the literature of typical Alzheimer's disease from both the pathologic and the clinical aspects, in which the age limit varied at the most between 37 and 41 years. The narrow variation of the age limit and the small number of these cases justifies their conservative attitude toward the creation of a nosologic variety termed "juvenile form of Alzheimer's disease." The doubt cast on the generally accepted conception of Alzheimer's disease as a presenile psychosis, doubt based on the occurrence precisely of the disease in its so-called juvenile form, is therefore somewhat premature. Additional evidence is needed for such a conclusion. A report of a case in which all clinical and pathologic data, exclusive of the age, correspond to Alzheimer's disease, illustrates the expressed ideas.

Roentgen Therapy of Hodgkin's Disease—From a survey of the clinical results of irradiation in 161 cases of Hodgkin's disease within the past decade Jacob and his associates conclude that 1. No unfavorable biologic changes were observed following irradiation by any of the methods employed. 2. Roentgen therapy in any degree has induced definite extension of life, as compared with the untreated patients. 3. Systemic irradiation has been no more effectual than repeated local irradiation in prolongation of the total duration of the disease in those cases now known to have died. 4. Future figures, more favorable to systemic irradiation, derived from that group of patients still under observation, and who have already exceeded the life span as determined from the known dead may be expected. 5. Systemic irradiation of all lymphoid areas is the method of choice, in the light of symptomatic response.

March Foot—According to Elward, the disorder of the metatarsal bones that is manifested by painful swelling of the forefoot with concomitant spontaneous fracture of one or more of these bones, is called generally in English "march foot," presumably because of its supposed association with military activities. He concerns himself chiefly with the imperative necessity for careful differential diagnosis between (a) sarcoma of the bone (b) Köhler's disease and (c) other pathologic and traumatic conditions. Of these the differential diagnosis from sarcoma is by far the most vital. For example, Dodd not long ago reported a case in which owing to an erroneous diagnosis of sarcoma a patient with Deutschländer's disease (march foot) submitted to an amputation of the foot, while in one of Strauss's cases excision of the metatarsal was performed for the purpose of verifying a doubtful diagnosis. In view of the customary absence of a history of trauma the presence of a sarcoma may very readily be assumed but closer study of the roentgenogram fails to reveal the so-called fanlike sun ray structure generally regarded as pathognomonic of osteogenic sarcoma. Serial

studies at weekly intervals usually serve to reveal the true nature of the disorder. The latter should likewise be differentiated from Köhler's disease, which attacks the distal ends of the metatarsals as well as from alterations in epiphyseal zones resulting from late rachitic changes, syphilitic diseases of bone, all other types of fractures and incipient flatfoot. Conservative treatment is indicated in the great majority of cases of the disease. Rest in bed, baking baths, massage and occasionally exercises designed to restore tone of exhausted muscles of feet and legs have all proved highly efficacious as therapeutic measures. The author gives the histories of two cases. The first case is believed to be the acute form because of the history of onset following sudden and unaccustomed strain in using a spading fork. This type is properly called forced foot (pied force). The second case represents the chronic form wherein the symptoms are not definitely dated but apparently follow prolonged strain as must necessarily ensue in a patient of excessive weight (200 pounds, or 91 Kg, in this case) who follows an occupation requiring standing for prolonged periods. The episode of high heeled shoes is possibly a factor, but probably a minor one. This type is properly termed overloaded foot (pied surcharge).

Pregnancy and Tuberculosis—After a perusal of collected studies by qualified observers who have investigated the risk of pregnancy in the tuberculous from various sides as to the type of the disease stage and end results, and with the author's own experience of long observation of many pregnant tuberculous patients Castlen is of the opinion that the risk of pregnancy for a tuberculous woman is no greater if she is properly treated, than for the nontuberculous pregnant patient. Those who become pregnant should have sanatorium care under proper careful direction and, if possible some form of selective collapse therapy should be carried out. After labor, treatment for tuberculosis should be carried on vigorously and no successful form of therapy be discontinued too early and in any event, only after careful study by one who is qualified in the handling of such cases. Therapeutic abortion is rarely if ever indicated in these patients and certainly should not be carried out after the fourth month of gestation, when the operative risks become practically as great as those of full term delivery. The question of pregnancy and tuberculosis should be given more attention not only by those who practice the treatment of tuberculosis but by that larger group the obstetricians to the end that the lives of these women may be preserved and so that the lives of a large number of their infants may be saved. With a better and more intelligent understanding of the problem and with proper management, physicians will see these young women emerge from an experience, once looked on by most of the profession as most dangerous and unjustifiable almost if not quite as safely as the normally pregnant woman.

Treatment of Tuberculosis of Skin by Heat—Owing to the appearance of tuberculosis cutis on exposed areas with exacerbations during cold weather and based on the work of

Duncan and Mariette on artificial fever in pulmonary tuberculosis, it occurred to Rusten and his associates to apply local heat and general hyperpyrexia for these lesions. The death point temperature of these organisms is so high that local necrosis would occur if the skin should be treated to this level with local heat. General hyperpyrexia at death point temperature of the bacilli is incompatible with life of the host. The method of treatment consisted of general hyperpyrexia in one case and local heat with the infra-red lamp in all cases. When local treatment was used the temperature of the skin was the highest that could be tolerated by the patient. Occasionally vesiculation occurred. The daily duration of treatment varied from one half hour to four hours or more. A variety of types of tuberculosis of the skin were treated by these methods. Biopsies were taken before treatment and guinea-pigs were inoculated with ground tissue or pus in all cases. Tissue inoculations were made on culture mediums, and ground tissue was injected into cold-blooded animals in some cases. Necropsies of these animals in six weeks were negative for tuberculosis. Ground biopsies of the same lesions were inoculated on Herrold's glycerin-egg medium after the specimens had been treated with 3 per cent hydrochloric acid and neutralized with sodium hydroxide. These cultures so treated were kept at room temperature and at 98 F, and resulted in no growth in eight weeks. Temperatures were taken with thermocouples at twenty-five exposed areas of the skin of three patients reported and a group of controls. The results of these readings indicated that there was little if any difference between skin temperatures of the controls and these cases, in spite of the erythrocyanotic appearance and clammy feel. The chronic or proliferative types show improvement which does not offer a great deal of encouragement over previous reported methods. The acute type mainly papulonecrotic tuberculosis erythema induratum and inoculation types, respond well to this mode of therapy. The results may be due to the inhibition of the growth of tubercle bacilli in the primary focus when generalized hyperpyrexia is used. This inhibition may be reflected in fewer lesions or absence of lesions for a period. The local heat, which was used in all cases, causes hyperemia, phagocytosis and absorption. Inhibition of the micro-organism must be considered. However, the resistance of the host is probably the most important factor. The response in the reported cases was such that this type of therapy may well prove a valuable adjunct in the treatment of tuberculosis of the skin.

Scleroderma Treated with Posterior Pituitary Extract
—According to Oliver and Lerman, many authors have con- sidered that there is a relationship between scleroderma and endocrine disorders of various kinds in fact, every one of the endocrine glands has been mentioned in association with sclero- derma After reviewing the literature on the relationship between scleroderma and the different endocrine glands, the authors point out that if there is an etiologic relationship between scleroderma and the glands of internal secretion, it is probable that in some cases at least there are various other causative factors such as trauma, syphilis, nervous shock, exposure to cold and disturbances of the sensory nerves, especially in association with hemiatrophy corresponding to the distribution of the fifth cranial nerve In many cases the sympathetic nervous system undoubtedly is involved The method of treatment in the authors' series of cases consisted of daily injections of posterior pituitary—in most instances an ampule of 1 cc of solution of posterior pituitary The injections were continued for from a few weeks to a month at a time, followed by an interval of a month or more without treat- ment Some of the patients were started on daily injections of 1 cc. of pancreatic extract for a month as a control series The authors report the clinical histories of three cases one of the morphea type, one of the linear band type and one of the diffuse type They summarize their observations as fol- lows Twenty patients with scleroderma of different types were treated with daily injections of solution of posterior pituitary In three cases of morphea some or all of the lesions disappeared completely, leaving slight pigmentation In the others varying degree of improvement were shown In two cases of the bandlike type improvement was marked In a case in which the condition was associated with a severe degree of hemiatrophy of the face, improvement at first was consid- erable but no further improvement was noted after the first few months Naturally the atrophy was unchanged In five cases of sclerodactylia associated with diffuse scleroderma of the face and neck marked improvement was noted in the face and neck, the skin becoming definitely softer In the other three cases of a similar condition some improvement was noted This improvement was manifested in several instances by ability to wrinkle the forehead and disappearance of the masklike expres- sion characteristic of this condition In one of these cases the skin of the neck become normal in appearance except for pig- mentation In three cases of sclerodactylia marked softening was noted in the skin of the hands as well as increased mobility and relief from pain In two cases the improvement was so

slight that continuance of the treatment was not thought worth while Sympathectomy was performed on the left side, with excellent immediate results in one of the last-mentioned cases.

Allergic Bacterial Dermatoses—Certain dermatoses, including chronic urticaria, erythema toxicum, erythema multi- forme and chronic eczema, Graham and Traub say, have been acknowledged in a number of instances to be of allergic bacterial origin They studied a group of thirty cases of involvement of the skin which they considered to be of allergic bacterial origin They consisted of twenty cases of urticaria, five of erythema multiforme, two of erythema toxicum two of eczema and one of prurigo In twenty of the thirty cases, streptococci were obtained on culture from foci of infection Twelve of these patients, who showed a positive cutaneous reaction to vaccine prepared from the culture, were treated with the vac- cine With regard to three of the patients who were treated, a focus of infection was removed tonsils in one instance and abscessed teeth in the other two Each of the three patients showed gradual improvement, with a final disappearance of the eruption long after the removal of the focus One patient was observed for fifteen months after treatment and there was no recurrence To determine how much credit for these results should be given to the removal of the foci and how much to vaccine therapy requires further study Of the other nine patients treated, five showed some improvement, which was only temporary, and four showed none These observations, the authors believe, demonstrate the importance of the role of focal infection in causing allergic dermatoses Removal of proved foci has apparently been effective in treatment Vaccine therapy, which in a number of cases favorably influenced the course of the eruption, failed to effect a cure The authors results are necessarily inconclusive, as for this preliminary study they limited their observations to infections due to strepto- cocci, also the number of cases studied is small They believe that this form of therapy has distinct possibilities

Benzyl Cinnamate in Treatment of Trachoma and Corneal Opacities—Jacobson declares that benzyl cinnamate has been found of great value in the treatment of trachoma. In an analysis of 244 cases of refractory trachoma there were fifty-three cases of slight improvement and 139 of marked improvement The army surgeons reported improvement in 73 per cent of 113 cases In the course of the author's mission in Tunis he noted a few cases of leukoma of gonorrheal origin in which the opacity had appreciably regressed under the influence of the injections of benzyl cinnamate He has studied the properties of this drug It is antitoxic and causes vaso- dilatation It provokes leukocytosis also However one has no right to conclude that the therapeutic action of the drug is

the result of these properties. But treatment with benzyl cinnamate causes pronounced vascularization, with vasodilatation at the site of the pathologic lesion and regression of the exudate and the chronic inflammation. Ophthalmologists have the added privilege of being able to observe this phenomenon in all its details with the slit lamp. The injection does not produce any general or local reaction, the tolerance is perfect. A focal reaction, which results from the hyperemia, is noted at the site of the lesion. This hyperemia differs from pathologic hyperemia in that it is not accompanied with exudation.

Cataract Following Dinitrophenol Treatment for Obesity—Horner believes that the total number of cases of cataract after the administration of dinitrophenol is more than sixty and probably under a hundred. New cases are still developing. For example, he saw four new patients during February 1936, making a total of eleven cases, all of bilateral involvement. Cataracts appear to follow the therapeutic administration of dinitrophenol in from 0.1 to 1 per cent of cases. The mechanism is at present unknown. The administration of this drug should be withheld pending further study. Cataracts identical in appearance with these may develop in women who have not taken dinitrophenol. A series of seventeen extractions by three different methods is reported, and vision was 0.8 or better in 82.3 per cent of the cases, without secondary operation.

Clinical Studies with Insulin Protamine—According to Smith, diabetic patients who have used regular insulin for some time before beginning insulin protamine often show an acute diabetic disturbance that may last from three to five days. Loss of control to some degree may immediately follow any slight change in unit dose or in time of insulin protamine injection. In the group of cases here reported, it was found that the insulin protamine had a unit value somewhat less than U-40. Usually from 4 to 8 units more was required with the insulin protamine solution. Since the zinc and the calcium combinations have been used there is evidence that these are more nearly the same in unit value as regular insulin of U-40 strength. Observations indicate that an interval between insulin protamine injections of twelve hours gives satisfactory results rather than giving the dose in relation to meals. Change from insulin protamine to regular insulin and back again to insulin protamine can be done without serious disturbance in control. All patients expressed a feeling of increased endurance and relief of periodic fatigue soon after beginning insulin protamine even before satisfactory control is obtained. Hypoglycemia may be difficult to correct because of the continued absorption of insulin and may appear at the beginning of the change to insulin protamine when regular insulin is taken at one or more periods. Subnormal values for blood sugar may be found without definite symptoms. This may require more frequent blood sugar tests especially in patients

with some cardiovascular complication. The more even blood sugar control should give greater safety for these patients in that there should not be the rapid drop in blood sugar that was occasionally found with regular insulin. Patients using insulin protamine should be warned of the necessity of keeping the preparation in the icebox after mixing, and to shake the bottle before each withdrawal of a dose. The combinations of insulin with protamine buffer, together with either zinc or calcium, give a more even blood sugar control throughout the full twenty-four hours than has been possible with regular insulin alone in cases of severe diabetes. Clinical observations for longer time will give the full picture of value for these new preparations, but the controls secured in the months they have been used offer great hope for the future.

Resection of Cancer of Colonic Flexures—Hoag shows that the new method of operative approach by a pericostal-transabdominal incision parallel to the actual nerve supply gives an excellent exposure of the colon and its flexures and permits their more rapid and complete removal. The use of this incision permits resection and reestablishment of continuity of the bowel rather than a permanent colostomy for a greater number of patients. It is hoped that the procedure will be a potent factor in reducing the morbidity and mortality of certain lesions of the colon. Recent investigations of the innervation of the abdominal and rectus muscles have shown it to be different from that long accepted by the older anatomists.

Some Common Surgical Complications in Senile Cataract C P Clark, Indianapolis—p 422
John Shaw Billings and the Centenary of the Army Medical Library E. F. Kiser Indianapolis—p 424

Proper Time for Rib Resection in Empyema—Berman shows that after localization of empyema there is little or no movement of the mediastinum or diaphragm or compressed lung margin on the affected side, with increased movement on the normal. Using this method as his criterion for surgery, he operated as soon as fixation occurred. Fluoroscopic examination is made on all patients on admission and then every other day until surgery is indicated. He used this method in twenty-seven cases and found that localization will occur on the seventh to the tenth day and, although the pus is thick in most of these it is very thin in some. If the general condition is grave, a blood transfusion is given prior to operation. After localization, the second most important consideration in the treatment of an abscess is adequate drainage. Rib resection was done in 100 of the 123 cases studied with a mortality of 4.9 per cent. The so called closed method with catheter drainage was employed in seven and repeated aspirations were done in sixteen. The mortality in this group was 15.4 per cent. These results, together with the fact that the treatment of empyema is essentially the treatment of an abscess after localization, led the author to adopt open operation with rib resection as the proper type of surgical procedure. He does a rib resection over the lower portion of the empyema. After the pleural cavity is entered a finger is introduced gently to break down partitions. Then all large clots of purulent debris are aspirated or manually removed. A nine-sixteenths inch rubber tube is introduced and anchored to the skin with a silkworm gut suture and a safety pin is placed through the tube to prevent aspiration. Whereas formerly irrigations were done daily the author has now dis-

continued all irrigations Dressings are changed as required, but always as infrequently as possible. After the seventh day the silkworm-gut suture is cut and the tube is allowed to "work its way out" This occurs as the result of rapid filling in of granulation tissue and some lung expansion If the tube is not out by the tenth day, a fluoroscopic examination is made. This will disclose fluid levels or "pockets" with fluid The time required for the obliteration of an empyema cavity may be exceedingly variable One cannot be dogmatic about the length of time during which drainage should be continued This depends on the fluoroscopic examination and the character of the pus After the tube has been removed, a petrolatum gauze dressing is applied Each day for approximately one week the crusts over the granulating sinus are removed and the tract is gently probed This is done so that healthy granulations are established and that local "pockets" may not form

*Studies on Inflammation VII Mechanism of Increased Capillary Permeability A Critique of Histamine Hypothesis V Menkin Boston.—p 485

Mechanism of Increased Capillary Permeability in Inflammation.—Menkin's present investigation deals with whether one or more substances can be obtained from inflammatory exudates which when introduced into normal cutaneous tissue, will induce local vasodilatation and an increase in the permeability of the capillary wall Furthermore the properties

of the active fractions that have been obtained from inflammatory exudates have been compared with histamine in an endeavor to test Lewis's hypothesis The experiments indicate that a diffusible crystalline-like material capable of increasing capillary permeability is present in inflammatory exudates By appropriate tests this active principle has been shown to lack the properties characteristic of histamine, thus apparently ruling out the latter as of any primary significance in inflammation Studies in a preliminary communication suggest that the twofold increase in potassium content found in exudates, as compared to blood serum, even as early as the first few hours of the inflammatory reaction, may be connected in some way with the active factor Organic compounds other than histamine, including various products of proteolytic breakdown, such as amino acids, usually found increased in concentration in an exudate, likewise seem to have some effect in augmenting the permeability of capillaries during the course of the inflammatory process The active factor manifests no property in common with histamine or presumably with the hypothetical H substance assumed to be closely related to histamine. This is indicated by the difference between the tissue staining pattern of the exudate or of its active fraction and that of histamine and opposite effects by histamine and the active factor found in exudates on the tonicity of the isolated strip of guinea pig intestine. The observations presented do not substantiate Lewis's hypothesis of histamine or of its closely related H substance as the primary cause of increased capillary permeability in inflammation The present studies are being continued in an endeavor to free of its impurities and to identify the active crystalline-like material isolated from an inflammatory exudate.

- *Asphyxia as Consequence of Nitrous Oxide Anesthesia with foreword by Y Henderson C B Courville Los Angeles.—p 129
Interrelation of Cerebrum and Cerebellum in Regulation of Somatic and Autonomic Functions J F Fulton New Haven Conn.—p 247

Asphyxia as Consequence of Nitrous Oxide Anesthesia.—Courville became interested in the asphyxial effect of nitrous oxide anesthesia when he saw a comatose patient who presented generalized muscular twitchings and rigidity, which developed after a period of apnea while under this anesthetic. The striking and characteristic changes in the nerve cells of the brain and the distribution of cortical necrosis suggested asphyxia as the cause of the symptoms In the last five years, thirteen such instances have been studied In the nine cases terminating fatally, necropsies were performed and a microscopic study was made of the tissues of the nervous system The results of these clinical and pathologic studies form the basis of his study The immediate nervous manifestations usually consist of generalized convulsive seizures, muscular rigidity and persistent coma, at times terminating fatally with signs of 'decerebrate rigidity' Delayed symptoms may occur in the form of a psychosis, a parkinsonian symptom complex or disturbances of special sensation, particularly in the form of a partial or complete amaurosis The patient may recover entirely after an anovemic episode, may survive for a variable period with residual symptoms or may die within a few days In fatal cases, death usually occurs within from two to seven days but may occur only after an interval of weeks or months. Anoxemia following administration of nitrous oxide may be the result of impure gas, faulty apparatus or a preexisting or suddenly developed pulmonary lesion Regardless of the exact

source of the trouble, the clinical symptoms and the pathologic changes are the effect of asphyxia and are not due to any toxic effect of nitrous oxide itself. The mechanism in most instances seems to be one of two types (1) sudden circulatory and/or respiratory failure with consequent cerebral damage due to the immediate utilization of the remaining small amounts of available oxygen or (2) prolonged exposure of the brain to a dangerous degree of oxygen want. The resulting cortical lesion necessarily depends on the degree of anoxemia and its duration. Changes in the nerve cells may be described as sclerotic, acute degenerative and ischemic and, in chronic cases, "calcified" nerve cells. Lipoidal degeneration is also a common form of cellular change. The microglia develop into compound granular corpuscles in the presence of necrosis. The astrocytes adjacent to the necrotic areas undergo proliferation to aid in the formation of the astrovascular scar. The oligodendroglia undergo acute swelling and variable degrees of proliferation particularly in the subcortical white substance. The arachnoid and pia may show cellular proliferation, and adhesions between these two membranes may take place. The lenticular nucleus seems to be affected to about the same degree as the cerebral cortex, and essentially the same architectural and cellular changes are found. Small globules of calcium are commonly observed in the small blood vessels in this structure similar to those found in carbon monoxide poisoning. The Purkinje cells of the cerebellar cortex are quite markedly altered. Not all portions of the cortex are uniformly or symmetrically involved. The earliest lesions are found about the pericellular and pericapillary spaces, which would suggest that the injury is a result of 'tissue respiration'—a disturbed carbon dioxide-oxygen exchange between the tissue fluids and the cellular elements. A careful analysis of all possible factors should be made at the time an accident occurs under nitrous oxide anesthesia to determine, if possible, the cause of the trouble. A detailed study of the brain should be made in every fatal case. The ultimate changes taking place in the brain after a prolonged survival period are as yet unknown.

Gastro-Intestinal Syndrome in Coronary Disease.—Bertucci points out that any physician of average knowledge is able to diagnose disease of the coronary arteries correctly when the symptoms are referable to the chest but that the question of coronary artery disease with symptoms simulating an acute abdominal condition is of greater importance and much more difficult to diagnose. This refers not only to the internist but more so to the surgeon who is called on in consultation and who must make a differential diagnosis between coronary disease and acute operable conditions. The author shows that coronary artery disease occurs more frequently in men past 40, especially in those leading a strenuous life which predisposes to early arterial degeneration. Previous history of periodic attacks of "indigestion," high blood pressure and dyspnea on exertion are significant factors in coronary disease. As a result of coronary occlusion the infarcted area in the heart may extend to the endocardium, resulting in a mural thrombus. This may result in embolism leading to various catastrophes. Coronary

arteries are not "end arteries," as anastomoses can be demonstrated. Pain is of an intense and persistent type and referred through the sympathetic system. Either coronary artery may be involved, but the anterior descending branch of the left is involved more often than the others. Onset of coronary artery disease may simulate any gastric disorder. The history, past and present, is of vast importance in evaluating the symptoms. The following points help in arriving at a correct diagnosis: dyspnea, rales in the bases of both lungs, fall in a previously elevated blood pressure, enlargement of the liver with tenderness, enlargement of the heart with weak and distant tones, irregularities and pericardial friction rubs. Fever and leukocytosis are usually present from twenty-four to forty-eight hours following the attack. The electrocardiographic tracing is of diagnostic importance in these cases. The author thinks that it should be used more often by physicians and surgeons alike. Coronary artery disease should be differentiated from cholelithiasis, cholecystitis, perforated peptic ulcers, gastric crisis of tabes dorsalis, subdiaphragmatic pleurisy, renal colic, tumors of the cord and herpes zoster.

Treatment of Varicose Veins with 2 per Cent Sodium Ricinoleate.—It has been Postlethwaite's experience that in persons whose varicosities were resistant to other sclerosing agents or which recurred after the administration of other sclerosing agents an excellent end result was obtained after the use of sodium ricinoleate. He gives the histories of nine such cases and says that in another group of five patients with small areas of varicosity varying amounts of from 1 to 4 cc. of 2 per cent sodium ricinoleate was injected with excellent results. He found that the incidence of reactions and pain following the use of sodium ricinoleate was much lower than that following the use of other sclerosing solutions in this

culous lesion in the spine, the prognosis is good. Laminectomies in this series have not hastened recovery. Cases with paralysis show a higher mortality rate than those without paralysis. The best treatment for the paraplegia is that which is best for the tuberculous lesion itself. The patient is placed in a position which prevents weight bearing and at the same time gives the best immobilization to the spine. When the paralysis has disappeared, a spinal fusion should be done to cure the tuberculous bone lesion.

Sicklemia in the Southwest—For the basis of their study, Killingsworth and Wallace examined the wet blood smear preparations of 1,766 unselected patients in Texas during 1933 and 1934, 1,205 were Negroes, 322 white persons and 239 Mexicans. Because of various medical and surgical conditions, 949 Negro patients came to the hospital. The other 818 were healthy medical students, nurses or Negro and Mexican school children. None of the white patients examined showed sickling. None of the Mexican males showed sickling, but three, or 1.2 per cent, of the Mexican females had sickle cells in their wet smear preparations. Sixty-five of the 1,205 Negroes examined showed the trait of sickling in their blood. Five of these patients had active sickle cell anemia and sixty the sickling phenomenon only. Twenty-seven of the sixty Negroes were males. In the 450 healthy Negro school children examined, twenty-seven showed sickling. Thirty-eight of the 755 Negroes seeking medical or surgical care showed the trait. Two of these patients were found in the fifty cases with the clinical diagnosis of tuberculosis, twenty-one in the 347 patients with all stages of syphilis, five in the forty-one with infections of the upper part of the respiratory tract, one in the ninety-nine pregnant Negro females, and four in the cases with miscellaneous diagnoses. The ages of the patients showing the sickling phenomenon ranged from a new-born female infant to a Negro man aged 71. The average age of the Negro school children examined who showed sickling was 11 years. The average age of the adults showing the trait was 39 years. In a review of the past histories of the sicklemia cases, 50 per cent showed unusually severe childhood diseases, 70 per cent gave a history of frequent infections of the upper part of the respiratory tract and 20 per cent complained of general malaise and weakness without cause. On physical examination, cardiac enlargement and functional murmurs could be demonstrated in 20 per cent of the cases. It is probable that this was due to the concurrent disease at hand rather than to the sickling trait. 50 per cent had greenish yellow sclerae, 15 per cent had unexplained abdominal tenderness, and slight generalized nontender adenopathy was present in 10 per cent of the cases.

Thyroid Crisis—Maddock and his associates consider the thyroid crisis one of the most disturbing conditions encountered in the care of patients with hyperthyroidism. In a review of 123 deaths from goiter from 1925 through 1933 at the University Hospital eighty-eight were found due to this cause. As one observes a typical thyroid crisis the impression is that the patient is being driven by a profound toxemia. The exact mechanism is not entirely clear but various conditions that bring on the reaction are known. Fright, anger, worry, the disturbing factors of an operation on any part of the body, an infection, fatiguing examinations and lack of sleep have all been shown to be precipitating elements. In the hope of furnishing more significant data on the exact mechanism,

studies of the liver function and of the epinephrine content of the blood were carried out on patients with hyperthyroidism. In many instances the blood bilirubin value was normal when abnormal amounts of the dye were retained, thus indicating the greater sensitivity of the latter as an index of liver function. Of the thirteen patients with toxic goiter, eight showed evidence of liver damage preoperatively. That there is a relationship between the severity of the disease and the liver damage was evidenced, first, by the preoperative observation of normal liver function in four nontoxic thyroid patients included as a control group, and, secondly, by the finding of an average basal metabolic rate of only plus 33 per cent for the five toxic thyroid subjects with normal liver function as against an average of plus 54 per cent for the eight hyperthyroid patients with liver damage. The effect of the operation on the liver in the hyperthyroid group was rather striking. On the first postoperative day their function, whether it had been normal before or not, was markedly impaired, the blood bilirubin being above normal and the dye retention being practically complete in the majority of cases. On succeeding days the liver function of the group improved, a variable time being necessary before it was back to the preoperative level. No true correlation was found between the liver function and the immediate postoperative course. No evidence was found of epinephrine in the peripheral venous blood of the majority of the patients who were responding nicely to the routine preoperative treatment. In patients whose progress was not satisfactory and in whom fever was present, the test occasionally showed the presence of a small amount of epinephrine. A few patients postoperatively showed a positive test, the highest values being obtained in the two patients of the group who developed severe thyroid crisis. The test has not been used for a long enough time to determine whether or not it is specific for epinephrine under conditions of disease. From the work of Goetsch, it is known that epinephrine can produce the restlessness, hyperthermia, tachycardia and other general characteristics of thyroid crisis. Besides these observations, acute pulmonary edema developed in these two cases. This feature of severe thyroid crisis can apparently be produced by epinephrine. In the past, this respiratory complication, in many cases the mucus and cyanosis being attributed to a bronchopneumonia or tracheitis, has been overlooked. One might ask whether epinephrine has anything to do with the liver damage observed in patients with hyperthyroidism. It has long been known that epinephrine disturbs the carbohydrate metabolism of the liver. Recently, a study has been made of the pathologic changes produced in the livers of dogs receiving epinephrine. With moderate doses well advanced fatty degenerations were found. This is essentially the major acute lesion observed by Weller and by Beaver and Pemberton in the liver of patients dying from hyperthyroidism.

Pyramidal Lobe of Thyroid in Hyperthyroidism—Contrary to the usual teaching, Beilby and McClintock have found that the pyramidal lobe of the thyroid can be demonstrated in 92.8 per cent of cases. The lobe varies in size from a few thyroid cells in a fibrous cord to a well developed process. The lobe possesses an adequate blood supply, quite independent of that to the main thyroid body. Postoperative hypertrophy of the pyramidal lobe is a frequent cause of recurrent symptoms in diffuse goiters. Careful inspection of the pyramidal lobe with such treatment as the surgeon deems adequate should be made a part of the surgical procedure in every operation for the relief of hyperthyroidism.

Meningitis in the New-Born—Craig gives an account of the clinical and pathologic features of twenty-one cases of neonatal meningitis. Observations were made and recorded in connection with twenty of these infants from the time of birth in the course of routine clinical duties. One child born at home, first came under observation after admission to the hospital on the third day of life. Postmortem examination was carried out in eighteen cases, in the other three cases permission for necropsy was not obtained, and diagnosis was based on the results of examination of cerebrospinal fluids obtained during life. The author shows that meningitis is usually part of a generalized septicemia but that it is not always possible to determine whether infection of the meninges has been by the blood stream or as the result of direct extension from other foci. The bacteriology of meningitis differs in the new-born from that found in older subjects. Neonatal meningitis is frequently the result of *Bacillus coli* infection, occasionally it results from infection by organisms of comparative rarity. In the twenty-one cases described, *Bacillus coli* was the causal organism in approximately half that number, in one infant meningitis resulted from septicemia due to an atypical organism of the *Salmonella* group. Morbid conditions of the skin, subcutaneous tissues or surface mucous membranes were present in fifteen cases. Their presence, especially in premature infants, constitutes a definite risk of meningitis. Infection of the mouth and nasal passages is associated with special risks on account of the ease with which extension may occur along the eustachian tubes and give rise to otitis media and subsequent meningitis. Neonatal meningitis cannot always be diagnosed. The classic signs of meningitis are often absent. Importance is attached to prematurity and the presence of infection as predisposing factors. Signs of intracranial disturbance occurring after the first week of life should always suggest meningitis, of these, ocular signs, sponginess of the fontanel and mental restlessness are the most common. Fever of a few days duration usually precedes death. Convulsions are rare. The condition has to be differentiated from pneumonia in afebrile cases and from intraventricular hemorrhage in the presence of signs arising from increased intracranial pressure. Lumbar puncture is essential for a final diagnosis. Neonatal meningitis illustrates the seriousness of the threat to survival in infection of the new-born. The skin and surface mucous membranes are common portals of entry for infection. The danger of infection can be greatly lessened by meticulous attention to the hygiene of the skin, mouth, eyes, nasal passages and external auditory meatus. This care should commence with the birth of the infant.

*Acute Infective Polyneuritis Report of Five Cases C Pinckney—p 333

Acute Infective Polyneuritis—According to Pinckney, acute infective polyneuritis is a comparatively rare disease, appearing at almost any time but mainly affecting men between the ages of 20 and 40. The disease has been shown by Wilson to be caused by a living virus, which was successfully transmitted from man to monkey and recovered in pure culture. The author points out that Collier describes the cases as falling into two types. The first is that of a four limb peripheral neuritis associated with an external ophthalmoplegia, the malady being apyrexial and painless with a rapid onset. The second group of cases show a slight pyrexia with a less rapid onset. They also show a four limb polyneuritis, but accompanied by a facial paralysis and often a slight general bulbar weakness. Here again the limb paralysis is in some patients the dominating part of the picture, while in others the facial paralysis predominates. A third group of cases, however, must be included which start as a lower limb polyneuritis, spreading rapidly upward to involve the trunk and finally the muscles of respiration. This group cannot be distinguished from what is known as Landry's paralysis, for there is little doubt that the two are due to a similar cause. In all these groups the paralyzed muscles are flaccid but do not show much wasting, and the reflexes are sometimes surprisingly obtained when voluntary power is almost absent. The paralysis also need not be truly peripheral and is often more proximal than distal. Sensory symptoms are usually present. The sphincters are hardly ever involved. Following a description of five cases, the author makes an attempt to fit these cases into the foregoing three clinical groups. He states that the prognosis must always remain somewhat uncertain, even later in the course of the disease, owing to the frequency with which exacerbations, with a further rapid increase of paralysis, may arise, but that recovery tends to be complete in the cases in which it occurs. The author has been tempted to give a prognosis based on the appearance and chemistry of the cerebrospinal fluid, a brown or yellowish tinged fluid with a high protein content, which points to a vigorous reaction appearing to justify a better prognosis than a clear fluid which shows slight or no alteration. There is no specific treatment but frequent lumbar punctures, especially when a high protein fluid is obtained, continued until that protein content falls, appears to hasten the rate of recovery.

Biliary Infection.—Phillips stresses that the essential cause of trouble in the biliary passages is microbial infection. Every symptom associated with stones in the gallbladder may occur with a gallbladder containing no stone. Provided no active infection is present gallstones may exist in the gallbladder or

the common duct without producing any symptoms of moment. Careful investigation will elicit symptoms indicative of biliary infection in many patients whose chief complaint is flatulence. Though in some cases infection within the gallbladder is slowly overcome, in most cases dyspepsia indicative of chronic infection persists for years. So long as infection is present there is a risk of some dangerous complication. Complications include (a) cholecystitis, which may go on to empyema of the gallbladder, (b) infection of the common duct (with or without stones) producing fever and jaundice, (c) infection of the hepatic ducts, which may be followed by general infective cholangitis, (d) pancreatitis—chronic, often associated with glycosuria, or acute, frequently fatal, (e) chronic toxic conditions, including disorders of the myocardium, muscles, fibrous tissues and joints. Removal of the gallbladder prior to the onset of complications is a relatively easy and safe operation and is generally followed by freedom from symptoms, which often leads the patient to express surprised delight because he had failed to appreciate how much discomfort he had previously had. There is therefore much evidence in favor of removal of any gallbladder that has been and is giving rise to a condition of biliary infection.

Role of Malaria in Cirrhosis of Liver—Tirumurti and Radhakrishna Rao direct attention to the fact that in a previous communication they pointed out that the common association of malaria and cirrhosis of the liver in India has given rise to divergence of opinion regarding the role of the former in the causation of the latter. They reinvestigated the whole question by improved staining methods. As a correct understanding of the problem under discussion depends on an accurate study of the nature and genesis of fibrosis, if any, in chronic malarial livers, they bestowed their attention on this line of investigation. From each of the specimens of chronic malarial livers, several thin pieces were taken so as to include in the parenchyma the different orders of the divisions of the portal and hepatic venous trees to study the changes, if any, at the different levels of the vascular and biliary trees. The pieces of the liver were fixed in 10 per cent neutral solution of formaldehyde. In the case of old museum specimens the pieces were first washed in running tap water in a histologic washing tank for twenty-four to forty-eight hours and then fixed in 10 per cent neutral solution of formaldehyde. For routine examination, paraffin sections were stained with Ehrlich's acid hematoxylin and eosin for staining the connective tissue the paraffin sections were stained with Weigert's iron hematoxylin and van Gieson stain. Frozen sections were stained with the Foot and Menard silver carbonate impregnation method to bring out the reticulum of the liver. The important histopathologic features in the liver in this series are absence of any loss of lobular pattern leading

of Kupffer cells with malarial pigment, and no noticeable increase of fibrous tissue in the liver. In none of the cases investigated was there any pseudolobulation or fibrosis similar to that seen in a typical case of cirrhosis of the liver. The indiscriminate use of the term "cirrhosis" for any and every type of fibrosis of the liver has no doubt added to the confusion regarding the role of malaria in cirrhosis of the liver. As pointed out by Rolleston and McNee, the possibility of slight necrosis of the hepatic parenchyma in acute or subacute malaria cannot be denied, but the liver possesses a remarkable capacity to regenerate so that such necrotic changes leave no permanent trace behind. In almost all the instances in this series, the chronic malarial liver showed no increase of fibrous tissue. The causes of cirrhosis of the liver are so many that each case should be thoroughly studied in order to arrive at the etiologic agent responsible for the disease. One of the authors (Radhakrishna Rao, 1933) showed from an intensive investigation of cases of cirrhosis of the liver that malaria "cannot be considered to be a causal factor in the production of cirrhosis of the liver, though it may be an important predisposing cause." It is important to remember that malaria and cirrhosis of the liver may coexist in a patient without the former exerting any influence on the latter condition. Finally, it may be said that the evidence presented in this paper proves that malaria as such is not a direct cause of cirrhosis of the liver.

Treatment of Pathologic Conditions of Fallopian Tube—Solomons remarks that palliative treatment is the method of choice in acute salpingitis. He shows that the tube appears larger when dilated by some kind of iodized oil. It leaves the uterus straight as a rule. Anesthesia interferes with peristalsis of the tube. Reference is made to work showing a definite relation between rhythmic contraction of the fallopian tube and the menstrual cycle. This may account for the cure of sterility in some cases by the injection of large doses of endocrine preparations. Kaufmann points out that the fimbriated end of the fallopian tube remains passive during the passage of the ovum. This seems to account for cures of sterility even after the removal of the fimbriated ends of the fallopian tubes. Iodized poppy-seed oil is not altogether safe. When operative treatment is considered the whole situation must be placed before the husband and wife. It must be pointed out that the chances of success except at the fimbriated ends, are extremely small. In view of even the small number of successes a further effort must be made to attain a better technic. Before operation is attempted the husband must be tested and the woman must

be in a fit condition. The results of a questionnaire are given. Some of the best known gynecologists in the world give their opinion as to whether or not to operate. Some never operate on the fallopian tubes, some operate only on the fimbriated ends, others operate on all portions of the tube. The average percentage of successes after operation is about 10.

Decreased Production of Gonadotropic Substance During Pregnancy—Henderson and Robson show that the pituitary is essential for the maintenance of ovarian function, for ovulation and for the implantation of the fertilized ovum in all species that have been investigated. The relationship of the further course of pregnancy to the pituitary activity, however, varies in different animals. In some species, removal of the pituitary after certain stages of pregnancy does not interfere in any way with the subsequent course of gestation; in others, its continued activity is essential throughout the duration of the pregnancy. In the human subject there is no evidence as to whether the pituitary is essential for the maintenance of pregnancy or not. The present case is of interest in that symptoms and signs of intracranial pressure were present which, in the absence of pregnancy, would have been associated with marked interference with the menstrual function because of a decrease in the pituitary secretion. The more acute symptoms appeared about the time of conception and yet gestation continued until artificially terminated at the sixth month. The case described is of interest chiefly because it has afforded an opportunity of investigating the production of gonadotropic substance under the exceptional circumstances of pituitary hypofunction during gestation and of comparing this production with that occurring during normal pregnancy. The examination of three separate specimens of urine consistently showed a low content of gonadotropic substance. The occurrence of a weakly positive Aschheim Zondek reaction also supports the conclusion that urinary gonadotropic excretion was below normal. The results of the placental examination are in keeping with those obtained on the urine. On the basis of this case it appears possible that the pituitary is not an essential factor in the maintenance of pregnancy, and that in this respect the human subject resembles such animals as the rat, the mouse and the guinea-pig, in which removal of the pituitary during the later stages of gestation does not necessarily lead to its premature termination. On the other hand, the evidence of decreased production of gonadotropic substance, derived from the quantitative estimation of the urine and placenta, does suggest that the pituitary is at least partly responsible for the enormously increased production of gonadotropic substance during pregnancy.

Scurvy as Result of Dietetic Treatment—During the last six years Platt has observed four cases of scurvy. The first case concerned a neurotic woman who had "dieted" herself and the other three cases concerned patients with peptic

ulcer who had received dietetic treatment. As all showed typical manifestations of developed scurvy, there was no reasonable doubt of the diagnosis. Further confirmation was afforded by the dietary history and (in three cases) the response to treatment, which consisted in the administration of vitamin C by mouth and by injection. After giving the histories of the four cases, the author says that the object of this report was to point out the dangers of prolonged treatment with diets lacking in vitamin C and also to call attention to the possibility of scurvy developing on such diets. The correct diagnosis had not been made in any of these cases by the doctor in attendance simply because it had not been considered, scurvy being nowadays such a rare condition.

Asthma—Harley shows that the evolution of the asthmatic state can be divided into three parts. 1 The predisposition of the individual to become hypersensitive, which is commonly inherited but may be acquired. 2 The development of hypersensitivity to one or more foreign substances, the contact with which results in reactions characteristic of the hypersensitive state. 3 The secondary nonspecific factors, which include nearly all possible forms of minor trauma (toxic and psychic, direct and reflex, and dietetic indiscretions). It has been suggested that they act by lowering the "tolerance" of the asthmatic patient to the primary specific exciting causes, so enabling the latter to provoke an attack in even more minute amounts than usually required. One is impressed by the large number of asthmatic persons presenting themselves for treatment in whom the asthma first appeared after or is associated with some infective process, often comparatively mild infections of the respiratory tract. Many of these cases give negative or only very feeble skin reactions to inhalant and ingestant idiotoxins, but bacteriologic examination almost always reveals marked qualitative or quantitative abnormalities. The excellent results of vaccine therapy in these cases support the hypothesis that the relationship between the bacteria and the asthma is one of cause and effect. Bacterial vaccine skin tests in the diagnosis and treatment of bacterial sensitization asthma have been widely used in recent years. The usual method is to prepare vaccines of the bacteria of the sputum and test the patient's skin reactions to them. Those which produce reactions are employed for therapeutic purposes. Unfortunately these vaccine skin tests have proved unsatisfactory, as it has been found that nonasthmatic individuals often give similar reactions to the vaccines and also that the vaccines of the normal intestinal gram-negative bacilli often cause bigger reactions in the skin of the asthmatic than do the infecting organisms from the sputum. Clinically, the two main types of asthma may occur separately or together, with varying predominance of one or the other. In discussing the treatment the author gives his attention to that therapeutic procedure which attacks the underlying cause from the immunologic standpoint. The success of this type of therapy depends on the accurate diagnosis of the type of immunologic mechanism involved in the individual case. He emphasizes that the tendency of the "advanced allergist" to consider all asthmatic patients in terms of skin reactions to nonbacterial substances, and to institute treatment accordingly, produces brilliant cures in certain cases but leads to disappointing results when the primary cause is bacterial. He feels that this is due partly to the use of the intradermal method of skin testing, which frequently produces "false positive" reactions in the absence of the corresponding clinical sensitivities, and to the failure to make a routine bacteriologic examination of all patients in whom the skin reactions are multiple and indistinct.

*Exchanges in Course of Gynecologic and Obstetric Operations in Different Narcoses and Their Practical Value in Treatment M. G. Serdukoff and Koroleva—p 399

Narcosis and Gynecologic and Obstetric Operations—Serdukoff and Koroleva say that the aim of every surgeon is to obtain a normal postoperative period and a prompt cure. It is important also to know the postoperative chemical changes in the patient. For this purpose the blood serves as the most perfect mirror of biologic changes. As a result of their studies on the blood following certain narcotics, they came to the conclusion that the chemistry of the blood influences the narcosis and other complications and plays an important part in the preoperative preparation of the patient. The most important single feature of their observations was the postoperative hyperglycemia, which reaches its maximum on the first or, occasionally, the second day after the operation. In the majority of cases the quantity of blood sugar returns to normal between the sixth and seventh days. The disturbance of alkali reserve is also an important element. In the majority of cases the alkali reserve diminishes in the blood and there is an increase of ketone bodies. Of sixty-six cases the alkali reserve was reduced in fifty-four and to a serious extent in one. The changes in blood nitrogen were studied in sixty-eight cases. Increase in nitrogen was observed in 60 per cent (thirty-eight cases). This was more marked in the cases in which operation was performed for cancer of the uterus. Attention was also directed toward the potassium calcium coefficient during the postoperative period. In the majority of instances the coefficient was lower and reached its minimum about the fifth or sixth postoperative day. During ether narcosis the blood chlorides increased within thirty to sixty minutes of the beginning of ether administration. The authors concluded from these studies that it is important to prepare patients carefully for an operation with these changes in mind. Furthermore, it is well to observe the changes in the blood chemistry and to make corrections for the oscillations in chemical values as far as possible.

*Dysentery in Children and Its Treatment. P. G. Eivine and G. I. Vechslor—p 512

Limits of Diagnostic Errors in Diseases of Children. M. Michalowitz—p 527

Treatment of Dysentery in Children.—Eivine and Vechslor report studies on 195 children observed by them during the years 1934 and 1935. Twenty-six of the children were less than 1 year of age, twenty-seven 2 years, forty-nine 6 years, forty-nine 10 years, and forty-four less than 10 years. One hundred and nineteen were boys and seventy-six were girls. Some of these children with dysentery were submitted to thoroughgoing bacteriologic examinations. Shiga's bacillus was found in the majority of positive cases and the Flexner bacillus in one. In most of the children, however, the bacteriologic observations were negative. Of the 195 children, forty-nine died, which gave a mortality rate of 25 per cent. The most serious prognosis is in nurslings and infants as well as in children having prolonged attacks. Treatment may be divided into three principal forms: specific, symptomatic and dietetic. The specific treatment consists in the use of the bacteriophage and antidyenteric serum. In nurslings and small infants there is often no relationship between the slight local symptoms and the severe toxic general state. Dysentery frequently has the aspect of an alimentary intoxication in nurslings. One of the indexes of gravity in older children is the quantity and quality of the stools. Vomiting in the course of dysentery in older children is always a sign of bad prognosis. In severe dysentery other complications such as infectious encephalitis may be encountered. In treatment, antidyenteric serum is effective.

Prolonged starvation is bad for the children and tends to prolong the course of the disease, predispose toward edema and increase the mortality rate. The dietetic regimen has a better effect in the treatment and should be composed of foods of sufficient caloric content but absolutely fresh, well prepared and well cooked. Treatment by medicines in dysentery in children has no particular importance.

Cancer of Neck of Uterus in Pregnancy. Treatment. M. Fagioli—p 1135

Gonorrhea and the Functions of Motherhood.—Mancini points out the importance of the relation existing between gonorrhea and the functions of motherhood. He believes that pregnancy stimulates gonorrhea by which several pathologic processes, such as granular vaginitis, Bartholin's, condylomas and rheumatism, complicate pregnancy. The most frequent gonorrheal complications in pregnancy are abortion and the localization of gonorrhea in the joints. Gonorrheal cervicitis can be the cause of abortion by premature rupture of the membranes. The evolution of labor in women suffering from gonorrhea and the operations that have to be performed in these groups of patients are the same as those observed and performed in normal women. Fever is not a frequent puerperal complication. When it appears regularly it is the result of propagation of the gonorrheal process to more internal genital organs rather than of the action of other bacteria complicating gonorrhea. The propagation of gonorrhea during the puerperium is grave from the functional point of view. Periovarian-salpingeal localization of gonorrhea is the most typical and grave late complication of the puerperium and it is the most frequent cause of secondary sterility. The weight of babies born to women suffering from genital gonorrhea is the same as that of babies born to normal women. If mothers are suffering from gonorrhea of extra-genital location, however, the weight of their babies is greatly diminished in comparison to that of babies born to normal women. The most frequent and dreadful action of gonorrhea on the babies is the development in the latter of gonorrheal conjunctivitis, a condition that demands immediate therapeutic attention.

*Percutaneous Administration of Insulin. G. F. Capuani—p 224

Still's Disease. Case. A. Veritti—p 229

Percutaneous Administration of Insulin.—Capuani reports a method for administering insulin through the skin. It consists of inunctions with 100 units of insulin in powder dissolved in 1 cc of water and incorporated in 9 Gm of pure wool fat. The mixture is placed in small tin tubes and labeled. To be used for rubbing in the proportion of 0.5 Gm of the salve (which corresponds to 20 units of insulin) for each rubbing. The back of the hand and the anterior aspect of the forearm are the regions at which the salve is gently rubbed in for three minutes. The palm of the hand should not be used, as it does not absorb the salve. The author verified the action of insulin in eighteen normal persons and in eight suffering from diabetes. He found that the clinical results of a dose of insulin given by this method are the same as when the same amount is hypodermically injected. The advantages of insulin through the skin are the simplicity of the administration, which can be done by the patient and the moderate expense of the treatment. It is advisable to use freshly prepared salve. The administration of insulin through the skin will be indicated for treating timid persons and children as well as for workers who have not the time to attend the physician's office. The hypodermic route, however, retains its place and importance for administration of insulin by physicians.

*Differentiation of Blood Serum in Pregnancy and in Cancer U
Borghetti and P. Natale—p 406
Absolute Interferometric Index of Blood Serum in Cancer and Diseases
Other Than Cancer E Tantini—p 413

Differentiation of Blood Serum in Pregnancy and in Cancer—Borghetti and Natale state that the Weltmann serum coagulation reaction enables one to differentiate the blood serum of pregnant women from that of patients suffering from cancer. The electrolytic threshold of normal blood serum to calcium chloride in Weltmann's reaction is 0.47. It is greatly diminished in the blood of patients suffering from cancer (0.23), whereas it is almost normal in pregnancy and puerperium (0.42 and 0.46, respectively). Moreover, there is a widening of the coagulation band, that is, deviation to the right in cancer and a band of coagulation almost normal with slight deviation to the right in pregnancy. According to the authors the test proves that the physicochemical structure of the blood serum is different in pregnancy from that in cancer. The results of the test indicate colloidal lability of the blood serum in pregnancy as well as in cancer, but the behavior of the electrolytic threshold and the different intensity of flocculation seem to indicate that the type of colloidal lability in pregnancy is different from that in cancer, that is a physiologic transient lability and a pathologic permanent lability, respectively.

Absolute Interferometric Index in Cancer—According to Tantini, the absolute interferometric index indicates the total amount of certain substances, especially proteins, in the blood serum. It is the result of a comparison between the figures of the interferometric index of a given blood serum and the distilled water (which is zero). The absolute interferometric index for groups is the average figure resulting from the figures of the individual values in the blood serum of several persons grouped according to their condition, normal or pathologic. The author made determinations of the absolute interferometric index in the blood serum of 126 persons including seventy-nine patients suffering from cancer. He found that the interferometric index is diminished, in comparison to the normal one, in pregnancy, in cancer of the digestive and genital organs and in fibroma of the uterus. The variations of the interferometric index have no diagnostic value. They indicate, however the existence of organic alterations caused by cancer and other tumors, such as cachexia, hydreemia and exaggerated disintegration of the proteins, as well as by certain physiologic conditions such as hydreemia in pregnancy. The absolute interferometric index is greatly diminished in the blood serum of patients suffering from cancer and treated by radium.

Transfusion of Preserved Blood—Sammartino reviews the results of transfusion with preserved blood and concludes that blood preserved in vials at a temperature of 1 or 2 C has not the same biologic properties as fresh blood. In making a transfusion it is advisable to use the blood most recently preserved, because the effects of transfusion largely depend on the relative freshness of the blood. The use of preserved blood is indicated in acute anemia due to grave hemorrhages for the poor who are unable to pay professional donors in preoperative and postoperative periods acute conditions trauma cancer and toxic conditions and also in preparing injections or transfusions with the plasma or the erythrocytes separately. The use of fresh blood is indicated in anemia leukemia and

organic debility of long duration. Transfusion of preserved blood gives satisfactory clinical and hematologic results without complications. All hospitals and posts for surgical and traumatologic work should have an abundant supply of preserved blood in refrigeration as one of the indispensable surgical resources. Preserved blood will be one of the most necessary therapeutic resources in future wars, to be used in cases of hemorrhage, grave trauma and toxic conditions. Preserved blood from cadavers is indicated when it cannot be obtained from living persons in cases of grave anemia due to hemorrhages, for the poor and for transfusion during war.

Pleural Irritation in Acute Rheumatic Fever—The sign described by González Podesta and Arias for the etiologic diagnosis of acute rheumatic fever consists in the presence of fine or average pleural rales at the base or at the fissures of the lung and rarely at the apex. The rales are the same during expiration and inspiration, independent of other percussion and auscultation phenomena, not modified by coughing, unrelated to the intensity of respiration and indicate irritation of the pleural serosa. In rare cases the focal place of origin of the rale is painful on external pressure or during deep inspiration. Pleural rales appear in 60 per cent of the cases of acute rheumatic fever before or simultaneously with the articular symptoms and, in all cases, before development of endocarditis. The sign is lacking in all cases of acute and subacute polyarthritis of nonrheumatic etiology and is of value in the differential etiologic diagnosis of rheumatic and nonrheumatic polyarthritis.

Prognostic Sign in Typhoid and Pneumonia—Chaminaud gives the paternity of the sign he describes to Brunati. The sign consists in the appearance of corneal opacities, which in the course of typhoid or pneumonia, indicate that death will take place within a few hours. The appearance of corneal opacities in several other diseases has no prognostic value especially in measles and smallpox, in which it is a common occurrence. The sign was verified in two cases of typhoid by Brunati and in a case of pneumonia by Chaminaud.

Transfusion of Conserved Defibrinated Blood—Until recently, Filatov says, the transfusion of defibrinated blood was considered inadmissible. However, defibrinated blood is not toxic, provided certain precautions are observed in the preparation and storage. The defibrination should be done in a paraffinized container. Following withdrawal of the blood it is stirred for from five to six minutes with a twisted glass rod during which time the rod becomes gradually covered with a thick layer of fibrin. With this type of defibrination, the blood loses approximately 10 per cent of its weight. Following defibrination the blood is stored in sterile bottles in the icebox at from 6 to 8 C. The author used the defibrinated blood in fifty-three cases. The time of conservation varied between one hour and fifteen days. In the majority of cases,

blood was used that had been conserved for two or three days. It was found it is inadvisable to use blood that has been kept more than twelve days, because after this term a partial hemolysis takes place. The quantities of defibrinated blood that were used for transfusion varied between 100 and 300 cc. In ten cases of profuse hemorrhage the defibrinated blood was transfused for the purpose of hemostasis and always had the desired effect. The defibrinated blood was used also in sixteen cases of hemorrhage and shock. As regards its substitutional qualities, defibrinated blood is only slightly inferior to fresh citrated blood. The remaining twenty-seven cases in which the citrated blood was used concerned infectious processes, burns and so on. The author emphasizes that, on the whole, the transfusion of defibrinated blood has the same effect as the transfusion of citrated blood. Serious complications or a fatality were never observed. Reactions in the form of a slight increase in temperature, general discomfort and occasionally chills occurred in ten (18 per cent) of the author's cases. He concludes that defibrinated blood is entirely suitable for transfusion.

Peroneal Phenomenon in Postdiphtheric Abolition of Patellar Reflexes.—In two cases of malignant pharyngeal diphtheria with subsequent development of paralytic symptoms, Zimmermann observed, before the abolition of the patellar tendon reflexes and practically as a precursor of this symptom, a hyperirritability of the peroneal nerves. After describing the history of these cases, she points out that in both cases comparatively large doses of strychnine (4 mg daily) were administered in addition to the diphtheria serum. However, she does not think that the increased irritability of the peroneal nerves is caused by these large doses of strychnine, for she administered the same doses in other cases of diphtheria and of scarlet fever and, although she watched for the peroneal phenomenon she did not detect it. She suggests that perhaps an increased sensitivity to toxin or other causes might play a part. Whether it was an accident that the peroneal phenomenon, which otherwise is known only in spasmodophilia, was present in those cases in which the patellar reflexes were later abolished, or whether this is an early symptom of postdiphtheric pseudotabes will require further investigations on a larger material.

Pupillary Phenomenon During Drop Anesthesia.—Heinrich points out that, if during drop anesthesia particularly with ether the pupillary reflexes are carefully watched, it can be observed that, beginning with a certain degree of narcosis, the pupils cease to respond to light. The anesthetist at the author's hospital detected that there is a degree of anesthesia during which there exists a reflex pupillary paralysis, if only one eye is opened whereas the opening of both lids still results in bilateral light reflex. The pupils fail to react to bilateral light stimulus only after the anesthesia has been made deeper. The author says that the sphere in which the pupillary reaction is still present to bilateral light stimulus, while a unilateral stimulus reveals a paralysis of the reflex is not wide. The phenomenon appears approximately at the beginning of the stage of tolerance and is found in the passage from slight to deep as well as from deep to slight anesthesia. The author maintains that this depth of anesthesia is adequate for all laparotomies and that it has to be deepened only in exceptional cases. It reduces the consumption of ether and also the danger of postoperative pneumonia. The practical utilization of the phenomenon is slightly reduced by the fact that the preliminary injection of morphine atropine prevents its appearance in some persons. However it often develops in spite of these injections.

- Question of Transmission of Congenital Syphilis to Next Generation. F Wendel—p 976

Diabetes Mellitus During Childhood.—According to Priesel, children with diabetes mellitus who always receive the proper amount of insulin and a diet that is calorically adequate to the age of the child usually develop normally. However, if a diabetic child fails to receive for long periods adequate amounts of insulin in order to utilize the quantity of food that corresponds to the age of the child, a condition may develop which is designated "insular infantilism." The linear growth ceases and the puberal development fails to take place. The author cites cases and thinks they will now be more frequent because, before the insulin era, the diabetic children as a rule died within two years after the manifestation of the diabetes. In one of the cases of insular infantilism, he observed an especially severe form of alveolar pyorrhea which had resulted in loosening of all the teeth and the falling out of some. Roentgenoscopy revealed atrophy of the alveolar process. The examination of sixty-two diabetic children revealed that eighteen had signs of alveolar pyorrhea. The author directs attention to local lipomatosis and local lipodystrophy, which occasionally develop at the sites of insulin injection. He thinks that a certain predisposition plays a part in these conditions, since they do not develop in all cases. He states that recently he observed a considerable number of diabetic children, girls exclusively, who immediately after the completion of puberal development developed generalized adiposity. It is extremely difficult to influence this form of obesity for it develops even in those girls who do not exceed their prescribed diet. The author considers it possible that a fat retaining action of insulin might play a part in the development of this type of obesity.

Prophylactic Ultraviolet Irradiation in Tuberculosis.—Schall points out that ray therapy is an irritation therapy and for this reason is advisable only in some forms of tuberculosis, such as the productive, nodose cirrhotic processes. The pulmonary tuberculosis of later childhood which is usually characterized by progressiveness and a tendency to exudative processes, is unsuitable for ray therapy. Not only does the artificial irradiation involve certain dangers, but even exposure to the natural sunlight, particularly during spring seems to exert an unfavorable influence. The author suggests that this factor may be involved in the exacerbations of the tuberculous processes which frequently occur in the spring. He points out that during the winter months, from November to March, the so called Dorno rays are practically absent in the latitudes of Germany and that their reappearance in the spring has an irritating effect. He emphasizes that in tuberculous children there is not only a seasonal fluctuation in the sensitivity to the ultraviolet irradiation but also a fluctuation that is determined by the disease process. He thinks that in order to overcome the seasonal fluctuations, particularly the irritating effect of the spring sun on some tuberculous processes the patients should be subjected to artificial ultraviolet irradiation during the winter time. However, in attempts to do this, exacerbations were frequently observed. The author thinks that these failures were the result of wrong dosage and emphasizes that, before the ultraviolet irradiations are begun, the sensitivity of the patient must be tested on small areas that are especially sensitive to light (chest, back or abdomen). In order to prepare for the prophylactic irradiation during the winter time, this test should be made in November. After the erythema dose has been determined the irradiations are begun with small doses. The author advises that at first only parts of the body be irradiated. Gradually it becomes possible to prolong the exposure time and at the return of spring the effect of the natural ultraviolet irradiation does not have to be feared.

Work Therapy in Open Tuberculosis—Lindig discusses the importance of the after-care in two respects as completion of the clinical treatment and as a new organization of the lives of patients with incurable open tuberculosis (permanent institutionalization). He considers the promotion of work therapy the key for a successful after-care. He shows that in order to insure the success of the work therapy it should begin during the period of active treatment. He shows how others and he himself have tried to solve this problem, citing the work sanatoriums and the work colonies as well as the method which gives the patients an opportunity for advanced schooling. He stresses that dilettantism must be avoided in work therapy, since this would result in its ultimate failure. In order to be successful, real value and accomplishment must be stressed in the work.

Vitamin C and Pulmonary Tuberculosis—In deciding to try vitamin C in the treatment of tuberculous patients, Hasselbach considered the following facts: 1. There frequently exists a latent vitamin C deficiency which among other conditions, develops also in infectious diseases, particularly the chronic ones. Important processes of defense against infection, of immunization and the power of resistance are connected with the consumption of vitamin C. 2. The various forms of hemorrhagic diathesis are often curable by the administration of vitamin C. From these considerations, the following problems arise with regard to tuberculosis: 1. Is there a vitamin deficiency in tuberculosis? 2. What are the relations between tuberculosis and hemorrhagic diathesis? Studies revealed that there is a vitamin C deficiency in patients with pulmonary tuberculosis which can be compensated for by exact dosage. It was found that, on the whole, the vitamin C deficiency was the greater, the more severe was the tuberculous process. In the treatment with vitamin C it must be the first aim to compensate for this deficiency. For instance if there is a deficiency of from 2,000 to 2,500 mg of ascorbic acid this quantity should be administered in about seven days (about 300 mg daily). After that the dosage can be gradually reduced until a daily dosage of from 100 to 150 mg has been reached, which is equivalent to the average daily requirement of the tuberculous patient. The author found the intravenous administration of vitamin C to be the most advantageous in that it caused less undesirable secondary effects than the oral administration of tablets. In the course of a year the author resorted to treatment with vitamin C in about seventy tuberculous patients, the main indication for its use being the determined vitamin C deficit. He considers vitamin C advisable also in certain forms of pulmonary hemorrhages and in tuberculous patients who require a tonic and thinks that the combined use of gold, tuberculin and vitamin C is likewise well founded.

Amebic Infection of Urinary Passages—Bachrach reports the clinical history of a man aged 46 who contracted amebic dysentery in China. There he was treated successfully with emetine. The following year he developed colonic ulcers which temporarily improved after treatment but then relapsed.

Renewed treatment, however, was followed by permanent cure. Several years later a hematuria developed, which was first thought to be caused by papilloma of the bladder until amebas were found in the urine. However later papillomatous villi were likewise detected and cystoscopy revealed villous papilloma. Finally, it was discovered that the patient had a combination of several disorders, namely, papillomatosis of the bladder, chronic gonorrhea and amebic infection of the urinary passages. He was given treatment for all these disorders but finally died. In discussing the case the author points out that the clinical manifestations of amebic infections in the urinary passages are not characteristic. The chief symptom is hematuria, which is frequently accompanied by dysuria.

Effect of Renal Decapsulation—Fuchs points out that in acute, subacute or chronic nephritis or in nephrosis the function and the disease process of the kidney is frequently improved. The effect of the intervention is quite understandable in cases in which the intracapsular pressure was increased and in which, following decapsulation, a formerly cyanotic kidney assumes a normal color. However, the decapsulation is effective also if the intracapsular pressure was not noticeably increased. The decapsulation is an intervention on the connective tissue apparatus of the kidney, and in order to understand the mode of action of decapsulation the morphologic conditions must be taken into consideration. The author gained the impression that the surgical decapsulation of a kidney may be considered as a drainage of the intrarenal connective tissue clefts toward the bed of the kidney. In the course of decapsulations, he watched whether a discharge would occur from the drainage system. He actually observed frequently a copious discharge of clear fluid from the lumbotomy wound. He noted, however, that the transudation became noticeable only when the bed of the kidney was drained. He mentions several other interesting observations, such as that exposure of the kidney without decapsulation is never followed by the appearance of transudate. He also cites and discusses case reports. In one of the described cases the decapsulation influenced the elimination of the kidney with the exactness of an experiment.

- *Abscess of the Lungs Based on Material Collected from the Hospital in Lwów A Stadnicki—p 693
- Influence of Normal Horse Serum and Postserum Diseases During Course of Typhoid B Jochweds and A Szeinberg—p 700
- *Perinephric Abscess H Drucker—p 702
- Therapy of Sciatica with Pancreas Extract Without Insulin (Angioxyle) Z Godlowski—p 706

Abscess of the Lungs—Stadnicki states that the etiology of abscess of the lungs is not clear and that a correct diagnosis is often made with the aid of roentgenology. He says that the choice of therapy is difficult. According to various statistics, the abscess heals by itself in from 15 to 40 per cent of the cases, generally in young persons but the author claims that this percentage is far too high. Anatomopathologists look on spontaneous healing of the abscess skeptically and say that it occurs only in small abscesses. The author's personal observation points in a different direction: 15 per cent of healing in male patients (three healed out of 200) and 16 per cent in female patients (one healed out of sixty-five). The operation for abscess of the lungs in persons less than 40 years of age offers a better chance for recovery, but beyond the age of 40 the results are poor and depend on the length of time the abscess has existed. This influences the decision as to the method of treatment. Conservative treatment is given for from six to eight weeks and, if that fails, operation becomes unavoidable although the outcome is rather doubtful. Treatment of abscess of the lungs has the advantages of (1) emptying the pus, (2) aiding expectoration and (3) raising the resistance, which is the most important point.

Perinephric Abscess—Drucker says that at the general hospital in the city of Lwów all patients suspected of having perinephric abscess undergo aspiration with trocar and needle for examination before operation. The puncture is done under local anesthesia just under the twelfth rib in the sitting position at the most painful and swollen site. No complication

has been encountered. Statistics show that perinephric abscess affects male patients oftener than female because males are more exposed to traumatic injury or infection. Perinephric abscess generally occurs between the ages of 20 and 40 and is rare in older persons. The incubation period varies from a few days to a year, it often appears in the acute stage but may develop slowly. The treatment of perinephric abscess may be conservative by roentgen rays, and aspiration with a trocar, or surgical. An incision is made from 8 to 10 cm long near the edge of the sacrospinalis muscle. The prognosis in general is good but depends a great deal on the cause of the abscess and on correct early diagnosis. Lethal cases are rare, death occurring through delayed diagnosis and negligence or when the abscess causes general infection and the resistance is not strong enough to overcome the infection.

Treatment of Syphilis with Syphilitic Antigens—Veviorovskiy reports animal experiments and clinical results with a syphilitic antigen prepared from organs infected with syphilis, from syphilitic fetuses or from spirochete cultures. Because of the importance of the skin as a defense organ in infectious diseases, the author administered his vaccine by rubbing it into the skin or by intracutaneous injections. Experimentally produced chancres in rabbits disappeared in a shorter time under this treatment than when treated with the usual methods. The grafting of the organs and lymph nodes of these rabbits into healthy rabbits failed to produce chancres or general manifestations of syphilis. Application of vaccine therapy in cases of dementia paralytica and syphilis of the brain resulted in an improvement in the state of the cerebrospinal fluid, the general state and the psychic state. Patients gained weight, their headaches disappeared, the speech improved and the behavior became rational. In individual cases there were noted disappearance of Romberg's sign, return of the pupillary reactions, improvement in the knee jerks, disappearance of ideas of persecution and of hallucinations, and improvement in the muscular power of extremities and in the gait. In view of the fact that the development of late syphilitic lesions of the central nervous system cannot be prevented in all cases by the administration of mercury or bismuth preparations or arsphenamine, the author considers his method to be the logical continuation of the radical treatment of syphilis. This does not exclude the treatment of early syphilis with the modern methods.

Anemia in Myxedema Patients—Of twenty-eight patients examined and treated by Holbøll during the last five years all were women and none had congenital myxedema. Two had suffered from exophthalmic goiter previously. The ages of the patients varied from 35 to 64 years. The diagnosis of myxedema was confirmed not only by means of clinical observations but through determinations of the metabolism. The majority of the women had been suffering from their disease for five or six years. A number of these patients had sought medical advice and had been admitted to a hospital. Most frequently

they had been treated for neurasthenia, cardiac disorders and what is of especial interest here, anemia. Six of the patients had been treated with stomach or liver preparations, and no less than twenty had been given iron. In thirteen the hemoglobin rate was below 70, and in seven between 70 and 79 per cent. In the majority the color index was normal or slightly subnormal, the lowest being 0.78. Besides, in the patients with pernicious anemia, the color index was increased in four cases. The conclusion is that in cases of anemia of unknown etiology, when the usual remedies fail, the diagnosis of myxedema should always be considered. Contrary to what is usually stated in manuals and textbooks, eosinophilia was never found. In the twenty-eight patients there was never more than 3 per cent of eosinophil leukocytes. There were no cases of abnormal leukocytes, especially the myeloblast-like cells also referred to in textbooks. In most cases, however, there was rather considerable lymphocytosis. The highest rate was 62 per cent of lymphocytes, while values of about 50 per cent were frequent. The number of monocytes was, as a rule, about 4 per cent, the highest value being 6. These results apply to the untreated myxedema patients. During the thyroid therapy the percentage of lymphocytes decreased a little in most cases, but completely normal lymphocyte figures were not always attained in the course of the first few months. In the majority of untreated cases the sedimentation reaction was increased. The increase of the sedimentation was usually higher than what could be ascribed to the anemia alone. Thyroidin therapy had a favorable influence on the anemic condition in all cases, both the hyperchromatic and the hypochromatic ones. The most rapid improvement of the red blood picture was obtained through combination of thyroidin with iron. A few attempts at reproducing the anemic condition indicate that the color index in the individual case of myxedema is still of the same character.

Polyarthritus Urethritica—Moltke concerns himself with five cases of acute polyarthritus with urethritis, superficially resembling the gonorrheal type but differing from it clinically, bacteriologically and immunologically in so unambiguous a manner that they must be regarded as a separate disease, one that apparently has had too little attention paid to it. All the patients were men. Urethritis of such slight degrees as these might easily pass unnoticed in women. On the other hand, the author has no recollection of acute polyarthritus in women with a clinical picture quite like these. Two of the five patients had previously had a gonorrheal infection. The clinical character of even these polyarthritides is far removed from the gonorrheal type. Gonococci were not found in the urethral secretion of any of these patients and the gonococcus complement fixation test was negative for all. Clinically, these joint disturbances present themselves in a manner which merely superficially has some resemblance to gonorrheal arthritis. The disorder has been polyarticular, on the whole of a brief and benign character. In several of the cases there was a distinct tendency to exudation in the affected joints, especially the knee but it disappeared spontaneously or after brief treatment. There was no approach to joint symmetry in the diffusion of the disease, and mostly the large joints were attacked. Thus the possibility of an atypical gonorrheal arthritis may be discarded as an explanation of these cases. Judging from all the facts, they must have been cases of some special disease, the principal characteristics of which are the febrile polyarthritus and the nongonorrheal urethritis. The author compares his cases with those described from Germany and by Kristjansens in Denmark. The only difference is that his cases have lacked the conjunctivitis which is so prominent in the records of the others. The similarities are so considerable that they outweigh the absence of this one symptom. That there is close connection between the urethritis and polyarthritus seems to appear from the fact that these two manifestations occur simultaneously in most of the patients. That it may be both an anterior and a posterior urethritis is shown by the fact that in two patients it has been possible to demonstrate the presence of "threads" in the urine. For the present the author is unable to decide whether the joint symptoms and the urethritis are collateral phenomena whether they are simultaneous manifestations of a common etiologic factor, or whether the urethritis is primary in relation to the arthritis (as in the gonorrheal type).

TUBERCULOSIS OF THE HIP IN CHILDREN

JOSEPH S BARR, M.D.
BOSTON

The data and conclusions of this paper are derived from the study of the records and roentgen examinations of 106 consecutive cases admitted to the New England Peabody Home for Crippled Children with a diagnosis of tuberculosis of the hip

DIAGNOSIS

In 15 per cent it was later found that an incorrect admission diagnosis had been made. It is most important to exclude such cases, as they have in general a much more favorable prognosis than tuberculosis of the hip.

The ninety remaining cases were accepted as tuberculosis for one or more of the following reasons:

1 Positive guinea-pig test from material removed by aspiration or operation. Twenty nine cases, or 32 per cent, were proved by this method.

2 Positive evidence of tuberculosis on pathologic examination of material removed at operation. In seventeen of the twenty-two cases in which pathologic material was examined, the histologic diagnosis was tuberculosis. The remaining five were reported as chronic inflammation not definitely characteristic of tuberculosis.

3 Positive intradermal (Mantoux) test with a clinical course of progressive destruction of the hip and the other characteristic features of acid-fast infection in the hip joint. In the sixty six cases in which the Mantoux intradermal tuberculin test was done it was positive in dilutions of 1:1,000 or higher in every instance. The other cases had been discharged before this test came into vogue. Our experience with the use of graded tuberculin leads us to believe that every case of active tuberculosis will show a skin reaction in dilutions of 1:1,000 or higher.

The average age at onset was 4 years. In 60 per cent of the cases the onset was prior to the age of 6.

TREATMENT

In the forty year period that has elapsed since the first case in this series was admitted with this diagnosis, the treatment has varied with the prevailing medical fashion. Until 1920 the treatment was expectant. The child was ambulatory except when unable to be up. The Bradford and Taylor hip splints were commonly used. Abscesses were often evacuated operatively, the cavity was wiped out with gauze and sinuses were dressed with little attention to asepsis. Plaster spicas were used for long periods of immobilization.

From the New England Peabody Home for Crippled Children, Newton Centre, Mass.
Read before the Section on Orthopedic Surgery at the Eighty-Seventh Annual Session of the American Medical Association, Kansas City, Mo., May 15, 1936.

During the ten years 1920-1930 the heliotherapeutic regimen of Rollier held sway. In every acute case the patient was placed on a Bradford frame and the hip immobilized by adhesive extension. No surgery was performed. The abscesses were allowed to rupture spontaneously. The patient's skin was exposed to the sun's rays, often supplemented by the quartz or carbon arc lamps. The progress of the disease was checked every six weeks by x-ray and physical examinations. The patient was allowed up only after all signs and symptoms of active disease had subsided. A number of cases were deliberately "overtreated," absolute bed care being maintained for as long as two years after the process had become quiescent.

In 1930, cautiously and belatedly following our New York brothers, we began to supplement the Rollier treatment with arthrodesis of the hip.

We have tried both conservative and operative methods without prejudice in a hospital with every facility for adequate prolonged care of the patient. An attempt has been made to ascertain by physical and x-ray examination the present condition in every case.

MORTALITY

There are two main causes of death. The first is tuberculous meningitis, which accounted for 47 per cent of the mortality. It occurs usually within the first two years after the onset. The blood stream infection that causes the hip disease may also account for the meningitis. It is quite probable that the mortality due to meningitis is about the same no matter what type of therapy is instituted. Complete bed rest might be of value, but there is no definite evidence that it has any effect in lowering the mortality rate of meningitis. Arthrodesis of the hip might possibly increase the mortality from this cause, it could hardly lower its incidence.

Deep seated secondary pyogenic infection of tuberculous sinuses with resultant amyloid disease and cachexia is the other great cause of death in tuberculosis of the hip. It accounted for six cases, or 40 per cent, of the deaths in this series. This deplorable complication, which is so commonly fatal, is almost if not entirely preventable. If no other point is made in this paper it will be worth while if I can draw attention to these facts.

(a) Tuberculous soft tissue abscesses develop from tuberculous hips in a very high percentage of cases (60 per cent in this series) at some stage in the evolution of the disease, no matter what treatment is used.

(b) These abscesses are occasionally absorbed without breaking through the skin but usually rupture through the skin.

(c) If a tuberculous sinus does not become secondarily infected it will always heal spontaneously.

When a cold abscess becomes superficial, the skin over it is cleansed carefully with soap and water and alcohol and a sterile dressing applied. We usually aspirate the abscess to obtain material for diagnostic purposes. Otherwise we allow it to rupture spontaneously. The dressings are changed as often as necessary, twice daily if the drainage is copious. The skin is cleansed with alcohol and is protected from maceration with boric strips. We use no irrigating solutions, tubes or wicks. Careful dry sterile dressing is all that is necessary. Since this regimen was instituted at the New England Peabody Home for Crippled Children, no sinus has failed to heal spontaneously, usually within a few months after rupture. The deaths from secondary infection in this series occurred in cases treated before this regimen was used or in cases in which secondary infection had already occurred when they were admitted.

The treatment of sinuses that are already secondarily infected is a problem not yet solved. We believe that judicious surgery to insure adequate dependent drainage is indicated in most instances. Amyloid disease already present will regress if the deep seated infection is controlled.

BIOPSY, JOINT EXPLORATION AND ASPIRATION

Suspected cases of tuberculosis of the hip often present great difficulty in early diagnosis. Clinical and x-ray examination may present no absolutely positive diagnostic points. I believe that aspiration may be justified in those circumstances in an attempt to obtain

material for examination. Our experience with biopsy and joint exploration in early acute cases had led me to believe that they should not be done. Table 5 presents the data on which this statement is based.

COURSE OF THE DISEASE

Tuberculosis of the hip, like tuberculosis elsewhere in the body, runs a most variable course. The evaluation of the effect of any given therapeutic measure is difficult, as the expected course of the disease in any given case cannot be certainly predicted. During the acute

stage there is marked decalcification and haziness of bony detail of the ilium and femur. Its presence seems to indicate active disease. In addition to decalcification and possible increase in bone destruction, as shown by x-ray examination, the presence of involuntary muscle spasm on attempted motion of the hip and abscesses or

sinuses are reliable indexes of an active process. The amount of actual bone destruction that occurs is extraordinarily variable. In some cases there is little or no bone destruction and the joint space is narrowed, allowing bony contact between the femur and the acetabulum but with the normal bone contour essentially unchanged. In other cases the head and most of the neck of the femur together with a large portion of the ilium may be completely destroyed. In over half of the cases abscesses develop. Eventually, however, every case of tuberculosis of the hip, uncomplicated by secondary infection, passes from the acute into a chronic or arrested state. Muscle spasm disappears, sinuses are healed and there is no evidence of abscess formation. X-ray examination shows at least fairly normal bone density and no further spread of the destructive process. In some of the cases apparent bone cavities seem to fill up. The blood picture shows a return to normal of the monocyte/lymphocyte ratio.

In other words, an inevitable histologic sequence to a pathologic process has taken place, the tuberculous process has become walled off by a zone of local defense. A barrier of fibrous tissue prevents the absorption of toxic products. The spread of the destructive process is "arrested." It has not yet been demonstrated that a tuberculous hip is ever "cured," i.e., that all the bacilli have been killed. Half of our cases became quiescent within two years after admission. All the cases were quiescent after four years of treatment.

HELIO THERAPY

For over twenty years heliotherapy in the treatment of bone and joint tuberculosis has been used at the New England Peabody Home. The term heliotherapy is used in Rollier's sense of sunshine, bed rest, fresh air and the like.

The effect of the sun's rays on bone and joint tuberculosis has been stated by author after author to be extremely beneficial, even specific. Our¹ results do not verify these conclusions. We find that the blood picture, the roentgenograms and the clinical appearance of cases that have been treated intensively by sunshine either natural or artificial, are no better than those of cases treated in the open ward with no direct solar irradiation.

We believe that complete rest, local and general, with a good general regimen such as is used in pulmonary tuberculosis does influence favorably the natural course of the disease. The natural course of the disease in an individual case may be mild or it may be extremely severe, but it is probably not appreciably influenced by intensive solar irradiation. A moderate amount of sunshine is of course good for almost any one, whether suffering from tuberculosis of the hip or not.

FUSION

Attempted arthrodesis in the early active stages of the disease is advocated by certain surgeons. Our follow-up study and comparison of our results with other pub-

the disease would take me far beyond the limits of this paper. The more valid objections to fusion in the presence of active disease are that

- 1 The mortality rate both operative and remote is much higher than in quiescent cases
- 2 There is probably no more than 50 per cent² successful fusion, no matter what method is used

Fig 2—Technic of removal of the grafts.

3 Even if fusion is successful, the focus can be eradicated only by the natural process of repair through local and general resistance to the disease. The "curative" effect of fusion is in

TABLE 5—The Effect of Arthrotomy on the Mortality and on Sinus Formation

fact simply the natural course of the disease toward an arrested state. That will occur inevitably, whether fusion is attempted or heliotherapy is instituted or any of the other purported cures are used.

Our attempts to restore "arrested" cases to normal activity without surgery have been most disappointing. Reactivation of the process as shown by pain, muscle spasm, abscess formation, increasing deformity, and the like occurred frequently even after four or five years of complete bed rest. We believe that a fused hip

Fig. 1—Diagrammatic illustration of the operative exposure

lished series leads us to believe that arthrodesis should not be attempted until the disease process is quiescent, as shown by physical and x-ray examination.

To discuss all the arguments for and against attempted arthrodesis of the hip in the active stage of

¹ Barr J. S. Heliotherapy in the Treatment of Surgical Tuberculosis. New England J Med 208:131-134 (Jan 19) 1933. Hoeffel G. and Jones D. Heliotherapy and the Peripheral Blood. Am J Dis Child 40:484-492 (Sept) 1930.

² Hallock, Halford and Toumey J. W. Hip Joint Tuberculosis Treated by Fusion Operation. J A W A 103:1836-1840 (Dec 15) 1934.

has a much better chance to remain arrested than one which has a little motion present. Rarely a conservatively treated patient will retain useful hip motion and the disease remain quiescent when full activity is allowed, but in most instances the amount of motion that is retained is useless and probably dangerous.

The treatment of bilateral tuberculosis of the hip is difficult. A satisfactory result was obtained in one case by arthrodesing one hip and doing a Jones pseudarthrosis in the other. A range of motion was thus obtained which permitted sitting, standing and walking.

OPERATIVE TECHNIC

Many methods of fusing the hip joint have been described. The reader is referred to Ghormley's³ excellent article for a summary of those chiefly in vogue.

Fig. 3—Grafts in position. In actual cases the grafts cover the neck of the femur farther anteriorly than is shown in the illustration.

Intra-articular arthrodesis, requiring dislocation of the head of the femur, excision of the articular cartilage and replacement of the denuded surfaces in contact, is mentioned only to condemn it. The mortality is high and successful fusion is obtained in less than half the cases. The massive graft, whether the technic is that of Hibbs, Albee, Chandler, Eikenbary or Ghormley, is technically difficult in children. There is considerable cartilage about the epiphysis of the great trochanter which may prevent bony apposition at this point. The attached abductor muscles may tend to displace the graft. The position of the leg must not be altered after the graft is placed because of the danger of losing bony contact. Exact maintenance of the position during closure of the wound and appli-

cation of a plaster spica is not easy. For these and other reasons it was decided to use multiple flexible grafts from the ilium. At first the technic of Wilson⁴ was used, bending the grafts over in "crown roast" fashion and leaving them attached just above the acetabulum. They tend to break as they are bent, thus leaving a vulnerable spot just above the joint line. With a growing realization that cancellous bone is the best of osteogenic material, we began cutting free grafts from the outer table of the ilium and placing them across the joint line.

We use tribrom-ethanol anesthesia (80 mg.) supplemented with ether. The hip joint is exposed through the Smith-Petersen incision. The capsule is incised longitudinally and dissected off the acetabulum and neck of the femur. The visible cartilage on the rim of the acetabulum and the head of the femur is removed, but no attempt is made to remove all the diseased tissue. With a sharp osteotome a cortical flap of bone is raised posteriorly, laterally and anteriorly from the neck of the femur and greater trochanter. These flaps are levered out carefully, being left attached inferiorly to the shaft of the femur. Three or four grafts are then removed from the wing of the ilium, each one from 3 to 5 inches long and from one-half to 1 inch wide and the thickness of the outer table of the ilium. The grafts are slid downward so that they surround the neck of the femur, the lower end of each one being firmly wedged beneath the raised femoral flaps. The upper end of each graft is in contact with the bare cancellous inner table of the ilium. A small "trap door" raised from the ilium just above the acetabulum is laid across the grafts. The anterior-superior spine is not removed, as there is sufficient bone available without using it. We feel that the pelvic contour is unnecessarily mutilated and that an essential landmark for measurement of the length of the leg is lost when the iliac crest is cut off.

The wound is closed carefully, and after application of a firm ace bandage spica over the sterile dressings the child is placed on a slightly hyperextended Bradford frame with the leg immobilized by from 5 to 8 pounds weight on a canvas stocking extension. This method of immediate postoperative treatment has several advantages. The elastic bandage prevents excessive bleeding and hematoma formation. In many instances there is practically no staining of the dressings. The child is not subjected to the additional shock of application of a wet cast at the end of a major operation.

Without undue haste the operative procedure can be completed and the child returned to bed in less than an hour.

The skin sutures are removed on the tenth postoperative day. A plaster spica is then applied from the ribs to the toes on the affected side and to the opposite knee. This is done without anesthesia. Minor changes in position of the femur may be made without pain if it is done slowly, thus immobilizing the hip in exactly the desired position.

The best position for the fused hip was found to be about 20 to 25 degrees of permanent flexion, from 0 to 15 degrees of abduction, and from 0 to 5 degrees of external rotation. It has been found necessary, in order to obtain that ultimate position, to place the leg

³ Ghormley, R. K. Use of the Anterior Superior Spine and Crest of Ilium in Surgery of the Hip Joint. *J. Bone & Joint Surg.* 13: 784-798 (Oct.) 1931.

⁴ Wilson, J. C. Operative Fixation of Tuberculous Hips in Children. *J. Bone & Joint Surg.* 15: 22-47 (Jan.) 1933.

in full extension with from 15 to 20 degrees of abduction, otherwise, flexion and adduction deformity was prone to occur, requiring later osteotomy for its correction. At the end of four months the patient is allowed to bear weight on the affected hip, using crutches and a single spica extending to the ankle. This apparatus is continued until solid fusion is demonstrated by x-ray examination. Prolonged physical therapy to develop good musculature and proper gait was necessary in most instances after the cast had been discarded.

Bony fusion of a hip once obtained changes the case from one of joint tuberculosis to tuberculosis of a long bone. The focus is not eradicated by the fusion and it is still necessary to rely on the natural body defense mechanism to produce complete arrest of the disease.

In most cases the juxta-articular fusion produced by operation is followed by eventual intra-articular fusion, but in certain instances the tuberculous process remains active and the destructive process continues to spread after bony fusion has been obtained. Such cases are

detected chiefly by x-ray comparison. It is important to follow all cases for a long period (at least five years) after fusion has been obtained. A false sense of security may be associated with fusion. There can be no muscle spasm or increasing deformity, and there is actually little pain present even when the disease is spreading in a fused hip. The danger signals have been removed but the danger remains.

OPERATIVE RESULTS

In twenty-three consecutive cases operation by this technic has been done. In two the end results are not available because they are too recent. There were no deaths and no operative complications (shock, sepsis and the like). Eighteen, or 86 per cent, of the patients have obtained solid fusion both clinically and by x-ray examination.

In one of the three failures operation has been done a second time with a second failure of fusion. Each failure has been checked carefully for the various possible causes. I believe that destruction of the grafts by extension of the tuberculous process was the cause in each instance. Areas of active disease were encountered in each of these cases at the time of operation.

SUMMARY AND CONCLUSIONS

Ninety cases of tuberculosis of the hip have been admitted to the New England Peabody Home for Crippled Children in the past forty years. The present status of all but sixteen of the cases is known.

Tuberculosis of the hip is often misdiagnosed (15 per cent of this series).

The chief causes of death are tuberculous meningitis and secondary infection of draining sinuses. For the first of these causes no therapy is available. The second one can be reduced to the vanishing point by scrupulous sterile dressing of sinuses and by refraining from any surgical intervention during the active stages of the disease.

Tuberculosis of the hip runs an extraordinarily variable course. Heliotherapy seems to have no specific curative effect on the disease. The word "cured" should be dropped for the more conservative "arrested." Fusion of the hip was successful in 86 per cent of a series of twenty-three consecutive cases. Failure of fusion was due apparently to extension of the disease to the grafts. In a few instances even after successful fusion in apparently arrested cases there was evidence of active disease present when the follow-up study was made.

Arrest of the disease with a useful range of motion occurs too rarely to make it an expected result in conservatively treated cases. Fusion is not a "cure" but offers the best chance for an arrested disease process to remain quiescent and give a stable weight bearing limb. We advise complete bed rest and interdict surgery during the acute stage of the disease, which may last from a few months to three or four years. The hip should then be fused and the case followed for at least five years longer. Under this regimen one may expect to reduce the mortality rate and to return almost all the remaining patients to fairly normal economic and social activity. This paper is not an "end result study." When these ninety patients shall all have died, I hope that some as yet unknown author will report the actual end results and plot graphically the course of the disease, which by that time will be a clinical rarity.

234 Marlborough Street

ABSTRACT OF DISCUSSION

DR. JOHN C. WILSON, Los Angeles. My experience with biopsy has differed somewhat from that of Dr. Barr. I have not fused hips without a positive diagnosis of tuberculosis. The diagnosis of tuberculosis cannot be made in the early stages without examination of tissue under the microscope. I have not observed any serious disturbance following a biopsy, provided the biopsy was carefully done. Tissues, of course must be handled gently. Tuberculosis may develop along the operative approach if the tissues are not properly packed off at the time the tuberculous focus is encountered. The period of rest prior to operation is of interest. I have not been able to obtain satisfactory rest of the tuberculous hip with mechanical devices. The operation is done to put the infected hip at rest, and an early fusion promotes early healing of a tuberculous joint. The early healing of the joint prevents a destruction of the capital epiphysis, which is of importance, because the preservation of this epiphysis limits the shortening. Dr. Barr has brought out another very important point with which I agree, that fusion of the hip transforms the tuberculosis from a joint infection to tuberculous infection of a long bone. In other words, tuberculosis is a constitutional disease, and the simple fusion or splinting of the hip in no manner effects a cure until the organism as a whole has supplied sufficient antibodies to build up resistance and produce healing.

DR. HALFORD HALLOCK, New York. The most important idea in Dr. Barr's paper is that he advises fusion as the treatment that will give the best prospect of a stable weight bearing extremity free from disease activity. At the New York Orthopedic Hospital we gave up conservative treatment because we could not get results with it. In 1928 Smith and Watters (*THE JOURNAL*, Jan. 21, 1928, p. 189) reported the results obtained by this method in 150 cases. These were 47 per cent still active, 27 per cent quiescent, two patients free from symptoms.

and with useful motion, and 24 per cent deaths. In 1934 Dr Toumey and I (THE JOURNAL, Dec 15, 1934, p 1836) reported the results in 170 unselected cases treated by fusion, 87 per cent are fused, 8.2 per cent of the patients have died. Dr Barr believes from his experience that biopsy should not be done. His figures for the patients subjected to biopsy alone are given in the accompanying table. In any comparative statistical study, one must determine what constitutes significant differences of percentage in relation to number of cases. In the study of fused hips, we set up the following standard. If the group of cases under analysis comprises less than one tenth of the whole series, 20 per cent is considered to be the least amount of difference to which significance can be attached, if from one tenth to one half, 15 per cent, if one half or over, 10 per cent. On this basis, Dr Barr's figures indicate an

Comparative Results of Biopsy

	Mortality	Sinuses	Amyloidosis
Biopsy cases.	9 22%	90%	11%
Total series	90 10.6	60	7
Percentage difference	5.4%	30%	4%

increased hazard only in sinus formation. I believe that the establishment of the diagnosis is of supreme importance because of the necessity for accurate treatment. But before opening a suspected joint, I have permission to fuse if tuberculosis is proved. Dr Barr states that in certain cases the tuberculous process remained active after fusion had been obtained. The subsidence of the disease does not immediately or rapidly follow on fusion, and for the complete replacement of the diseased area by healthy appearing bone, usually three to five years is required. If, however, roentgenographic intra-articular disease activity continues for six months or more after fusion has apparently been obtained, or if the ultimate result of fusion through the diseased area is not secured in from three to five years, I feel that that hip is probably not fused.

DR. J. S. BARR, Boston. The present status of the ninety cases is as follows. Twenty-eight of the hips are fused clinically and on x-ray evidence, and thirty-two are not fused. One patient has a Jones pseudarthrosis, thirty-three are dead or with an unknown or an acute condition. Bilateral tuberculosis of the hip still presents an extremely difficult problem. I have been unable to solve it, but I have approached one case in this manner. I did an arthrodesis on one side and a Jones pseudarthrosis on the other side. The boy is able to walk short distances without apparatus of any kind. Outdoors he carries a pair of crutches but uses them more for balance than for support. It is interesting to note that, after the pseudarthrosis was done, the hip developed complete intra-articular fusion on that side. Every one has his own pet method of fusing hips and assumes that, because he fuses them in a certain way, therefore the results are good. I have no particular brief for the method that I use. It is a slight modification of Dr Wilson's method and I feel that it is an efficient one. I could show slides of a whole series which show in general fusions of that type. The point I am trying to make is that I believe that tuberculosis of the hip, like tuberculosis of the lung, is not a disease to be treated in a general hospital; that, when the diagnosis is made, the patient should be placed in a sanatorium and be put to bed. Then when the disease becomes quiescent, the hip should be fused. Dr Hallock said that they have given up conservative treatment in New York. I am quite certain he didn't mean that in the way he said it because, after a hip is fused there is at least six months or a year of treatment in a plaster cast, and obviously that is conservative treatment. If the fusion doesn't take place intra-articularly for four or five years, he is still treating the patients conservatively, giving them bed rest and as much fresh air and sunshine as possible and a good general regimen which is known to be useful in tuberculosis. The only difference in opinion, I believe between the two schools is that they feel that fusion actually hastens the process of repair. I believe that rest with traction, in bed will produce that arrest about as quickly and with much less danger than will fusion done early in the disease.

MAINTENANCE OF NORMAL WATER EXCHANGE WITH INTRAVENOUS FLUIDS

FREDERICK A. COLLIER, M.D.
VERNON S. DICK, M.D.
AND
WALTER G. MADDOCK, M.D.
ANN ARBOR, MICH.

One of the most important advances in modern medicine is the ability to supply the sick patient with water, food and other chemicals when their normal ingestion from the gastro-intestinal tract has been disturbed. The need for and the value of this parenteral therapy are well established. Prolonged nausea and vomiting may warrant its use, or rest of the gastro-intestinal tract may be desired following operations on it, hemorrhages in it, or inflammations involving any portions of its length. Occasionally inanition may be so marked that fluid and food must be so supplied. In many instances this therapy is the chief aid in carrying a sick patient over a critical period of his illness, and fortunately in recent years physicians have done better in eliminating reactions from such treatment.

Opinions vary somewhat as to the choice of fluid for parenteral administration.¹ A number of factors are involved in the selection, but the fundamental proposition is that of supplying as nearly as possible what the patient needs. In the majority of cases water is of first importance, and our purpose in this paper is to present the results of an investigation on the efficiency of the commonly used solutions in maintaining a normal water exchange. A brief discussion of the amount given and its combination with dextrose and sodium chloride is in order.

From a series of studies on the water requirements of surgical patients, the quantity needed by them daily under various conditions of disease and treatment was determined.² A few statements from the data obtained will develop the reasons for the amount of fluid given to the patients of this study.

Water normally becomes available from fluids drunk and food eaten and is excreted in urine, in the stool, and by vaporization from the skin and lungs. In persons in whom the intake of fluid and food is stopped, available water is importantly affected. Ordinarily the food of a routine maintenance diet furnishes from 1,200 to 1,500 cc of water daily, but in starvation rarely more than 500 cc of water becomes available from the body material oxidized for energy, and with no fluids drunk this is all there is to balance the daily output. Practically, this amount is too small for consideration and can well be forgotten in estimations of the water needs of the seriously ill individual.

On the outgoing side, the surgical patient, the same as the healthy person, excretes water for two physiologic functions: the dissipation of heat by vaporizing water from the skin and lungs, and the excretion of waste materials in solution through the kidneys. The

water loss in feces is insignificant in most surgical conditions and can generally be disregarded. Water vaporized by the average adult patient convalescing uneventfully amounts to from 1,000 to 1,500 cc daily. The sick surgical patient, frequently the one with increased metabolism from hyperthyroidism or fever, vaporizes from 1,500 to 2,500 cc daily, with a fair average of 2 liters a day. Water for urine is the next problem and should be an amount that will enable kidneys of various concentrating ability to excrete the daily waste materials presented to them without having to work at their maximum rate. For the sick surgical patient this should be a urine output of at least 1,500 cc a day, and accordingly 1,500 cc of water is allowed daily for this purpose. Then there may be abnormal losses of fluid to consider, such as by vomiting, drainage from intestinal or biliary fistulas, or sputum. To summarize the amount of water to be given to the sick surgical patient to provide for his daily water excretions and thus to maintain body fluids at their normal level can be calculated as follows: (1) water for vaporization, 2,000 cc, (2) water for urine, 1,500 cc, (3) abnormal losses—vomitus and so on, total, 3,500 cc.

If one is dealing with a dehydrated patient, this maintenance amount of water is not enough and some extra water must be provided to restore the fluid previously lost.² Since the subjects used in this study were not dehydrated, they were given about 3,500 cc of intravenous fluids daily.

Dextrose should be supplied to all patients receiving parenteral fluids. When no food is taken by mouth the glycogen supply of the body rapidly becomes exhausted. Fat, which then forms the main food, tends to be incompletely oxidized and the consequent accumulation of butyric and diacetic acids results in ketosis. This faulty metabolism is prevented when dextrose is provided. The advantage of the protection afforded the liver by carbohydrates must also be considered, along with the value of the number of calories supplied.

The importance of administering sodium chloride solutions parenterally to some patients has been well established. The experimental work of Hartwell and Hoguet,³ Orr and Haden,⁴ and McIver and Gamble⁵ has demonstrated that, after the production of a high intestinal obstruction with its associated pernicious vomiting the lives of animals could be continued indefinitely if they were given a sodium chloride solution intravenously, whereas untreated animals or those given other solutions even if isotonic, were not saved. Clinical experiences in dealing with patients who have lost appreciable amounts of gastro-intestinal secretions from any cause have corroborated the unquestionable value of salt solution parenterally in such instances.

The two fluids most commonly used to restore lost electrolytes are physiologic solution of sodium chloride which contains 8.5 Gm of sodium chloride per liter, and Ringer's solution, which besides having 8.5 Gm of sodium chloride also contains 0.3 Gm of potassium chloride and 0.2 Gm of calcium chloride per liter. Potassium and calcium ions have been shown to have a beneficial action on the heart beat, and their presence in Ringer's solution in approximately the same ratio to sodium as that of the blood serum is thought by some

surgeons, notably Horsley,⁶ to make Ringer's solution preferable to plain physiologic solution of sodium chloride.

From the work on intestinal obstruction, the value of saline solutions is so well known that there is a definite tendency to use them for all administrations of intravenous fluids. In 1924 Matas⁷ pointed out that such a plan is not without serious drawbacks and dangers, degenerative changes in heart muscle and kidneys, and edema of the lungs being warned about in particular. To the alert observer, edema of the dependent portions of the body from the excessive use of salt solutions is not an uncommon observation in the surgical services. In 1933 Jones and Eaton⁸ presented a review of thirty-four cases in which edema was noted postoperatively. Twenty-one of the patients had diseases of the gastro-intestinal tract, the most common being peptic ulcers, gastric malignant growths and perforated appendixes. In most instances the edema was of the dependent portions of the body. Five patients, however, had edema of the lungs, and one patient died from edema of the intestinal wall with resultant partial obstruction. It was thought that the most important element in the production of the edema in these cases was a low serum protein consequent to undernutrition. Additional factors considered to be of importance were the administration of excessive amounts of fluid and salt, profuse surgical drainage, the general effects of sepsis, and loss of serum protein by massive hemorrhage. Corroboration of the influence of these factors on the production of edema was obtained by these authors and White⁹ in an interesting series of experiments on animals.

From observations over a period of several years on edema developing postoperatively, it was our impression that while many factors predisposed to the retention of fluids the precipitating factor was frequently the excessive use of sodium chloride solutions. Among other things, a study of the efficiency of the commonly used intravenous fluids in maintaining a normal water exchange offered a chance to substantiate this opinion.

METHOD

Three groups of sick surgical patients who could not or were not permitted to take anything by mouth and therefore needed fluids parenterally were selected for study. Each group received primarily 5 per cent dextrose in either physiologic solution of sodium chloride, in Ringer's solution or in distilled water. For one point of interest, a control group of patients in good general condition was studied. The fluid was given intravenously by the drip method at a rate of about 450 cc an hour, this being the method preferred rather than subcutaneous infusions. None of the patients gave evidence of renal disease or cardiac decompensation. The study was generally started on the first postoperative day. In several instances after the effect of one solution was determined the fluid intake was changed to a different solution, given either intravenously or by mouth.

The procedure for the determination of the water exchange of surgical patients has been described previously.² In brief, we obtained the weight of the patient each morning at 8 o'clock, and the weights of

all intake and output for the next twenty-four hours. The water balance, including water vaporized from the lungs and skin, was then calculated for each day.

Blood chemistry studies considered to be desirable and carried out by standard methods were the total

serum proteins, serum albumin, carbon dioxide combining power, chlorides and nonprotein nitrogen. The excretion of chlorides in the urine also was determined.

In deciding whether the water exchange was satisfactory, the weight of the patient each morning was used

* Change in weight of patient was used as a simple criterion of water exchange. Since the caloric intake was below maintenance requirements a daily loss in weight should have occurred as a result of the oxidation of body substance for additional energy. A gain in weight or even maintenance of body weight under these circumstances meant water retention.

as a simple criterion. In health an adult's weight is fairly constant, showing only minor variations from day to day as a result of water being retained or given up. The patients studied took no food by mouth and were undernourished. They received about 175 Gm of dextrose daily in the intravenous fluid, but its calorific value was always less than the energy requirements and consequently some body glycogen, fat and protein were burned for additional energy. With the loss of these food substances and the water held by them, a daily loss in weight should occur, amounting to roughly 400 to 600 Gm for an adult. A gain in weight or even a maintenance of body weight under such circumstances meant retention of water. Since the patients studied were not dehydrated, this addition of water would be an undesirable feature and indicative of a disturbed water balance. If great enough, clinical edema would appear.

RESULTS

The data for the twenty-one patients studied are shown in the accompanying table. The values given for the serum proteins were those obtained at the start of the study.

COMMENT

An investigation of this type is more complex than it appears to be at first glance, and many points of interest arise, particularly in relation to body chemistry. Comments have been largely limited, however, to facts significant to the purpose of this paper.

1 Patients Receiving 5 per Cent Dextrose in Physiologic Solution of Sodium Chloride—All the sick surgical patients in this series retained water and gained weight, one of them, patient 3, developing definite edema of the lower part of the back and ankles. The first five of them had diseases of the gastro-intestinal tract and presented various degrees of undernutrition. No clear correlation was found, however, between their serum protein and the retention of water. The critical level for total serum protein at which edema begins to develop is given by Moore and Van Slyke¹⁰ as 5.5 ± 0.3 Gm per hundred cubic centimeters, for serum albumin, 2.5 ± 0.2 Gm per hundred cubic centimeters. In relation to edema the serum albumin is considered to be more significant than the total serum protein. None of the patients of this first group had serum albumin values down to the critical level, this probably accounting for the lack of correlation between this value and the retention of water, as found by other observers.¹¹

To substantiate our impression that the general condition of being sick had a great deal to do with the water retention when salt solution was given, the group of surgical patients whose general condition was excellent was included here. Patient 6 retained water and gained weight when given the 5 per cent dextrose in physiologic solution of sodium chloride during the period of his acute infection. Three weeks later, when the drained area was healed, no water was retained under otherwise the same circumstances. Patients 7, 9 and 10 were convalescing uneventfully from major operations and to all intents and purposes could be regarded as healthy. Patient 8 was being treated for a chronic peripheral vascular deficiency, but his general condition was excellent. None of these four patients retained

water when given 5 per cent dextrose in physiologic solution of sodium chloride for two or three days. Salt solution did not disturb their water exchange.

The water balance of the sick patients receiving 5 per cent dextrose in physiologic solution of sodium chloride was not satisfactory. Water was retained when it was not needed. On the basis of the beginning plasma carbon dioxide combining power and chloride values there was no indication for giving the saline solution to them. Per se there was no evidence that the water retention produced did any harm to the patients studied, but the common observation of waterlogged tissues of surgical patients coming to autopsy may well be the result of such indiscriminate use of physiologic solution of sodium chloride. In our subjects the kidneys, at least, were called on for the additional work of excreting many grams of excess sodium chloride.

The data from this first group corroborated our opinion from clinical observations that when edema develops in sick surgical patients receiving intravenous fluids it can be stopped in the majority of instances by stopping the administration of sodium chloride. There is no need for the limitation of fluid intake or the use of diuretics. The importance of simply eliminating the

Demonstration in case 3 postoperative gastro-enterostomy of the production of edema with the administration of 5 per cent dextrose in a saline solution intravenously and the subsequent disappearance of the edema when the sodium chloride was omitted.

salt element was well shown in patients 3, 4 and 5, who, when the change was made to approximately 3,500 cc daily of 5 per cent dextrose in distilled water, promptly gave up their retained water and lost weight. This was so dramatic for patient 3 as to be worthy of graphic representation in the chart.

2 Patients Receiving 5 per Cent Dextrose in Ringer's Solution—The second group of sick surgical patients was given from 3,000 to 3,500 cc. of 5 per cent dextrose in Ringer's solution daily. Of the seven patients so treated six retained water, two gaining more than 3 Kg. The one patient who lost weight when given Ringer's solution plus dextrose had the highest serum protein and serum albumin in the group. His response approximated that of a healthy person.

A comparison of the data from the two groups of sick patients receiving salt solution showed that there was a tendency for a little greater retention of water when physiologic solution of sodium chloride plus dextrose was given than when Ringer's solution plus dextrose was used. Several points substantiated this

¹⁰ Moore N. S. and Van Slyke D. D. The Relationships Between Plasma Specific Gravity, Plasma Protein Content and Edema in Nephritis. J. Clin. Investigation 8: 337 (April) 1930.

¹¹ Jones and Eaton. Jones, Eaton and White. Moore and Van Slyke.

impression in spite of the fact that the effects of various factors predisposing to edema were probably not exactly equal in the two groups. In general, the amount of water retained was somewhat greater for the group of patients receiving physiologic solution of sodium chloride plus dextrose. Then patients 13 and 15 gained a little more weight when the intravenous fluid was changed from Ringer's solution plus dextrose to physiologic solution of sodium chloride plus dextrose. Patient 13 also had the lowest serum protein and serum albumin in the series, the values shown being well within the critical level at which edema tends to develop, yet with 5 per cent dextrose in Ringer's solution for three days the weight gain was only 100 Gm. From the standpoint of water exchange there is apparently some advantage in the use of Ringer's solution over that of physiologic solution of sodium chloride, but it is well to point out again that six of the seven patients to whom the Ringer's solution was given retained water. Its use does not obviate the occurrence of edema.

Concerning the blood chemistry, the adjustments of plasma carbon dioxide combining power and chlorides were entirely satisfactory with the Ringer's solution.

3 Patients Receiving 5 per Cent Dextrose in Water

—The four sick patients of this group did not retain water. For each of them a decrease in weight occurred as a result of the oxidation of body glycogen, fat and protein for energy, both these materials and the water normally held by them being lost. The water exchange was the same as if no food had been eaten and the dextrose solution had been taken by mouth.

Patient 18 was particularly interesting in that, although the serum protein and serum albumin were down to the critical level for the development of edema, no water was retained in spite of a good intake of fluids intravenously for six days.

That there need be no concern for the sodium chloride content of body fluids if salt is not being lost through abnormal channels and only water and dextrose is given intravenously was shown by the plasma carbon dioxide combining power and chloride values for patients 18 and 21 being practically the same at the end of the period of study as at the beginning. The chemical economy of the body under such circumstances was apparent when the excretion of chlorides in the urine was reduced to less than a gram daily.

SUMMARY

In many conditions associated with disease, the parenteral administration of fluids has proved to be of great value. While some difference of opinion exists as to the choice of fluids to be given, the proposition is that of supplying as nearly as possible what the patient needs. Water is generally of first importance and, since all patients unable to take water by mouth are also short on food, some dextrose is needed. Whether this is administered in distilled water or in a saline solution is the important point.

From the observations of a number of investigators, the value of saline solutions for patients who have lost sodium chloride has been well established. A distinct tendency exists, however, for the use of these solutions as a routine for all parenteral fluid administrations, without regard to whether sodium chloride is needed or not. Warnings have been given concerning the development of edema with such a procedure. From our experience and that of others the occurrence of edema in surgical patients receiving parenteral fluids is not

uncommon. Many factors such as undernutrition, the excessive administration of water and salt, and the general effects of sepsis have been presented as setting the background for the retention of water. These factors are commonly found in the sick surgical patient and it has been our impression that while they are important, the precipitating factor is generally the excessive use of sodium chloride. To corroborate this opinion a study was made of the water exchange of a group of sick surgical patients, who were given the commonly used intravenous fluids as a part of their necessary postoperative care.

It was found that twelve of the thirteen sick surgical patients receiving 5 per cent dextrose in physiologic solution of sodium chloride or Ringer's solution retained water and gained weight. The amount of water held was a little less with Ringer's solution than with the physiologic solution of sodium chloride. When administration of the salt solution was stopped and fluids were taken by mouth or changed to 5 per cent dextrose in distilled water intravenously, all of the group promptly lost the water previously retained. This last point is worthy of special emphasis. It was not necessary to stop the administration of intravenous fluids to get rid of the water retention or to use diuretics, when the sodium chloride was omitted, the edema fluid disappeared even with a good water intake.

No water was retained by a group of sick surgical patients given 5 per cent dextrose in distilled water, their daily exchange being approximately the same as if the solution had been taken by mouth. A loss of weight occurred, but this could be accounted for by the loss of body tissue oxidized for energy. One in the series, patient 18, had a total serum protein and serum albumin value down to the critical level at which edema tends to develop. From our experience, water would most surely have been held if a sodium chloride solution had been used, but with the daily administration of 3,450 cc of 5 per cent dextrose in water for six days no retention occurred. Throughout the whole study the suitability of this solution for maintaining a normal water exchange was apparent.

Warnings about the production of edema with salt solutions are well founded and should be heeded. While actual edema was noted in only one of our patients, several of them were well on the way to developing it and would have done so if the salt had not been stopped. The only reason that gross water retention is not seen more frequently with the indiscriminate use of saline solutions is that it is generally not given for more than two or three days. The first thought of the surgeon on finding edema in a sick patient who has been receiving fluids parenterally should be "How much salt solution has been given?" Often little is required to cause water retention. We have seen several instances in which a liter a day for a week or so to a seriously ill patient was enough to produce edema of the lower part of the back and the ankles. When parenteral fluids are necessary, the thoughtful physician will avoid these errors by supplying the amount and kind of materials needed.

CONCLUSIONS

1 Retention of water is a frequent occurrence when saline solutions are given intravenously to sick surgical patients. Edema from this cause is not uncommon if the solutions are given for more than a few days.

2 Five per cent dextrose in distilled water intravenously provides for a normal water exchange.

ABSTRACT OF DISCUSSION

DR. THOMAS G. ORR, Kansas City, Mo. It is refreshing in this age of physiologic and biochemical surgery to hear a practical paper that is not operative. Unquestionably many lives have been saved by the recognition and proper treatment of patients suffering from dehydration, chemical imbalance and metabolic imbalance. The authors have shown how one can estimate the water needs of the patient. I was especially impressed by their figures estimating the needs of the patient in the first twenty-four hours. The ordinary daily intake plus 6 per cent of the body weight is an excellent working basis, easily estimated in any particular case. This is a practical means of treating patients who come in with very definite dehydration which can be easily determined by the general clinical appearance of the patients and by blood chemistry. Hypertonic solutions have been too much in vogue among many surgeons in recent years. Hypertonic solutions have a definite use but it is rather limited. The indications are not many. For a patient coming in with a marked hyponatremia after persistent vomiting, a hypertonic salt solution perhaps only one dose is indicated, but certainly that should not be overdone. The same applies to dextrose. I find that in certain places they are giving 50 per cent dextrose with the idea of feeding the patient. It is my impression that they are dehydrating him. This should not be done except in certain injuries to the brain. The authors have spoken of other dangers, notably those to the heart and the kidney, and of edema. Certainly that should be taken very much to heart. An overdose of sodium chloride will unquestionably produce edema and injure the circulatory apparatus. All therapeutic methods are overdone when first introduced until the proper evaluation has become established. Another danger is that of embolism and thrombosis following prolonged intravenous administration. Such an important treatment as intravenous therapy cannot be discontinued because there may be an occasional accident of that type but it is well to keep it in mind. Nature never intended that we should be fed and watered by the vein. Patients should not be treated by this method any longer than is absolutely necessary. The way to give food and drink is by mouth, and that should be controlled so far as possible. Every surgeon should study this paper carefully for by such study he will become a better surgeon and will save more lives.

DR. WALTER G. MADDOCK, Ann Arbor, Mich. The authors have shown that approximately 3,500 cc. of fluid is needed daily by the sick patient to provide water for vaporization and a good urine output. If abnormal losses of fluid due to vomiting take place, the 3,500 cc. amount is not sufficient. There are several causes of anuria, but dehydration often resulting from abnormal losses of fluid is the most common one and can be readily detected by a check-up and the finding of a negative water balance for several days previous to the insufficient urine output. In dealing with the dehydrated patient an extra amount must be given to restore the fluid previously lost, besides providing water for vaporization and urine. A study of dehydrated subjects showed that the common signs of this condition are readily recognizable when the body has lost an amount of fluid equal to about 6 per cent of the body weight. This figure can be used in calculating the additional amount of water to be given to a dehydrated patient. The total water calculation for such a patient weighing 60 Kg. would then be for vaporization 2,000 cc., for urine 1,500 cc., to relieve the dehydration (6 per cent of 60 kg.) 3,600 cc. = a total of 7,100 cc. Studies of several dehydrated patients have shown that such volumes are first necessary to provide for a good urinary output. The authors have presented evidence to show that retention of water is of common occurrence if saline solutions are given indiscriminately to sick surgical patients. That such solutions are not generally needed was shown when an analysis of the reasons for giving fluids intravenously to 100 general surgical patients showed that only 20 per cent of them had lost appreciable amounts of sodium chloride chiefly by vomiting and needed some salt. The remaining 80 per cent had not lost sodium chloride but because of their disease or because of the treatment, could not or were not permitted to take in sufficient fluids by mouth to maintain a normal water exchange. What they required was sufficient water to provide for vaporization

and a good urinary output, and enough dextrose to prevent ketosis. This can be well supplied by 5 per cent dextrose in water. The whole subject of water balance forms an important part of preoperative and postoperative care. Its skilful handling, with due consideration to both the amount and the kind of fluid, will yield very gratifying results.

THE CONSERVATIVE TREATMENT
OF ABORTION

JAMES R. REINBERGER, M.D.

AND

PERCY B. RUSSELL, JR., M.D.

MEMPHIS, TENN.

The better method of treatment of abortion is still a controversial question. This lack of accord contributes its share to the one third of all obstetric deaths resulting from abortion. In the obstetric service from 1933 through 1935, since the majority of deaths followed infection from criminal abortion, it was apparent that criminal induction bore a definite relationship to the death rate. Criminal abortion is definitely on the increase, for criminal induction was admitted in 17 per cent of the 707 cases studied. It is safe to assume that an additional 10 per cent may be added conservatively (table 1).

Self instrumentation superseded those abortions induced by physicians. Use of the catheter and instrumentation were the most common methods employed and were done mainly by white patients. Self instrumentation demonstrates that the seriousness of this procedure is not generally appreciated. It is apparent that the Negro is ignorant of the possibilities of doing away with unwanted pregnancies, but future enlightenment will increase the number of abortions tenfold. Because of criminal induction, the death rate was twice as great for the white, even though the Negroes outnumbered the white patients.

Criminal induction was the most determined cause of two thirds of the total number of deaths in which two thirds of these resulted from infection. It is evident that the major barrier was the control of infection.

Experience demonstrates that a definite history of criminal invasion of the uterus was not often obtained until after many days of hospitalization. The unreliability as to whether criminal invasion had been done with the certainty of infection, plus the large number

of patients admitting criminal induction, made it imperative that all measures to prevent any possible dissemination should be carried out by nonintervention. The classification of abortions is self explanatory. The discrimination between febrile and afebrile abortions deserves discussion. The presence of fever does not necessarily indicate whether virulent organisms have been introduced and if so to what extent the

TABLE 2—Classification of Abortions

1	Spontaneous	Onset without apparent cause
2	Induced	History of abortifacient or instrumentation
3	Complete	Definite history of pregnancy with passage of products of conception. No evidence of uterine activity or bleeding
4	Incomplete	Definite history of pregnancy with passage of some part of the products of conception. Evidence of uterine activity and bleeding
5	Febrile	Elevation of temperature on admission with or without active signs of infection
6	Afebrile	No elevation of temperature or active signs of infection on admission
7	The presence of fever on admission rather than later as a guide seems more logical for classification particularly for those who invade the uterus as a routine	
8	Late septic	History of abortion with considerable lapse of time before admission to the hospital. Evidence of blood toxic or the presence of extra uterine infection such as parametritis, thrombophlebitis, peritonitis and bacteremia

infection has spread. Febrile cases may result from the absorption of degenerative fetal products, while in afebrile cases there may be virulent organisms harbored in the uterus. Elevation of temperature on admission was found to be the best guide as to the presence of infection. Its presence does not have any bearing on our conservative management, but it should be used advantageously by those who actively invade the uterus as a routine. The question of race, antepartum attention, parity and duration of pregnancy had no effect on the response to therapy. There were many more nonclinic patients than clinic ones. Abortion was more common in the

multipara. The duration of pregnancy was equally divided. Syphilis played a small part as an etiologic factor in second trimester abortions. Anemia was present in a considerable number of cases but probably had no bearing. It is even questionable whether or not the anemia resulted from the abortion or was present prior to the pregnancy (table 3). A considerable number of patients had completely aborted with cessation of uterine cramps and bleeding

before admission and required no treatment. A still greater number of abortions had completely separated the products of conception from the uterus and presented only the slightest evidence of uterine activity with slight bleeding. A very small number presented evidence of partial separation of the products of conception with continued bleeding. It was observed that the simple retention of the separated products of conception in the lower uterine segment rarely caused any moderate and never profuse hemorrhage. The administration of oxytocics almost invariably brought about the expulsion of such products. It is true that the experienced operator may possibly remove such products from the lower uterine segment with little or no harm, but the teaching of interns has demonstrated to us that, unless close supervision of this procedure was carried out, more often complete exploration of the uterus was done. Therefore it follows that, since many of the abortions are completed and require no treatment and that even a greater number of incomplete abortions

TABLE 4—Treatment

1	Preparation of vulva. Vaginal speculum was introduced only in cases of moderate or profuse hemorrhage. The lower uterine segment was not invaded. Tissue protruding through cervix was removed with sponge stick.
2	Blood transfusion was given immediately on admission for massive blood loss. It was used rather frequently in others to maintain resistance against infection.
3	Elevation of the head of the bed to promote drainage.
4	Icebag to lower part of abdomen to promote contractility of uterus.
5	Fluidextract of ergot, 30 minims (2 cc.) every four hours for the complete type.
6	Solution of posterior pituitary, from 0.5 to 1 cc. every four hours for incomplete type with slight bleeding. Fluidextract of ergot, 30 minims (2 cc.) every four hours after passage of products of conception.
7	Solution of posterior pituitary, 1 cc. every hour for moderate or profuse bleeding for incomplete type until products of conception have passed, followed by fluidextract of ergot 30 minims (2 cc.) every four hours for four days.
8	Invasion of the uterus rarely necessary, done only following the failure of oxytocics.
9	In a small number of cases continued bleeding necessitated the use of sponge stick, curet or pack.

responded to oxytocics, the routine invasion of the uterus was not only unnecessary but inadvisable and was never done until oxytocics had failed. Continued bleeding after the cessation of uterine cramps indicated that some of the products of conception had not been expelled. A small fragment of placental tissue adherent to the uterine wall was encountered in a small group of cases. Oxytocics proved of little value. Operative intervention was indicated. A study of such cases with their sporadic occurrences signified that overenthusiasm rather than actual clinical and blood signs was often responsible for active invasion of the uterus. In a small group of cases of continued bleeding, active invasion failed to reveal the presence of placental tissue. This suggested that infection of the uterus wall was responsible for the bleeding. Violent manipulation and sharp instrumentation was never used for fear of perforation. A sponge stick or dull curet was used for exploration in such cases. It was thought that second trimester abortions would give considerable trouble when the conservative plan of management was introduced as a routine. However, end results indicate that this belief was based on a false premise, for in only two such cases was operative intervention necessary. We adopted this conservative type of treatment in this group of cases based on our

experience with the handling of retained or adherent placenta complicating full time labors. Experience demonstrated that in the majority of cases the placenta was almost invariably expelled without active invasion of the uterus. The good results of this procedure in full term labors was again substantiated in the management of second trimester abortions.

It did not matter whether the uterus was emptied when once infection had extended beyond the uterus. It was generally accepted that no active intra-uterine manipulation should be carried out but that all efforts should be directed toward building up the patient's general resistance. The deaths in this series indicated that almost a fatalistic attitude must be assumed, for with the exception of an occasional case of blood stream or parametrial infection practically all patients died. The active treatment to combat thrombophlebitis and general peritonitis seemed almost hopeless. Sufficient evidence gained elsewhere indicated that ligation in thrombophlebitis and drainage in peritonitis were practically of no value.

There is no doubt that the postponement of medical care, too late to establish localization, was found to be more dangerous than the presence of infection. The

An immediate inventory of the patient's general condition was as important as the information whether or not the uterus was emptied. Immediate blood transfusion saved many patients from almost complete exsanguination while in others it fortified body resistance sufficient to overcome infection.

Transfusions were performed 148 times in 707 cases. The number of transfusions was certainly not out of

18 operations performed to 118 incomplete abortions or 15%

necessity of immediate conservative treatment with its good results was substantiated in contrast to the eight of the nine patients who died presenting evidence of extra uterine infection on admission to the hospital.

One hundred and eighty-nine of the abortions were completed and 518 were incomplete prior to admission. One hundred and sixty-one of the total number of abortions were febrile while 545 were afebrile. The incidence of operation was comparatively small for only eighteen operations were performed in the 518 incomplete abortions. Dilation and curettage accounted for 50 per cent of all operations and were done for prolonged bleeding following the failure of oxytocics. Uterine packing was occasionally employed and only after instrumentation had failed to reveal retained tissue. Manual removal used only in three cases demonstrated that immature placenta caused very little trouble (table 5).

Morbidity and hospitalization were considered by many to be an indication for routine emptying of the uterus. The average number of days for morbidity of the entire group of cases was two and eleven twelfths. The morbidity was slightly larger in febrile cases. The average number of hours necessary for oxytocics to empty the uterus was twelve and one half. The average number of hospital days for all cases was seven.

The seriousness of the abortion problem submerges the question of morbidity and hospitalization and demands a plan of treatment that results in the smallest number of deaths.

proportion, for only 148 were given to 215 patients who had less than 3 500 000 red blood cells (tables 3 and 6).

The analysis of deaths reflected that the method of treatment of emptying the uterus played no part. The three patients who died within the first twenty-four hours were immediately dismissed from the discussion. The second group of so-called late septic abortions were likewise completed and had no bearing on active invasion or conservatism. All these patients presented extra-uterine extension of infection.

There remains only three cases for discussion that would actually come within the realm of this subject.

TABLE 7—Analysis of Deaths 1933-1935

1 Cases not associated with hospitalization	3
(a) Postabortal complete estivo-autumnal death in two hour	
(b) Postabortal complete criminal three weeks exsanguinated died five hours after admission	
(c) Postabortal complete criminal general peritonitis died in sixteen hours after admission	
2 Late septic cases from 3 to 8 weeks after abortion	9
(a) Complete criminal three weeks died of peritonitis on fifteenth day	
(b) Complete criminal three weeks pelvic thrombophlebitis positive blood culture nonhemolytic streptococcus autopsy pyemia lung abscess died fourteenth day	
(c) Complete spontaneous eight weeks thrombophlebitis continued bleeding dilation and curettage died fourteenth week questionable surgical judgment	
3 Cases admitted within five days after induction	9
(a) Incomplete abortion criminal two days conservative treatment uterus emptied in two hours died of peritonitis ninth day	
(b) Complete criminal four days blood cultures anaerobic streptococcus died of peritonitis on fourth day admitted with peritonitis	
(c) Complete criminal four days exsanguinated admitted with peritonitis died tenth day	

One of these cases was admitted four days after complete abortion. Death occurred from peritonitis on the fourth day of hospitalization. A second patient was admitted exsanguinated four days after complete abortion and had a transfusion but died from peritonitis on the tenth day. The third case was an incomplete abortion. The uterus was emptied by oxytocics within ten hours. The patient died from peritonitis on the ninth day.

In the final analysis, it is apparent that only one of the deaths could be associated with the question of intervention or nonintervention, for the remaining cases were admitted with no evidence of retention of the products of conception.

It seems that the major problem, at least in this group of cases, is not a question of intervention or nonintervention. It is felt that delayed hospitalization for immediate effective therapy was the factor that must be emphasized because of the low death rate associated with early treatment of abortion. Just what can be done about this delay is hard to state. Economic distress and the attempt to shield the presence of an unwanted pregnancy as a reason for delayed hospitalization will always remain the same problem.

CONCLUSIONS

Deaths resulting from abortions constitute the large proportion of the total maternal mortality. The number of criminal abortions is increasing. It is imperative that more conservative treatment be employed for controlling hemorrhage and for combating infection. Under the plan of nonintervention, which has been in use for three years, invasion of the uterus was rarely necessary for control of hemorrhage and was never used to combat infection. Blood transfusions proved

TABLE 8—Summary of Results of 707 Abortions 1933-1935

their value for checking infection and for restoring blood volume. Records of a series of cases emphasized the infrequent need for operative intervention and the low mortality. The seriousness of the abortion problem submerged the question of morbidity and days of hospitalization. It is believed that conservative treatment should be more universally employed in an effort to reduce the number of deaths from abortion.

1045 Madison Avenue

ABSTRACT OF DISCUSSION

DR J. C. LITZENBERG, Minneapolis. I was impressed with the fact that the authors could give such a remarkable report from a community, largely colored, where hygienic surroundings are poor. My mind reverted back twenty-nine years when a commission appointed by the American Medical Association to investigate the treatment of puerperal sepsis (including septic abortion) reported its recommendations, among which was the condemnation of all such cases. The recommendation of active treatment illustrates how long it takes to instill into the medical profession principles which have been established by experts. That was twenty-nine years ago this month and yet there are few hospitals that can give the statistics that the authors have revealed today. They reported only one death, and intervention was almost eliminated. Criminal abortions are greatly on the increase. Thousands of mothers are losing their lives through improper treatment of septic abortion. Dr. Fred Taussig states that there are performed at least 700,000 cases of criminal abortion annually in this country. The birth rate is decreasing alarmingly. Therefore it is up to us as a profession to save all the conceptions that do occur so that we may maintain our population. It may astonish some to know that we have already reached in the United States a birth rate

which is barely capable of maintaining our population. When our population begins to decrease, perhaps we shall be awakened to the fact that a decreasing population means a degenerating civilization. That is what happened to Rome and Carthage. Perhaps we cannot do much about lessening the number of criminal abortions, perhaps we cannot do much about increasing conceptions, but we as a profession can do a great deal by conserving all the conceptions possible that do occur and by conservative handling save for future child bearing these mothers who are threatened by death on account of septic abortions. It is rather discouraging to hear the authors speak about those who intervene. Twenty-nine years ago the commission deprecated such intervention, well supported by statistics and by a long-time investigation, and yet we all know that intervention by curettage is the method of treatment in too many hospitals. The paper of Drs. Reinberger and Russell puts a new emphasis on the necessity of conservative treatment of abortions.

DR. THOMAS K. BROWN, St. Louis. In a series of 500 consecutive abortions treated at St. Louis City Hospital active treatment was employed. The therapeutic principle involved is drainage of a wound site which is found to be contaminated in 60 per cent of the cases. The bacteriologic studies in these cases have been helpful in showing the probable source of such contamination, the vaginal tract. Soule and I have previously reported anaerobic growth in 60 per cent of vaginal cultures on patients in the obstetric clinic. In the present series the cases with positive intra-uterine cultures, 60 per cent, showed the incidence of anaerobic organisms to be 92 per cent. As to questions of permanent damage to the pelvic organs and future sterility, both of which have frequently been observed in such cases, I wish to state that subsequent to early active treatment, pelvic examination reveals the presence of no residual pathologic condition and further pregnancies promptly occur if no contraceptive measures are used. No prolonged period of convalescence is noted. As to deaths occurring in the two series, one finds that in each group the patients were virtually moribund on admission, were under observation for a relatively short period, and made little or no response to any type of therapy used. The average period of hospitalization after active treatment was 6.3 days. By early active treatment, bleeding has been promptly arrested and the need for blood transfusions has been considerably reduced. By active treatment is meant gentle evacuation of the uterine cavity by means of a Forester sponge holding forceps. No curettage is done. Because of the close parallelism in the two sets of results and the absence of evidence of any real damage being done in a series of 500 cases treated by junior interns under proper supervision, it seems to offer further support to the policy of active treatment. In the final analysis what more have Drs. Reinberger and Russell accomplished than to attempt to obtain evacuation of the uterus by medical rather than by mechanical means? When failing in the former method, they resorted to the latter. In view of the similarity in results obtained in these two series, it seems logical to attempt to bring the disease process to a more abrupt termination by ending it mechanically and to avoid the period of watchful waiting during which time a localized process may become more widespread.

DR. RUDOLPH W. HOLMES, Chicago. I have had a rather unusual experience with abortions, particularly criminal. In 1898 I was appointed chairman of the Committee on Abortion of the Chicago Medical Society and thereby was accredited to the coroner's office and for five or six years was a deputy coroner. As a result of our investigations the committee concluded that for every baby born alive in Chicago in that day about 30,000 to 32,000, one baby was destroyed by a criminal operation. Our conclusion was that criminal abortions destroyed as many fetuses as did all other causes of early interruptions of pregnancy. Our committee was responsible for more apprehensions of culprits and their convictions than had obtained for many years previously. Repeatedly, we found on post-mortem examination that the uteri were perforated at times there was strong presumptive evidence that the perforations were sequential to the secondary operation, and in others the evidences were conclusive that they were the result of the unwise and contraindicated curettages. Such intra-uterine instrumentations frequently convinced the coroner's staff that

holding the abortionist to the grand jury was futile, as any jury would be convinced as we were that the attending physician had greatly contributed to the death of the woman. In former times it was quite the vogue to curet as a routine before hysterectomy as part of the operative toilet in my own practice and in that of Dr Thomas Watkins, we never found more than half the uterus touched by the curet. I state this to show how futile is the attempt to curet the uterus for sepsis. Further, most have forgotten the reaction zone of Bumm, which is tantamount to making the infected uterus an abscess cavity. Who teaches the curettage of an abscess wall? Dr Barrett is correct. In the presence of severe hemorrhage do a digital curettage but use no instruments. A well placed tampon in appropriate cases is good if there is slow bleeding. The teaching of Drs Reinberger and Russell should be given heed. Conservative methods will give better results than operations.

Dr. W. T. PRIDE, Memphis, Tenn. Dr Barrett must have been mistaken in his interpretation of the cases when he complained about not curetting in all and the transfusions. In my service the patients in whom transfusion is done come in almost exsanguinated, they are in bad condition and it wouldn't matter whether the contents of the uterus were still there, they would need the transfusion just the same. I deal with a class of people whose circumstances are different, and when you say 140 transfusions it seems like a great deal, and yet with 700 patients of that type it is not a great number of transfusions. One remark was made with which I do not agree and that is the advisability of irrigating an infected uterus. I do not irrigate. Dr Barrett brought up the question that if these nine who died had been curetted maybe they would be here, but how about all of those who wouldn't be here if they had been curetted? For the past three years I have treated all these cases conservatively and I leave to you the results.

Dr. JOSEPH B. DE LEE, Chicago. I had the honor to be the chairman of the committee to which Dr Litzenberg referred in 1905 or 1906. The committee was appointed for the study of the treatment of puerperal infection. In those days the treatment of puerperal infection was wash, curet brush, sponge and do everything one shouldn't do. Williams was on the committee, Litzenberg and one other. We communicated with every professor of obstetrics in the United States and every assistant professor and many abroad, and we combed the literature at home and abroad, and the report the committee brought in was that the conservative treatment of puerperal infection including abortions was the best. There is no difference of opinion between the two sides that have been taken here this afternoon. They both agree that the uterus ought to be emptied, but how—medically or surgically? It will be noticed that the surgeons are treating infection much more conservatively than they used to with a great deal less cutting. For septic abortion, medical treatment is what I recommend. Quinine 3 grams (0.2 Gm) every hour for five doses if the patient can stand quinine, followed by solution of posterior pituitary. Most of the cases will terminate themselves. If the woman has a high fever and she bleeds too much, a transfusion and a packing of the vagina are in order, after removal by gentle traction of pieces of the placenta sticking out of the cervix. There is no invasion of the uterus, packing of the vagina temporarily, trying to tide the woman over until her local and general immunities have been developed. That is the essence of the treatment that I have found the most successful. I watch the literature very closely, reading articles defending both sides of this moot question and I believe that in world literature of today the balance is in favor of conservative treatment.

Dr. LYLE G. MCNEILE, Los Angeles. Ordinarily it is not within the province of the chairman to discuss a paper but I think that the subject merits a wider discussion. I was trained by Dr De Lee and then I went to the Los Angeles General Hospital where the treatment of abortions was in the hands of those who called themselves gynecologists. They scraped every uterus well and faithfully. After five years I was able to remove the abortions to the obstetric department. Then the abortions came under the conservative treatment. We reduced our mortality at least 75 per cent by going from this curet method to the same general trends that Dr De Lee has mentioned and Drs Reinberger and Russell discussed in their paper.

We have been on that regimen for the last twenty years and we are going to continue the conservative treatment, which is, I think, the same treatment in infected abortions.

Dr. JAMES R. REINBERGER, Memphis, Tenn. I prefaced the presentation of slides with the remark "the better treatment of abortion is still a controversial question." I believe that the discussion has borne out this statement. The consistent number of deaths from abortion, not only in our hospital but throughout the entire nation, suggested that some dogmatic regimen should be adopted to find out whether or not the therapy played any part in these fatalities. Owing to the fact that so many of the patients admitted criminal induction, while others came in with infection spread beyond the uterus, it was advisable to adopt the conservative method of treatment. For the past three years this plan has been in vogue. The end results in this series indicate that it has been effective. Dr McNeile's remarks relative to the shifting from radical therapy to conservative treatment reminded me of my intern days in Bellevue Hospital, for there I saw the same evolutionary change. The same low incidence of operative intervention is again demonstrated in the series of cases just presented. I am not so sure that perhaps in a closed institution caring for only clinic cases or in private practice the uterus may not be emptied in a routine manner under the guidance of an experienced hand. But generally we feel that a plan of treatment should be universally adopted that is applicable to all men under all conditions where neither experience nor facilities are available, if the death rate is to be reduced.

MEDICOLEGAL ASPECT OF ARTIFICIAL INSEMINATION

FRANCES I. SEYMOUR, M.D.

AND

ALFRED KOERNER, M.D.

NEW YORK

The science of artificial insemination has been known for many years among animal breeders who desire pure stock. Within the last few years, however, artificial insemination among human beings has attracted quite a little attention, owing to the success attending its practice.

Unfortunately, or fortunately, the physician is bound by many legal restrictions in the practice of medicine, and, however morally certain he may feel in aiding or abetting certain acts, he must live within the legal restrictions and also comply with the dictates of society, which form the moral code of the country.

The question of the legitimacy of a child born in wedlock, as a result of artificial insemination from a donor other than the father, has not been brought to trial as yet. It is with this in mind that we are presenting this paper in the hope of answering some of the many questions asked us by physicians. We will present the legal relationships of all parties, one by one, and give what suggestions we have to offer and the ways in which we handle the matter. The question will be taken up only from a legal point of view.

First, let us take up the question of the legality of the mother's position. Adultery, by the New York State law, is defined as "the physical relationship between a woman or man with a partner other than the legal mate." This interpretation automatically dispenses with any such question in a case of artificial insemination, as the prospective mother does not even know or see the donor. However, we have found it necessary and advisable to insist that the woman's hus-

band be made to give a written consent that his wife be inseminated. We use a specific form as the one suggested herewith.

The signatures of both the husband and wife are affixed to the document and sworn to before a notary.

We have the wife affix her signature on the same sheet after her husband's, making a very definite statement that she too joins her husband in the request for an artificial insemination. This rules out any question that the wife did not know what was going to be done. There is one other feature that we insist on, namely, the fingerprinting of both the husband and wife—right and left thumbs—which are placed on the margin of the consent sheet next to their respective signatures. This is done for the reason that most of our patients are referred and we have no proof that they come to us for the sole reason of the insemination. We do not know whether the man with whom the wife presents herself is the legal husband or not. Although the

CONSENT FOR ARTIFICIAL INSEMINATION

I, _____, residing at _____ of my own free will and volition have requested Dr. _____ to inseminate my wife artificially with the sperm of a male selected by Dr. _____. This request has been made with the full knowledge and consent of my wife whose authorization is hereto annexed. I am making this request because it is not possible for me to procreate and because both my wife and myself are extremely anxious to have a child and because our mutual happiness and the well being of my wife will be best served by this artificial insemination.

(L. S.)
On this _____ day of _____, 193____, before me came _____, to me known and known to me to be the person described herein and who acknowledged to me that he executed the foregoing consent.

I, _____, join in my husband's request above stated and hereby authorize Dr. _____ to inseminate me artificially with the sperm of a male selected by Dr. _____.

(L. S.)
On this _____ day of _____, 193____, before me came _____, to me known and known to me to be the person described herein and who acknowledged to me that she executed the foregoing consent.

[Fingerprints of both partners]

chances of deception are rather remote that a woman would know two sterile men in her acquaintanceship, the possibility exists. We insist on a physical examination of the man to determine his sterility independent of the history presented by the doctor who refers him. This is an added precaution, first, to make sure that the man presenting himself as the husband would not be able to have any of his own children and is actually sterile. A testicular puncture is made and the material obtained is examined microscopically. This is done in addition to the usual condom specimen obtained in diagnosing such cases. This definitely proves the man's sterility. The finger-printing of the examined man identifies him as the person presented by the woman as her husband. This establishes any misrepresentation by the woman as her guilt alone and does not implicate the physician. There might be a condition arising in which the real husband is opposed to having his wife artificially inseminated and she might use a ruse by introducing to the doctor some one willing to help her attain her wish. This makes it doubly difficult in that the man whom she would have to present would also have to be sterile.

Such a precaution in itself would defeat the majority of such situations. The consent sheet is signed in duplicate, notarized and witnessed. These consent blanks are then separated and placed respectively in the vaults of separate banks and forgotten unless a

legal complication should arise. These consents legitimize the child under our present laws and establish it as the legal heir of the family unit. It also acts as a mental binder on the husband, in that he knows he can never deny having authorized the creation of his wife's child.

One may by a stretch of the imagination surmise certain hypothetical situations that might arise. Supposing for some reason in about ten years after the birth of the child, the legal father should tire of his spouse and institute divorce proceedings. It would be very easy for him to obtain a divorce if these papers were not in existence in New York State, for all he need say to a jury would be "Gentlemen of the jury, I have been sterile for all my marital life and before marriage, and I can substantiate this statement by presenting evidence and also through the testimony of doctors who have examined me at frequent intervals." The jury certainly would believe him and would not believe what they would consider the apparently fantastic story of the wife. She would plead that her physician was dead and that he would have been able to say that her husband gave her special permission for such an arrangement. This would not be sufficient testimony to convince any jury of her sincerity and no jury in the world under these circumstances would hesitate to grant a divorce to the husband. However, if the husband knew that these papers which he signed years ago could be subpoenaed, whether the physician is dead or alive he would not even institute proceedings. To obviate this possibility, therefore, any physician entering this field should train a younger surgeon in the work, familiarizing him as to the whereabouts of the records and making necessary provisions so that in case of his death his successor can carry on, because the legal complications that might arise may be far in the future, perhaps after the child has reached its majority, in the case of inheritance of his father's real property. On the other hand the wife, in her turn, could plead in the court that she did not know what she was doing and had believed that her husband's spermatozoa were to be used. The husband might even plead the same thing and then the doctor would be in for a pretty lawsuit because the jury would naturally sympathize with the plaintiff. All that would be needed to prove their suit would be the testimony as to his sterility by a physician who examined the husband's secretions prior to the birth of the child.

There is little likelihood of the mother's ever bringing suit except in the event of cross-insemination when the surgeon allowed the identity of the donor to become known.

The mother's relationship to the husband is strengthened after the birth of a child obtained in this manner. Her admiration for his broadmindedness and for her personal consideration is limitless. The bitter years of disappointment of childlessness are behind her. She now has something which she desired most of all. She bends every effort to have the child please the man who is really responsible for the child's being. The mother's moral caliber must be of the very highest or she would never have reached a physician's office asking aid in her problem. The woman of low morality would have resorted to more natural means and would have prevented her husband from ever knowing of his sterility by bearing him one or more children by questionable sources.

The mother's relationship to the physician is of necessity one of utmost confidence and sympathy. The phy-

sician has already taken the precaution that the mother does not know who the donor is and she has consented to this arrangement legally in writing. Her curiosity is met with an assurance that he is exactly like her husband. This does two things: it blocks any future idle hours of conjecturing which may torture her and she concentrates, focusing her attention on the husband, where it should very properly be.

The husband, on the other hand, having been denied paternity, sublimates his feeling and raises the child even more carelessly than he would his own. He realizes that the child is a eugenic baby because the doctor has spent a great deal of time in procuring the right type of donor and that if he, as the father, gives the child the proper opportunities in life there is no limit to what he can develop him into. His respect for the mother has greatly increased. In the case in which the husband is anxious for an heir, she has consented to bear him a child under unusual circumstances. Then again, when the woman insists on entering into such an arrangement, the husband still feels that she is primarily bearing a child to make up for his deficit and would not have had to resort to this measure had he been normal. So the marital relationship turns out to be greatly strengthened.

The husband's relationship to the physician is, of course, the same as his wife's.

We now come to the question of the donor, protecting him as well as all others concerned against any possibilities of blackmail. The donor is required to deliver his specimen at a different address or apartment or at a different time than the arrival of the patient. Another simple method is to keep the two hospitalized during the period. We find this much easier. It eliminates the question of possibility of blackmail by the donor. He has no possible way of knowing who the recipients are and no one can learn the identity of the donor.

If the physician should consider it preferable for any reasons of his own to transfer the sperm in his office, and should the donor by any chance enter into collusion with a third party and have both entrance and exits of the office watched, there is little danger, because of the number of patients going in and out during office hours.

There is one more legal aspect to this question, and that is the donor's relationship to his own legal wife. It is preferable that the donor be married, as it eliminates a tendency to promiscuity. However, notarized permission from the legal wife stating that her husband may participate in this scientific venture is essential. We do not know but that such a venture on the part of a husband may be a violation of the laws against adultery. Therefore, as in New York State, if the wife is cognizant of the condition and has so signified in writing, she is unable to obtain a divorce on these grounds, as condoned adultery nullifies grounds for divorce.

It is with all these hypothetical legal entanglements well in mind that a specialist undertakes this type of work. The surgeon who does an artificial insemination should never become the obstetrician in the same case. The pregnant woman should choose another obstetrician in about the seventh month who is not familiar with the unusual circumstances of the pregnancy. He can in all good faith make out the baby's birth certificate under the direction of the parents and give that child a document irreproachable in the eyes of the law. The child is then established as the legal offspring. This may be a subterfuge but it is a necessary one. It is a protection for the child, and the responsibility of

the child is primarily the physician's. Morally the physician is bound to see that all possible unhappiness is avoided. It is easy to understand that when the child reaches adolescence, assuming that it is a normal unit in his own family, there would be great danger, if by some inadvertent remark the child should discover any irregularity in his creation. The damage to its psychology make up would be disastrous. An inferiority complex would be set up with a root that psychoanalysis could not destroy and the child's maladjustment to society would result.

We feel very strongly that the responsibility lies with the physician not only in the creation of the child but in its future welfare, particularly in its adjustment in its own family unit.

Another phase to the question arises when the sterile husband asks to have a relative be the donor. This should never be consented to. The usual request by the husband is that one of his brothers act as the donor because he is sure that the child would look like him. Genetically, of course, this need not be true. Psychologically this would be unsound, for if the mother should know who the actual father of her child was there would be danger of the transference of her affections to the brother, especially as he resembles her husband, particularly if he is single. If, on the other hand, he has a wife and child of his own, there would be the danger of breaking up two families if the feeling should be reciprocated. This is usually followed by a suggestion that the brother be used without the knowledge of his wife. However, as the brother or near relative may succumb to the human failing and tell her at a later date, causing extreme mental shock, this also is unwise. Furthermore, if he should be married, the brother could not be used without the permission of his wife, and this would entail many people knowing the situation, all except the wife. Legally, the brother's wife would have a case against both the doctor and her own husband, if she were not told and later discovered the fact. Under these circumstances, with so many knowing, the child would eventually be told. The husband then might naively suggest that his brother be brought to the office under some pretext and a specimen obtained which could be used on his wife, the idea being that the brother would not know anything about it. This, of course, is absolutely impossible for a physician to do under any circumstances, it being dishonest as well as unethical. Such a suggestion should be immediately refused and the idea of stealing impressed on them, because we regard this worse than ordinary thieving. If such a case should ever arise, punishment to a doctor participating in such a crime should be meted out in full. Further a relative should never be used as a donor, even with his permission, because at a subsequent date he might become so attached to the child that he would sue for custody of the child, and a jury would be inclined to favor him.

There have been recent cases in the New York courts in which an effort has been made to prove the paternity of the child through the determination of peculiarities of hereditary characteristics shown by blood grouping. This should also be considered in selecting a donor, choosing one whose blood group corresponds with that of the husband.

It would be well to bear in mind that a child born in wedlock is the legal heir unless his paternity is disproved and a "final adjudication is handed down by a court." Unfortunately the father in these cases does not wish to go through the formal legal adoption pro-

ceedings (although this would be a safeguard for the child to inherit his real property), for it would publicize the one thing he desires to conceal, namely, the cross-insemination of his wife. If the man feels uncertain that the child may be blocked from inheriting such real property as he wishes to leave it, as for instance in a case in which a wife, wishing to inherit all the money or control it, might seek to disprove the child as her demised husband's legal heir, he can draw a will stating that if any action is taken by any beneficiary the one so doing forfeits his or her share under the will. To make it even stronger he can insert a clause canceling any bequest to the wife should she marry within one year and a day from the date of filing the will for probate. Then the child's legality is protected as time for any legal action will have expired.

These are some of the many considerations of artificial insemination from the medicolegal point of view. Some suggestions are given to aid in avoiding some of the complications that may arise and so to prevent them from casting a shadow of unhappiness over the child we have helped create whose sole excuse for being is to bring happiness to an otherwise unhappy marriage.

53 East Ninety-Sixth Street

THE PRESENT STATUS OF CYSTOMETRY

D. K. ROSE, M.D.
ST. LOUIS

Cystometry¹ embraces more than bladder pressure more than vesical volume pressure. It is a sensory vesical volume pressure with sphincter control diagnostic procedure. As the bladder immediately accommodates itself to incoming fluid it is necessary to use a two-way catheter to provide a fluid intake as well as a recording compartment for the instantaneous return pressure to obtain a complete graph in the process of filling. This means, as nearly as possible an uninterrupted tracing of muscle contraction and relaxation of the bladder wall on which line sphincteric reactions, sensations of temperature, the first desire to void and degrees of overdistention can be noted. The relationship of volume pressure to sensation and sphincter control is often abnormal and is of more value in cystometric diagnosis than any one factor alone.

The clinical value of this procedure lies chiefly in its identifying the bladder to clinicians as an organ of practical physiologic importance in differentiating all types of neurogenic from physically obstructed bladders, so that treatment may have a better foundation and in offering bladder function tracings to explain symptoms and determine the results of treatment in dysuric bladders. Clinically in my experience, it quite alters the usually accepted view of bladder importance in prostatic and bladder surgery, particularly in relation to infection. It differentiates types of dysuria after surgery, childbirth trauma and disease or injury of the brain or spinal cord.

For experimental work undoubtedly a continuous graph is necessary,² but for clinical or bedside work

methods of interrupted readings, that is introducing 50 cc and then taking a reading, are satisfactory. It was the method used in the first cystometric work³ and the general ideas were verified and simplified by Muschat⁴ in developing his cystometer. With such methods however, the fine oscillations in pressure cannot be obtained, and in oscillations of wider excursion it is impossible either to take the reading exactly at 50 cc, for example, or to determine the type of oscillation as in cystometrograms in pyelitis of pregnancy⁵ or in the spina bifida work of Langworthy and Dees⁶.

Further as a most important adjunct in the efficacy of the procedure it was soon noted that obtaining a second tracing at each examination was absolutely necessary not to verify the first but to note on the second curve the influence of the first filling. In general the normal or irritable bladder is stimulated to decreased capacity and increased pressure while the low sensation type of neurogenic bladder shows diminished sensation with increased capacity after the distention of the first filling.

Flat or low pressure often noted in the first graph was thought to be due to breaking down or decompensation of the bladder wall, but I now attribute such readings, particularly in the first curve, to inhibition as well as to decompensation. That it was due to inhibition in some instances was first pointed out by Denny Brown and Robertson⁷ and later verified by Parker and Rose⁸. It is now accepted in our clinic that in the majority, initial low pressure tracings in the first two readings show that the case is of the non-neurogenic type although occasionally they show bladder wall decompensation, usually inhibitions are psychic from fear or reflex from instrumentation⁹. The differential diagnosis can be made only by doing at least two fillings in the first cystometric examination.

Lewis, Langworthy and Dees¹⁰ point out that injury to the motor pathways renders the consequent frequent small amplitude waves of bladder contraction "ineffective in emptying the bladder." The stretch reflex of the muscle of the bladder wall, they point out is hyper-

Chart 1—Typical cystometrogram showing delayed sensations and the effects of the first filling in an anesthetic low pressure bladder in that the second curve shows greater capacity, diminished sensations and lower pressure than the first curve. In other words the first filling breaks down the resistance of the bladder wall which secondarily influences the sensations. The asterisk in these charts indicates the first desire to void.

active "with release of cortical control." Muschat⁴ places the sensation of a first desire to void above 250 cc in the hypotonic and under 150 cc in the hypertonic bladder. I believe that correlation of points such as these, together with observation of the behavior of

the sphincters in their cystometric interpretation, will be enhanced by taking two readings instead of one

The two types of imperfect sphincter control causing incontinence to be noted are whether the fluid is expelled as a voiding or whether it slowly leaks out around the catheter. The position of the catheter in its relation to the body points definitely to the status of the voluntary sphincter.⁹ If it approximates a 90

Completely contracted bladders back of traumatic or congenitally deficient outlets challenge an attempt to influence their innervation and so restore, at least an increased volume, a low pressure acceptable

I favor the opinion that sympathetic and parasympathetic action or function is present but that such an anatomic division cannot be correlated with function, that is that the sympathetics in their principal anatomic distribution are by no means alone the nerves of bladder filling nor the parasympathetics the nerves of bladder emptying. It is important to establish this as it influences such surgical procedures as presacral nerve resection.¹²

There are pain, some bladder dilator but many con-tractor fibers in the sacral nerve supply (parasympathetics) as well as in the hypogastric (sympathetics) nerve supply to the bladder. It has been demonstrated that, with complete section of the spinal cord below the sympathetic supply to the bladder, stimulation of a sacral somatic area can produce reflex inhibition of bladder contraction.⁶

Chart 2—The patient had 900 cc of uninfected residual urine removed just previous to the taking of the cystometrogram. Retention was secondary to prostatic hypertrophy. A hypertrophic wall is demonstrated by the steeply ascent after the sensation of fullness (F). The relationship of manner of rise of pressure to 520 cc in curve 1 and to 270 cc in curve 2 suggests inhibition in 1. The decompensation is physiologic that is, back pressure anesthesia or adaptation with an anatomically thickened bladder wall. In such a bladder I have come to expect about this degree of reaction to the first filling. These deductions would be impossible from a single cystometric curve.

degree angle with the body there is spasm or an increased sphincter resistance. If it parallels or drops below the plane of the body, it shows a diminished resistance. This mobility of the posterior urethra is an important factor in sphincter control. It is essentially a disalignment of the internal and external sphincter openings⁹ and occurs in both males and females. It is less forceful in the latter.

The main subdivisions of cystometric interpretation are myogenic and neurogenic and their interrelationship. When an altered reaction, primary in the musculature, is secondary to scar infection overwork, obstruction or trauma it is considered myogenic. When the changes are primary in the nervous system with consequent alteration in the function of the wall of the bladder, it is considered neurogenic. In these instances the neurogenic changes may be of the wall itself or of the sphincters, considered the "bladder lock" by Muschat.³ In this regard it is to be hoped that the sphincterometer developed by Simons¹⁰ will be of help. The neurogenic changes may be either an increase or a decrease of irritability and tone of either the bladder wall or its sphincters. They may be either directly central or peripheral or entirely reflex.

Any increased resistance by the outlet causes a hypertrophy of the bladder wall to a point sufficient to overcome the obstruction. This process is gradual and its degree can be interpreted by the cystometrogram. Should the bladder wall break down or decompensate back of an obstruction¹¹ that is, allow a residual urine to occur, it would compensate rapidly on catheterization in the myogenic and slowly in the neurogenic particularly if there should be marked diminution in sensation. In the hypertrophic bladder, removal of the catheter drainage without removal of the obstruction leaves a small capacity, high pressure, traumatized and so absorptive surface.

In cases of dysuria in the presence of a normal central nervous system, this reflex inhibition is clinically important. It plays its part in postoperative and postpartum retentions. It can also be associated with extraneous trauma even with a fractured hip. For example, should a person suffer such an accident and soon after develop a retention with overflow yet give a history of no dysuria previous to the injury from a cystometric analytic standpoint as long as the patient is comfortable our cue is watchful waiting on the ground that it is a reflex low pressure retention. With an uninfected urine and normal kidney function and the knowledge that this reflex inhibition will disappear it is best to leave him just as the accident found him. Should the bladder remain overdistended with paradoxical overflow too long after the accident a single catheterization to compensate or contract and thicken the bladder wall may be indicated, delaying it in the hope that an infection can be avoided.

Psychic influence is one of inhibition, and recently it has been demonstrated that even in markedly irritable bladders voluntary inhibition can be demonstrated on the cystometric chart. Section of the cord above the bladder supply removes this psychic inhibition,⁶ for example, in a patient with some senility whose cerebration is further and rather abruptly interfered with by toxicity. If such an individual has a hypertrophic or compensated bladder wall, when the inhibition disappears urine may either drip constantly or spurt frequently in small amounts, owing to the continued contraction secondary to the release of inhibition. In such instances catheterization would only increase or

prolong incontinence by further contracting and irritating the thickened and released bladder wall. I believe that nocturia, frequently the first symptom of prostatic hypertrophy, is due to the release of inhibition by sleep plus the increased strength of contraction of the bladder wall, compensated to the early obstruction.

Neurogenic bladders, by the aid of cystometrograms, can be studied with interest and classified to some extent. The procedure in these attempts is supplemental only. The greatest value lies possibly not in locating the lesion of the central nervous system but in demonstrating its effect on the bladder function and so enabling the clinician to wait with safety or to institute the proper procedure from the point of view of obtaining drainage of urine or infection.

In classifying neurogenic bladders cystometrically, whether the lesion is of the brain or cord or is peripheral, one must simplify it to terms of bladder function, that is, alteration of tonus of the bladder wall and outlet and the possible effects of one on the other, together with associated sensation. Opposing action of the bladder wall and internal sphincter as to contraction and dilatation is one unit, but their alteration in tone may associate with or be diametrically opposite to that of the voluntary, external sphincter. The latter is more complex than the action of the internal sphincter, comprising as it does direct urethral compression within the triangular ligaments as well as mobility of the prostatic urethra. Innervation of the skeletal muscles of the voluntary sphincter is by the pudic nerve.

On rare occasions pudic nerve neuritis is diagnosed on the basis of a spastic, irritable urethra and bladder without infection or other causative factor being demonstrable.

Considerable excellent work has been done in the past few years both on cystometry and on bladder physiology. It is work that, in time and with its better

correlation, will give final and secure information, which can be used in cystometric interpretation.

Langworthy and Dees,⁴ using their continuous record method, feel that it is possible to distinguish posterior from anterior root damage. The work done in spina bifida is based on the type of curve they obtain between the intermittent fillings of the bladder with 50 cc of fluid. In this connection they stress that the mercury manometer is not as satisfactory as water. This adds a new principle, something more akin to the electrocardiographic

Chart 4—Three tracings taken at one sitting demonstrating the type of bladder function occurring with cortical control release due to toxicity in an individual with an early prostatic hypertrophy and a hypertrophic wall previously established.

tracing, and deserves further study. They feel that large atonic bladders are due to injury of the posterior spinal roots. The statement of Denny-Brown and Robertson⁵ that apart from the faint background of maintained tonic activity spontaneous vesical activity takes the form of waves of contraction appearing in rhythmical progression lends hope that the type of the wave in a cystometrogram may be of diagnostic importance.

Cystometric determinations of brain tumors offer interesting speculation. We are assured of the inhibitory influence of the cerebrum. This can easily be proved by asking a patient to inhibit while a cystometrogram is being made.⁶ It can be shown that the effect of removing this inhibition is, in general, decreased bladder capacity, if one remembers always to consider any complicating myogenic factor in making these observations.

Chart 5—The two curves represented in 4 are bladder tracings in a 10 year old boy with spina bifida with a complete sacral anesthesia posterior urethral anesthesia and a slightly spastic anal sphincter which on stimulation by palpation, opens actively and remains in dilatation of increased tonicity. Besides spina bifida the child has a hydrocephalus of mild degree, probably associated with an early operation for spina bifida, congenital dislocation of both hips and club foot. There was constant incontinence so that orthopedic surgery was impossible. Hydraulic distention had been carried out once a day for a week when B, as represented by the last two curves was obtained. The patient had a tremendously spastic bladder which remains the pressure is still high but the capacity is definitely increased. Associated with this bladder function incontinence practically ceased so that orthopedic surgery was possible on the hips.

Watts and Uhle¹³ conclude that "abnormalities of bladder function, tone and sensation in patients with brain tumors are probably the result of a disturbance of bladder representation in certain parts of the brain and present evidence of 'bladder representation' in the cerebral cortex, the region of the hypothalamus and even more caudal in the brain stem."

Enough work has been done to give promise to future endeavor or to associate alteration in bladder function with specific brain disorder. As yet, however, in this regard the cystometer helps in the greatest degree in analyzing the change in bladder function so that it may be treated more intelligently.

3720 Washington Boulevard

ABSTRACT OF DISCUSSION

DR LLOYD G LEWIS Baltimore My co worker Dr Orth 110 R Langworthy was able to show experimentally that the urinary bladder is controlled by reflex arcs in the brain and spinal cord and that nuclei exist in the cerebral motor cortex and in the midbrain. By cystometric studies he showed the effects produced by interruption of either the motor or the sensory pathways in the brain and spinal cord. These are fundamental conceptions. Based on this experimental evidence, we set out to study the effect of isolated neurologic lesions.

¹³ Watts J W and Uhle C A W Bladder Dysfunction in Cases of Brain Tumor A Cystometric Study J Urol 34:1030 (July) 1935

on bladder function in man. Last year it was my privilege to demonstrate before this section cystometric graphs in lesions of the motor pathways. This picture is nearly complete. We have continued to study the effects of sensory and complicated lesions of the brain and cord. We believe that it may be possible by correlation of data to know the neurophysiology of bladder control. I believe that Dr. Rose will concur that a cystometric study cannot replace a careful neurologic examination. A thorough neurologic examination is indispensable for the interpretation of cystometric data. The cystometric study does not obviate the necessity of performing complete urologic examination. We have used the cystometer to aid in the differential diagnosis between malfunctioning bladders produced by obstruction and neuropathology. But the cystometer is of paramount importance in the differentiation of neurologic lesions themselves. Is the lesion on the motor or the sensory side of the reflex arc? At what level are the arcs interrupted? What effects may drugs have on vesical function? Can relief of symptoms be expected by an operative procedure? These questions can possibly be answered by the aid of cystometry. In our simple laboratory and clinical equipment we have put up with clumsiness and inconvenience for the sake of graphic representation of every slight variation in bladder pressure. Dr. Rose should be congratulated on first devising a cystometer with a graphic recording apparatus. We prefer the water to the mercury outfit. We have tried both continuous and interrupted methods of filling using both two-way and single catheters. We discarded the continuous inflow method because we found that two consecutive readings did not correspond. Dr. Rose's interpretation of these observations demands consideration, but we believe that interrupted filling by 25 or 30 cc. increments gives added information by allowing us to study the stretch reflex. In upper motor neuron lesions, striated and bladder muscles behave alike in their response to sudden stretch, and hyperactive reflexes are obtained. There is no typical syphilitic bladder, there is no typical spina bifida bladder, there is no typical bladder involvement produced by transverse myelitis or brain tumor. The bladder abnormality depends on sensory or motor tract involvement.

DR. A. LLOYD STOCKWELL, Kansas City. No. Cystometry offers the most practical method to determine the normal or variations from normal filling of the bladder with urine under controlled conditions. Its limitations are largely lack of experience of the observer and obtaining accurate readings. Ever since Mosso and Pellacani first recorded, in 1882, fluctuations of the filled bladder on a smoked drum studies on the bladder, particularly by the great investigators Rehlfisch, Adler, O. Schwarz, Samuel Amberg, Muschat, D. K. Rose and particularly Langworthy and Cobb and Lewis, have made common knowledge the various expressions which the bladder registers against increasing distention in various normal and abnormal conditions. The outstanding work, however, is that of Denme Brown and Graeme Robertson, in which the fundamental statement is made that to understand anything about the abnormal functions of the bladder one must first understand and determine how the bladder that has some degree of autonomy is still subjugated to the control of the will. I have been investigating bladder incontinence in children for the last year and a half, using a cystometer sphincterometer of my own design that utilizes a two-catheter principle. It has produced results enabling me to increase accuracy in diagnosis and therapy for the child when he presents himself for relief of incontinence. The important fact about bladder control is that an enuretic individual has to learn to develop an inhibitory control. In other words vesical control in the conscious (awakened state) or subconscious (sleeping state) is largely an inhibitory effect of the reactions of vesical distention. When interpreting cystometrograms one must consider the position of the patient and fluctuation of psychologic factors at the time of examination and must correlate the desire to void, appreciation of temperature, the total curve, appreciation of discomfort and distention, and intactness of the sphincter or its lack of intactness at capacity. Evaluation permits a fairly accurate idea of intactness of central nervous system pathways, peripheral paths and local neuromogenic factors.

DR. RICHARD CHUTE, Boston. To the urinary surgeon the practical importance of cystometry is the ability to be able to

decide between a neurogenic bladder and prostatic obstruction. Just about once or twice a year I have a case in which it is very hard to tell whether it is a neurogenic bladder or prostatic obstruction. The muscular tone of the bladder may have been broken down by a prolonged losing fight against prostatic obstruction, with a mounting residual urine, and it may act like a neurologic bladder, and I think that the only way one can surely differentiate is by a neurologic examination, including cystometry, with possibly the use of drugs such as meclochol. Cystometry will tell the difference between a neurogenic bladder and prostatic obstruction and will prevent operations for prostatic obstruction in a case of neurogenic bladder. I saw a man of about 60 who had had an abdominoperineal resection of the rectum for carcinoma. Not long after this he developed complete retention. One couldn't feel his prostate, of course, and by cystoscopy one couldn't tell. Through cystometry it was found that he had a neurogenic bladder and that there was no purpose in taking out the prostate, as had been recommended by another urologist.

DR. D. K. ROSE, St. Louis. It is a great pleasure to have this discussion. I think the work of Dr. Lewis has been a most valuable contribution. It is more of that type of work that is going to supply data on which to develop cystometry.

GROSS HEMORRHAGE FROM PEPTIC ULCER

ITS MORBIDITY, MORTALITY AND TREATMENT

LEON GOLDMAN, M.D.
SAN FRANCISCO

Many physicians believe that hemorrhages from peptic ulcer are rarely fatal. The potential dangers of this condition, therefore, are not fully appreciated. If one concludes, from his individual experience, that gross hemorrhage from peptic ulcer is rarely or never fatal, one is likely to offer a good prognosis, adopt a laissez faire policy and wait for the bleeding to stop. The records of pathologists, coroners and large city hospitals, however, show that the mortality of this complication is much higher than is generally believed.

For the purpose of arriving at a better understanding concerning the management of these patients, a study was made at the San Francisco Hospital of the 1,025 entries of 890 patients with peptic ulcer, from Jan. 1, 1928, to Dec. 31, 1934. Three hundred and forty-nine patients (38 per cent) entered the hospital because of gross hemorrhage from peptic ulcer¹ or developed this complication during the period of hospitalization. Of this number, thirty-nine (11.1 per cent) died of exsanguination while an additional seventeen (4.9 per cent) died of conditions associated with the bleeding, such as perforation of the ulcer, pneumonia and cerebral or cardiac thrombosis, thereby bringing the total mortality of gross hemorrhage from peptic ulcer to 15 per cent. The reason for this apparently high mortality will appear later.

As bleeding peptic ulcer is not uncommon, such figures indicate the need for careful consideration of the problems involved.

From the Department of Surgery, University of California Medical School (the University of California Service at the San Francisco Hospital).

Read before the Section on Surgery, General and Abdominal, at the Eighty-Seventh Annual Session of the American Medical Association, Kansas City, Mo., May 13, 1936.

The term gross hemorrhage in association with peptic ulcer refers in this discussion to the vomiting of bright red or dark blood or the presence of tarry stool in addition to secondary anemia sufficient to produce weakness, pallor, dyspnea or rapid pulse. Patients with blood streaked or occasional coffee ground vomitus, occult blood in the stool or rare tarry stools are not included in this definition as these are considered merely as signs of the activity of the ulcer.

PATHOLOGIC ANATOMY

By its very nature, it must be assumed that an ulcer which erodes a blood vessel and produces a gross hemorrhage is active and progressing. Ulcers in the stomach or along the anterior wall of the duodenum are more likely to heal early than those in the posterior wall of the first or second portion of the duodenum. The latter show more tendency to become chronic and to cause severe bleeding. The invasion of the retro-duodenal and pancreatic tissue by an ulcer in the posterior wall of the duodenum causes an inflammatory

process with adhesions to the periduodenal structures, thereby holding the ulcer open and enhancing chronicity. Fatal hemorrhage usually is caused by erosion of a large artery along the posterior wall of the first or second portion of the duodenum where it overlies the pancreas. In

Chart 1—Mortality percentage of all peptic ulcer cases by age groups

advanced cases, the bed of the ulcer is found in pancreatic tissue and the wall of the duodenum has been destroyed. In the crater there is a large sclerotic artery, running longitudinally or perpendicularly into the ulcer. In the chronic cases the arterial wall is surrounded by a variable amount of granulation or scar tissue, which assists in holding the artery open so that the lumen gapes and often will admit a fair-sized probe. The age of the patient is not necessarily an index of the inelasticity of this artery, as there is some evidence to suggest that the presence of chronic inflammation may produce arteritis or periarteritis and rigidity of the local vessels. In a smaller group of fatal cases, superficial ulcers are present with erosion of the submucosal vessels. Occasionally small granulating ulcers are found which, in the absence of other demonstrable cause must be assumed to be the source of the fatal hemorrhage.

The gastroduodenal artery, a branch of the hepatic artery, bifurcates, forming the right gastro-epiploic and the superior pancreaticoduodenal arteries. The latter vessel usually is the one involved in duodenal ulcer, because it supplies the area most commonly affected. The inferior pancreaticoduodenal artery is a branch of the superior mesenteric artery, and the vascular anastomosis behind the duodenum is so diffuse that it is unlikely that bleeding can be controlled except by the ligation of all these vessels. Bleeding from a gastric ulcer usually arises from one of the coronary vessels of the lesser curvature because the vessels lie between the layers of the lesser omentum closely applied to the wall of the stomach. Severe bleeding from ulcers of the greater curvature is rare because of the infrequency of benign ulcers at this site and the fact that the gastro-epiploic artery is not in direct contact with the wall of the stomach.

SYMPTOMS

The symptoms and signs of gross hemorrhage from peptic ulcer vary with the volume and rapidity of the loss of blood which usually, although not always, corresponds to the size of the artery eroded. Exacerbation or recurrence of the symptoms of ulcer usually immediately precedes the onset of hemorrhage. Occasionally however bleeding occurs suddenly in the patient who has been without symptoms for a long

time, or even in the patient with no history of such symptoms. Dietary indiscretion or indulgence in alcohol may immediately precede the onset of the hemorrhage. Nausea usually is the first symptom and may be followed by the vomiting of dark red, liquid or clotted blood, and by fainting. Either hematemesis or tarry stools may occur alone, or both may occur, whether the ulcer is in the stomach or in the duodenum. Tarry stools may not be present for some time after the hemorrhage although, if it is severe unchanged blood may be expelled from the rectum soon after the initial hemorrhage. Shock ensues after severe hemorrhage with a marked fall in blood pressure, rise in pulse rate, cold perspiration, and pallor. The extent of the hemorrhage cannot be judged early in its course by the hemoglobin or red blood cell count, as the loss is quantitative and not qualitative. It is not until the volume of the blood is restored by fluids from the tissues or by parenteral administration, that the drop in hemoglobin and red blood cell count becomes evident. In estimating the severity of the hemorrhage, therefore and determining whether or not it has been controlled one should be guided early in the course by the blood pressure and later by the hemoglobin and red blood cell count as well as by the pulse rate, stool, and general condition of the patient. Gross hemorrhage from peptic ulcer must be differentiated from other causes of gastro-intestinal hemorrhage such as ruptured esophageal varices, carcinoma, polyps or hemorrhagic diathesis.

MORBIDITY AND MORTALITY

There is obvious difficulty in evaluating statistical reports concerning peptic ulcer especially as regards the bleeding type. That such difficulty exists is shown by the variation in statistics from different clinics. Eggleston² reported copious hemorrhage in 19 per cent of 500 patients with peptic ulcer and this was present in 17 per cent of gastric and 14 per cent of duodenal ulcers in W. J. Mayo's³ series. Balfour⁴ reported the incidence of hemorrhage in 25 per cent of all patients with duodenal ulcer, followed over a period of ten years. Paterson⁵ found severe or recurrent gross hemorrhage in 30 per cent of all patients with ulcer. The incidence in Crohn's⁶ series was 29.5 per cent in gastric and 19.5 per cent in duodenal ulcer while Hurst and Stewart⁷ encountered 18 per cent in gastric and 19.5 per cent in duodenal ulcer. They as well as Crohn concluded that the incidence of gross hemorrhage in patients who are hospitalized is approximately 25 per cent while, if the ambulatory or outpatients are included the incidence is about 10 per cent.

Chart 2—Incidence of gross hemorrhage by age groups

Reports from several hospitals indicate that it is not infrequent for patients with peptic ulcer to bleed to death. Chiesman⁸ gave the mortality as 25 per cent of those patients having severe gross hemorrhage. Ross⁹ of Melbourne reported 58 per cent of deaths in forty-three cases of severe bleeding peptic ulcer. The mortality in Allen and Benedict's¹⁰ series was 14.5 per cent

Chart 3—Mortality from gross hemorrhage by age groups

in 138 cases of sudden, massive duodenal hemorrhage. They believed the age of the patient and the presence of arteriosclerosis to be the most important prognostic factors. According to Lahey's¹¹ experience in his private hospital practice 5 per cent of patients with gross hemorrhage died in the hospital before they could be prepared for surgical treatment.

Hurst and Stewart, as well as Crohn, felt that the greater number of deaths occurred from the original brisk hemorrhage and that, if it did not cause death, subsequent bleeding would be relatively safe. Reports from other clinics, however, do not support this observation.

EXPERIENCE AT THE SAN FRANCISCO HOSPITAL

The San Francisco Hospital, a city hospital, cares for varied groups of patients, many of whom are in poor social and economic circumstances. These patients enter the hospital for urgent or emergency treatment. Because of the difficulties they encounter in following adequate therapy, the majority of those with peptic ulcer enter this hospital because of some serious complication. A very high incidence of hemorrhage can therefore be expected in this group. These statistics are from hospital patients of whom only a few returned for follow-up care.

During the seven-year period from Jan 1, 1928 to Dec 31, 1934, patients with peptic ulcer made up 11 per cent of all the hospital entries. Of this group of 1,025 entries (890 patients) 349 patients, or 39 per cent, entered because of gross hemorrhage, or this complication ensued after admission. 209 or 23 per cent, entered because of perforation of a peptic ulcer, and 332, or 37 per cent, entered because of obstruction, for medical care or for other reasons.

In a study of seventy-three cases of gastric and 165 cases of duodenal ulcer, proved by x-ray examination, surgery or autopsy, we found that in the former, 64 per cent had hematemesis, 65 per cent had tarry stools, and 31 per cent had both. Of the duodenal patients, 50 per cent had hematemesis, 84 per cent tarry stools, and 34 per cent both. In general it may be said that tarry stools occur more often and hematemesis occurs less often in duodenal ulcer, but in a given case, one cannot conclude from these factors alone on which side of the pylorus the ulcer is.

The total mortality of patients with ulcer was 17 per cent (chart 1), increasing in direct proportion to the age of the patient, that of patients with perforation, both operated on and not operated on, was 32 per cent, the mortality rising with the number of hours elapsing before surgery. The mortality of gross hemorrhage was 11.1 per cent from exsanguination alone but rose to 15 per cent when the deaths from complications associated with hemorrhage were added. It should be emphasized in this connection that the additional 4.9 per cent mortality includes six patients in whom perforation ensued following the onset of hemorrhage, thus presenting two serious complications. Autopsy showed that in three of these patients an ulcer in the posterior wall of the duodenum had extended laterally in a circumferential manner and had perforated into the peritoneal cavity. Such evidence refutes the common impression that bleeding ulcers do not perforate. The remaining eleven patients of this group died of pulmonary, cardiac, cerebral or renal complications. We feel that these cases should be included in the mortality statistics, but, because the hemorrhage was apparently controlled in most of them, they are classified separately.

The incidence of gross hemorrhage reaches its peak during the fifth decade and seven tenths of the hemorrhages occur after the age of 40 years (chart 2). In considering the mortality from gross hemorrhage by age groups only those patients who were exsanguinated as determined by autopsy or those who died without other cause of death being specified, were included in our study. In all of these the hemoglobin was below 30 per cent and the red blood cell count below two million; there were, in addition, signs of syncope and clinical evidences of bleeding. The average age of the patients who died was 54 years and the highest mortality was between the ages of 40 and 70 years when arteriosclerosis plays a part (chart 3). Of this group 70.6 per cent showed evidences of arteriosclerosis. Of the patients who

died of exsanguination approximately twice as many had duodenal ulcer as had gastric ulcer.

Chart 4 showing the mortality in relation to the number of hemorrhages demonstrates an abrupt rise in the mortality after the second hemorrhage. Approximately 40

Chart 4—Known number of gross hemorrhages and mortality

per cent of these patients had had at least one hemorrhage before the onset of the illness for which they entered the hospital. This chart shows the mortality from hemorrhage alone as well as that from the complicating causes of death such as perforation, pneumonia, cerebral thrombosis and cardiac disease, though the bleeding ceased before death occurred.

The presence of a single gross hemorrhage or of recurrent hemorrhages indicates that the ulcer is not likely to heal under medical treatment. Jordan and Kiefer¹² found that, in 30 per cent of patients with a history of one gross hemorrhage from a peptic ulcer

bleeding recurred within two years after medical treatment was instituted. In patients with a history of two hemorrhages before treatment, the incidence of recurrence was 63 per cent within two years. In a five-year follow up of all their patients with duodenal ulcer they found that symptoms recurred in 54 per cent and concluded that gross hemorrhage was one of the chief signs that the ulcer probably would not yield to medical treatment. Repeated hemorrhage therefore, means that the ulcer is likely to be intractable to medical treatment, that it will show little tendency to heal permanently under conservative treatment, and that, consequently, surgery is indicated.

TREATMENT

The immediate treatment of gross hemorrhage from peptic ulcer is essentially a problem both for the internist and for the surgeon, requiring close cooperation between them. By an understanding of the basic principles of therapy, hemorrhage might be controlled in a greater number of cases. Opinion is divided about many aspects of the management of such patients, but experience in the University of California Surgical Service at the San Francisco Hospital has led us to conform, in general, to the following plan:

- 1 The patient should be kept absolutely quiet in bed and, if shock is present, should be treated accordingly. As complete immobility as is possible should be maintained.

- 2 Morphine should be given in large enough doses to bring about mental and physical rest as well as to allay gastric peristalsis. It may be used in conjunction with atropine for the first few doses in an attempt to relax the muscularis and inhibit the formation of gastric secretions.

- 3 Frequent determinations of the blood pressure, hemoglobin and red blood cell count should be made during the critical stages.

- 4 Food by mouth should be withheld. As long as the patient is ingesting material into his stomach, gastric peristalsis is stimulated and, with the stimulation of peristalsis, permanent clot formation is attained with difficulty. The taking of food likewise stimulates the secretion of gastric juice, which is undesirable. Alkaline powders, however, may be administered. Feeding should be resumed only when there is conclusive evidence that the hemorrhage has stopped and has not recurred for at least forty-eight hours, as evidenced by the increasing blood pressure, the lowered pulse rate, rise in hemoglobin, and the general appearance of the patient. If the hemorrhage has ceased, small feedings may be instituted and gradually increased to a full Sippy regimen.

- 5 During the first twenty-four to forty-eight hours, parenteral fluids should be withheld in order not to decrease the viscosity of the blood. We give no fluids intravenously, except blood, during the active bleeding phase as the rise in blood pressure may stimulate further bleeding. After the first day or two saline solution with or without dextrose, may be given by subcutaneous infusion or rectal drip.

- 6 There are many contradictory opinions concerning the values and dangers of the transfusion of blood, and some feel that it is better not to transfuse for fear of raising the blood pressure and causing further bleeding. Though in our series only 5 per cent of the patients who died from bleeding peptic ulcer had received transfusions of blood we recommend this procedure for the

reasons to be set forth. In our patients who died, the average length of life after the onset of bleeding was four and one-half days. In other clinics where transfusions have been used more freely, the average length of life was sixteen days. These comparative figures suggest that many hemorrhages can be controlled by transfusion. Allen and Benedict reported that in their opinion the transfusion of blood aided in checking the hemorrhage far more often than it started bleeding again, they advocated the transfusion of 300 cc of citrated blood when the systolic blood pressure dropped below 70 mm of mercury. Hurst and Stewart agreed that all patients should have the benefit of transfusions when the hemoglobin dropped below 40 per cent. In deciding whether or not a patient requires transfusion after an initial hemorrhage, Lahey estimates whether that patient could withstand another such hemorrhage. If it seems that a second hemorrhage probably would be fatal, the blood stream is replenished at once.

In our opinion, therefore, when a patient continues to bleed after adequate medical treatment, the slow administration of from 200 to 300 cc of blood should be instituted before his blood pressure, hemoglobin and red blood cell count reach a hazardously low level. The beneficial effect on the anoxemia as well as on the mechanism of coagulation outweighs the possible dangers of transfusion. Obviously a suitable donor should be available at all times, as the patient may suddenly bleed considerably while under observation. The use of transfusions during the later stages encourages more rapid convalescence.

- 7 In our experience, the administration of so-called coagulants, such as thromboplastic substances or calcium, has no effect on the hemorrhage. The administration of epinephrine or astringents by way of a stomach tube probably has no effect if the bleeding is very severe.

- 8 Gastric lavage during bleeding from peptic ulcer has been advocated by some, but we feel that this should be reserved for those patients in whom the stomach becomes distended by the accumulation of blood clots. The tendency of lavage to break up a fresh clot and provoke further bleeding is too great to justify the use of this measure in a routine way.

If the foregoing regimen fails to stop the hemorrhage and bleeding persists or recurs while the patient is still fasting, we believe that early surgical intervention is indicated.

The prognosis for recovery on conservative treatment is poor in patients who continue to have serious hemorrhage or in whom repeated hemorrhages occur in spite of proper medical treatment (including the transfusion of blood). This is especially true in the patient over 40 years of age. One would like to defer surgery, if possible, in such cases, but it is probable that some form of surgical intervention will be necessary if the patient's life is to be saved.

Judgment of each case on its own merits is essential. The patient in question may have only a 20 to 30 per cent chance of surviving under further conservative treatment. One can reasonably assume that he is bleeding from a large artery, and the longer one waits the less his chance of survival will be. Three patients in our series were operated on too late during the acute bleeding phase—ten days or longer after the onset—with 100 per cent mortality. After from one to two weeks of intermittent or continuous bleeding, trans

fusions afford very temporary benefit and the patient is poorly nourished has a poor coagulating mechanism and is a poor surgical risk. For all these reasons we urge earlier surgical treatment in this type of case.

If operation is done during the phase of acute bleeding a direct attack on the ulcer is advisable in most cases. If the ulcer is in the stomach the vessels on all sides should be ligated and the ulcer sutured, or, if the patient's condition permits it should be excised and gastro-enterostomy performed. In the treatment of duodenal ulcer, excision may be impossible since many of these ulcers are on the posterior wall of the duodenum. Because of the higher incidence there, ulcer of the duodenum should be suspected if the stomach appears to be normal. The operation devised by Allen and Benedict is the procedure of choice when surgery is indicated for bleeding duodenal ulcer during the acute phase. The stomach is transected between clamps at the prepyloric region, and the duodenal end is elevated. The blood vessels entering the ulcer are ligated outside the duodenal wall and the duodenal end is turned in. An anastomosis is then performed between the stomach and the jejunum. This affords the greatest protection against recurrence of the ulcer or subsequent hemorrhage. Suturing the bed of the ulcer in the posterior wall of the duodenum is not practical because of the friability and fixation of the inflamed tissue. It is at such a time that one's surgical judgment must be the deciding factor. Gastro-enterostomies have been done during the acute phase, with cessation of hemorrhage, when attacking the ulcer directly did not seem feasible. In a high percentage of cases in which this method is used, however, recurrence of the hemorrhage takes place.

We feel that, in the case of a first hemorrhage the patient should be given a chance for relief under medical care unless he was following a strict regimen at the time the bleeding began. If hemorrhage recurs, however, surgery is indicated during a quiescent state. Even though transitory healing has taken place and roentgen examination after from three to four weeks of medical care fails to demonstrate the presence of an ulcer, the lesion may recur at the same site. At operation during such a stage, only a small dimple may be seen at the site of the previous erosion.

When the operation for bleeding peptic ulcer is done in the quiescent stage rather than during a phase of active bleeding, the procedure of choice if the patient's condition and other factors permit it is removal of the area around the ulcer by partial gastric resection with anastomosis of the proximal portion of the stomach to the jejunum. This procedure removes the vulnerable portion of the duodenum and brings about such profound changes in the gastric physiology that the mechanical and chemical factors which were chiefly responsible for ulceration are more or less completely and permanently controlled thereby offering freedom from recurrence in the majority of cases. Indirect procedures such as gastro-enterostomy or pyloroplasty are followed by a relatively high percentage of recurrences as well as by the added danger of gastrojejunal ulcer but the operative mortality is relatively low. The direct procedure of partial gastric resection on the other hand carries a higher mortality but a lower incidence of recurrence. Many times induration and inflammatory reaction about the duodenum cause difficulty in its inversion. In such cases it is probably advisable to allow the ulcer to remain and to transect the duodenum proximally, ligate the vessels and per-

form a gastric resection. Surgical judgment of all the factors involved must determine the procedure to be undertaken.

SUMMARY

A study of the cases of bleeding ulcer at the San Francisco Hospital reveals a higher mortality than was previously supposed. Death occurred rarely below the age of 40 years but was not infrequent between the ages of 40 and 70 years. Arteriosclerosis is an important factor affecting the incidence and mortality of this condition. Death from bleeding duodenal ulcer is twice as common as from gastric ulcer because of the higher incidence of duodenal ulcer and its tendency toward chronicity. Repeated hemorrhage shows a rising mortality with each attack indicating that the ulcer is likely to be intractable to medical treatment and hence surgery should be considered. Early direct surgical attack on the ulcer should be considered for the patient in the sclerotic age who continues to bleed from a peptic ulcer while under adequate medical treatment—including transfusions.

Room 111, University of California Hospital

ABSTRACT OF DISCUSSION

DR. S. L. LEDBETTER JR., Birmingham, Ala. Dr. Goldman reports 1025 entries of 890 patients with peptic ulcer, and of this number 349 patients (or 38 per cent) entered the hospital because of gross hemorrhage. Of 603 cases in a series in Birmingham of the past three years forty-nine patients (or 81 per cent) were admitted on account of massive hemorrhage thus showing a much smaller percentage than he reports. Dr. Goldman's statistics show that 23 per cent of all ulcer patients entered because of perforation, while 18.5 per cent of the Birmingham patients entered on account of perforation. His records show that massive hemorrhage is much more common than perforation, while our records show that perforation occurs over twice as often as massive hemorrhage. I do not know how to explain this unless it is due to the fact that the type of ulcer seen in our locality is smaller and less extensive. American surgeons visiting abroad report that the type of ulcer seen there is much more extensive and accompanied by more infiltration and inflammation than ulcers seen in this country. The ulcers that I have seen have almost all been small duodenal ulcers with a tendency toward perforation rather than toward hemorrhage. As Dr. Goldman reports 11 per cent of deaths from exsanguination from the records of the San Francisco City Hospital, I was interested in comparing statistics from the private hospitals here with those from our local county hospital. Several of our leading internists have not had a private patient die from massive gastric hemorrhage. During the past three years in our local county hospital twenty patients were admitted with massive hemorrhage with three deaths a mortality rate of 15 per cent. In the private hospitals there was only one death in twenty-nine cases, a mortality rate of 34 per cent. This shows conclusively that the private patient who is receiving adequate medical care is less apt to have a hemorrhage and if he does treatment is instituted more promptly and with a much lower mortality. Only 69 per cent of our cases were admitted to private hospitals on account of hemorrhage whereas 108 per cent of the admissions to the Charity Hospital were on account of hemorrhage. Fifty-four cases (or 29 per cent of all ulcer cases) were admitted to the County Hospital on account of perforation whereas fifty-eight (or 158 per cent) were admitted to private hospitals. I am in accord with Dr. Goldman in practically everything he has said regarding the treatment. It is one of complete rest to the individual complete rest to the stomach and transfusions when indicated. As morphine nauseates a fair percentage of persons it is advisable to attempt to promote rest by the use of barbiturates or other sedatives. When there is pain morphine is necessary. Atropine is useful to relax the spasm of the pylorus. In addition to saving life blood transfusion hastens convalescence. With improved resistance the patient is in better condition to withstand possible concomitant disease.

DR. J. WILLIAM HINTON, New York. Dr. Goldman's presentation is valuable because he has such a large number of cases. He reports 349 bleeding ulcers in 890 cases, or 38 per cent, with thirty-nine deaths, or 11 per cent mortality. In the Fourth Division of Bellevue Hospital since 1928 we have encountered 100 bleeding ulcers. This covers a bed capacity of 200 patients, with an average weekly admission rate of eighty patients, with 361 ulcers admitted to the whole hospital annually, or ninety ulcers per division each year, with an average of twelve bleeding ulcers for the past eight years. In other words, 14 per cent of our total hospital admissions have shown severe gross hemorrhage. I am, of course, reporting for a city institution, and it is interesting to review the figures that the author shows, in which approximately 25 per cent of the hospitalized patients have gross hemorrhage and 10 are ambulatory patients. That has certainly not been our observation. Since 1928 we have had 761 peptic ulcers under observation in our clinic. Of this number 577 have been ulcers not operated on, of that number only twenty have bled, or 3.3 per cent. These patients have remained under close observation and made a sum total of 14,232 visits. As to the treatment of bleeding ulcers I essentially agree with Dr. Goldman but feel that it is essential to divide the patients into five groups. In the first group are patients who have been under competent medical care. As I have stated, we had only 3.3 per cent in that group. I feel that it is not necessary to operate on these patients with the first hemorrhage. If they have a recurrent hemorrhage it may be necessary, but so far we have had but one patient out of these twenty bleeding ulcers for whom we have advised operation. In the second group are patients who have been operated on for acute perforated ulcer or for chronic ulcer and who have never bled for months or years following operation. In that group we had 12 per cent of our cases. In the third group are patients who have been operated on for bleeding ulcer and who have continued to bleed. Seventeen per cent of our ulcers have been operated on for either acute perforation or for bleeding ulcer and have continued to bleed. We do not operate on these patients unless a definite marginal ulcer can be demonstrated, and that has been done in approximately 20 or 25 per cent. The fourth group is the important group. In that group we have had 14 per cent of our patients and it is here that we have our mortality. These patients with a severe hemorrhage have never had any ulcer symptoms at all until they collapsed as a result of the hemorrhage. Of these we have had nine deaths. All the patients were treated by conservative measures, and I should like to state that their condition was so extreme, or they died so rapidly, so soon after entering the hospital, that surgery could not have been undertaken if one had so desired.

DR. LEON GOLDMAN, San Francisco. As far as the occurrence of perforation with hemorrhage is concerned, especially in the duodenum, one may conclude that, if the ulcer is in the posterior wall of the duodenum, hemorrhage may occur because of anatomic reasons. It is on the posterior wall of the duodenum that the large vessels are found, namely, the branches of the hepatic artery which supply this part. The anterior wall is flexible and covered by peritoneum, so that an active ulcer which penetrates may perforate into the free peritoneal cavity. A penetrating ulcer of the same type in the posterior wall is more likely to cause hemorrhage. For this reason, perforation and hemorrhage do not very often occur at the same time. I think that a more active policy in the control of bleeding peptic ulcer must be adopted. It was the conception of many of us that death from hemorrhage is very rare. In the study of our cases we were much surprised by the incidence and high mortality of this condition. We feel that if, after giving the patient the benefit of conservative measures, hemorrhage still continues and the patient is above the age of 40 with arteriosclerosis, something more has to be done, otherwise the patient's chance of surviving the hemorrhage is very poor. I do not wish to give the impression that operation should be performed on every patient who enters the hospital with a bleeding peptic ulcer during the acute stage. I do, however, believe that there are certain patients, above the age of 40 and with arteriosclerosis who bleed in spite of what can be done for them medically. If something more active is not done, the mortality rate, which is rather high, will continue to be so.

THE RELATION OF THE SANATORIUM TO THE TREATMENT OF TUBERCULOSIS

LEROY S. PETERS, M.D.

ALBUQUERQUE, N. M.

With the discovery of the tubercle bacillus in 1882, the world expected tuberculosis as a disease affecting mankind had been as effectively conquered as had small pox after the introduction of vaccine by Jenner. Dr. Trudeau had sought the Adirondacks, where he proved at least that his life was not to be snuffed out in the twinkling of an eye and later established the Cottage Sanatorium for the treatment of tuberculosis. Here he proved by the trial and error method that rest plus good food and fresh air could arrest the disease in a fair percentage of cases. He learned in the school of hard knocks what is common knowledge today but lived to give all who came after him a comprehensive knowledge of the disease and the fundamentals in its treatment.

Climatic treatment of tuberculosis had been empirical up to this time, and patients had been advised to change climates as far back as records can be traced. Mountains, seashore and deserts all had their day, but it was Dr. Trudeau's experiment in the Saranac Lake section that started the country on a sanatorium-building period which ultimately placed sanatoriums in practically every state in the union.

EARLY DAYS OF SANATORIUM TREATMENT

The Southwest and Western seaboard saw the majority of private institutions built, while the East began the erection of state and later county and municipal sanatoriums. The movement spread like wild-fire and the modern treatment of tuberculosis was begun in earnest. Again we were behind Europe as to priority, but once the movement started we outstripped them in things accomplished. In the mad race to build home institutions climate was forgotten and the slogan "Stay at home and be cured" cut the percentage of climate chasers to the minimum. However, up to the world wide chaos of 1929 those who could afford the luxury of climate still kept the health resorts full to overflowing. Then the crash, and with it the empty pocketbooks. The home institution came into its own. By home institutions I mean the state, county and municipal and not the private sanatorium, that suffered along with its climatic relative. People flocked to the place that made it possible to cure with little or no expenditure of money, and the wails of the private sanatorium owner both east and west mingled in one mighty cry, which still echoes from Maine to California and from Canada to the Gulf. But more about this later. These individuals have a real grievance.

In the early days the sanatorium treatment consisted of rest, good food, fresh air and expert supervision. There was little else to offer a patient. The progress of the disease had to be watched and the prognosis given by what the clinician could gather from physical examination and clinical symptoms alone. The advent of the X-rays and the various laboratory tests for determining activity and the progress in general were yet to come.

Read before the Section on Miscellaneous Topics, Section on Tuberculosis at the Eighty-Seventh Annual Session of the American Medical Association, Kansas City, Mo., May 13, 1936.

For this reason, namely, close supervision, patients needed an institution and were more successfully treated there, as their regimen was outlined for the entire twenty-four hours and, what is more to the point, some one saw that this routine was carried out. When one asks for an argument relative to the value of sanatorium over home treatment and the questioner has stated that he will follow the same advice on routine at home, tell him it has never been done and that the proof of the pudding is the eating—sanatoriums can boast results that were never dreamed of by home treatment.

My personal experience also bears out this statement. For eighteen years I was directly connected with institutions, most of those years as medical director, and for the past twelve years I have been doing a private practice. For satisfaction from all angles, the institution is far superior. In order to offset partly the disadvantage of private work I attempt to place all patients in the beginning under sanatorium care in so-called open institutions. Here there is nursing supervision and routine is carefully looked after. Still I firmly believe that a sanatorium with a medical director in charge is preferable.

I have attempted to show that in the beginning the sanatorium was a necessity for properly carrying out the rest regimen. Nor has the advent of collapse therapy made it of less value to the patient who has just been given his diagnosis and must be started on his tuberculosis education. Education of the tuberculous is best accomplished in the institutions. There is no more comparison between the sanatorium-educated patient and the home patient than there is between the correspondence school pupil and the student of a recognized university. The one is as handicapped in his fight for continued health as the other in his struggle for economic existence.

COLLAPSE THERAPY AND ITS RESULTS

Collapse therapy has changed the attitude of many specialists in tuberculosis in their relation to the sanatorium. In many cities, patients are given artificial pneumothorax at dispensaries and allowed to continue work in the early months of treatment. The lay magazines are making much of this "new cure" for tuberculosis. Even medical men are carried away by the spectacular results obtained with the inevitable result that the average patient thinks that if he or she can have a pneumothorax needle thrust into the pleural space or a phrenic nerve pulled out, their troubles are immediately at an end and the longed-for cure accomplished.

I realize as keenly as any of my colleagues that economic situations alter cases and that what can be done for an individual in one stratum of economic life cannot be done for one in a lower stratum. Many times a patient comes to my office with barely enough money to buy bread. He has reached the desert, chasing a will o' the wisp, hoping that the dry air will restore a worn-out physique and the sunshine contract a cavity which occupies a third of his lung. That man must have something done for him. There are no charitable institutions in New Mexico, but there are people running sanatoriums with the milk of human kindness tugged away inside. I put this patient to bed for a period long enough to collapse the bad lung and let him work. No doubt the dispensary care in large cities I referred to comes under that classification. Something must be done for that type. By collapse therapy we have made it possible for this patient to resume his occupation and,

if the collapse is complete, rendered him no longer a menace to those with whom he may come in contact.

But when we advocate this type of treatment it is because of economic necessity. It is not the ideal in compression therapy. It's a makeshift and must be looked on as such. A collapse of a lung doesn't cure tuberculosis, it merely gives nature a chance to effect a result. It is unfortunate that medicine is penalized and forced into makeshift methods by a society that penalizes human beings and makes it necessary to offer half-way measures to prolong downtrodden lives.

To those more fortunate individuals, time makes for much better end results. They can and should be advised to enter a reputable sanatorium and there under proper conditions the patient has the advantage of study and when this study is complete, sane advice can be given as to methods of treatment. It may or may not be some form of collapse but if collapse it is, continued residence in the institution of choice makes for a successful outcome.

I have spoken of pneumothorax and I think hinted at phrenic exeresis but have not touched on thoracoplasty, which brings us to major surgery and therefore calls for a discussion of the properly equipped sanatorium for all types of collapse treatment. The institution of early days needed a well appointed kitchen, an attractive dining room, a recreation hall and units for the accommodation of patients. Perhaps an infirmary could be found in a few if one searched long enough. A laboratory was a necessary adjunct for the routine examinations, later, X-ray machines became a necessity, but until recent years many plodded along with meager equipment. Now if an institution gives the best that is possible in the care of the tuberculous it must add a surgical unit or have access to a general hospital in a relatively short distance from the sanatorium grounds, so that the close cooperation between surgeon and tuberculosis specialist may exist, for this relationship or lack of it spells many times the difference between success and failure.

Where surgical units or access to nearby hospitals are lacking it becomes necessary for the patient to travel long distances and to be placed in the hands of a surgeon who knows nothing of the individual except that some doctor wants his ribs removed. In the final analysis the medical man is the one whose judgment prompted the operative advice, and the successful chest surgeon is the man who understands this fact and works in close association with his medical colleague.

PRIVATE SANATORIUMS

I now come to the last phase of this discussion. What of the private sanatorium and its struggle for existence? Where will this struggle end? Unless something is done to meet the situation, the answer is failure. There can be nothing else under existing conditions. The state, county and municipal institutions are taking the private patient at the expense of the privately owned sanatorium. The man who owns his institution should have some protection. He along with the rest of the tax-paying group is helping support the institution that is forcing him into bankruptcy. When these institutions were built it was the opinion of most of us, I believe that they were for the care of indigents or people who could ill afford private sanatoriums. If we were right in this opinion, time has changed the purpose for which they were erected. Now any one can enter these institutions and get away with it. The waiting list is long, and, in many, patients wait months

before there is a vacancy. Often this prolonged wait spells failure to regain health. And yet nothing is done about it.

It all resolves itself into the present-day agitation for lower cost for medical care—a problem which merits careful consideration, another entering wedge for state medicine which is fast becoming a reality in one form or another. Let me digress long enough to say that I have no quarrel with state medicine per se, but I do object to practicing state medicine in a capitalist society. No group should be singled out and legislation enacted to cover that particular group. As long as the profit system exists, doctors should be given the same chance that our government extends to the magnates of industry.

But we are not dealing with economics. Something constructive must be suggested for the private sanatorium owner. In New Mexico we are without a state sanatorium. For years we have recognized the fact that something must be done for the indigent who are residents of the state. Our present plan, backed by the state board of health and all health agencies, is to get a sufficient appropriation through the legislature to place these people in existing institutions. In that way overhead can be cut and empty beds can be filled. It seems to me that by concentrated effort on the part of individuals and associations such as this, some pressure could be brought to bear on all existing state, county and municipal institutions to force them not to accept patients who are able to pay for private sanatorium care. Further, rather than have more expenditure of state moneys to add beds to already existing institutions, awaken sentiment for such plans as New Mexico is attempting and which is already being done in Colorado, Texas and I suppose other states.

Further than this I have nothing constructive to offer, but I still feel that collective effort by such organizations as ours may in time bear fruit and if such effort proves wasted, the private sanatorium will live only in the memory of pioneer workers in the field of tuberculosis.

221 West Central Avenue

ABSTRACT OF DISCUSSION

DR. ALEXIS M. FORSTER, Colorado Springs, Colo. In spite of Dr. Peters' dark picture, I believe that the best of our private sanatoriums will survive because they offer certain advantages which will not be overlooked either by physicians or by patients. All the factors working against us have now reached the peak. I believe with Dr. Peters that the three chief factors have been the economic situation, the propaganda against climate and the rapid development of chest surgery. With improvement in economic conditions, patients will again seek the advantages we have to offer. There are sufficient doctors still left who recognize that favorable climate together with the essentials of care and treatment do offer the patient a better chance of recovery. Scattered over the country in general hospitals are many orthopedic patients who could derive incalculable benefit from the abundant natural heliotherapy available in the West. I believe that these private institutions must seek a subsidy of some sort. It must be recognized that no hospital can keep up the present high standards of care and treatment with the funds its patients are able to contribute. Those of us who have struggled through these years of adversity ask of our fellows a fair consideration of the advantages we are able to offer. Favorable climate, natural heliotherapy, privacy and close individual care many times may turn the scale. I believe that the private sanatorium with up-to-date medical and surgical equipment and with endowment public or private will continue to receive adequate support from the profession throughout the country.

DR. C. M. HENDRICKS, El Paso, Texas. It seems that Dr. Peters' remarks could be divided into two phases, viz., Should a private patient be sent to a private sanatorium? and Can the private sanatorium be saved? I do not believe that any member of our profession would argue against the fact that a sanatorium-trained patient is of less danger to his community than the home-trained patient. There is no substitute for rest in the treatment of pulmonary tuberculosis and certainly this rest can be carried out much more efficiently under the watchful eye of the attending physician in a sanatorium than in the home. Then too comes the question of the greatest good to the greatest number, which means the isolation of every open case. It seems that if we are eventually to win the fight against tuberculosis, we must bend our efforts toward the isolation of the open case as well as the early diagnosis and education of the patient. All three can best be accomplished in the sanatorium. Now what can be done to save the private sanatoriums from bankruptcy? I have no quarrel with the tax-supported institutions; they are absolutely necessary and I am for them whenever and wherever they are needed. I think that every physician does, however, have a quarrel with the existing laws and customs under which tax-supported institutions are conducted. Certainly no man should expect to receive sanatorium or hospital care for any disease at the expense of his fellow taxpayers. I know of many tax-supported institutions which admit patients at 5 or 10 dollars a week, the law providing for this regardless of the patient's financial status. The word "indigent" has never been properly defined by law. The first step then toward the protection of private institutions would be to secure as soon as possible a change in the laws governing some of the tax-supported institutions also to assist the state, county and city and reducing their waiting list by having provisions made by these governments whereby the empty beds in private sanatoriums may absorb these patients rather than construct new additions to the already oversized tax-supported institutions and I recommend that you work for a law in each state compelling the isolation of the open case. Today the position of the chest specialist and the private sanatorium should be a warning to all other branches of medicine and surgery.

DR. VICTOR STRONG RANDOLPH, Phoenix, Ariz. I want to say a word on a phase that has been neglected in the discussion of Dr. Peters' paper. I am not financially interested in any sanatorium. I am, however, interested in chest surgery, and Dr. Peters mentioned the fact that sanatorium treatment has lapsed to some extent because of the advent of collapse therapy. My brief remarks are to this effect. The sanatorium routine and the sanatorium treatment are still the most important feature in the treatment of tuberculosis. And that should be heralded just as the fact has been heralded in recent years that many patients do need collapse therapy early. The sanatorium man today is recognizing that fact. And we as chest surgeons also should point out that the sanatorium routine is important for the preparation of the patient to get him into shape so that he will be benefited by surgery and in addition that the results of surgery will not be effective unless the sanatorium routine is carried out after he has had his surgical treatment.

The Tonic Innervation of the Colon.—The alimentary canal may be regarded as having two reservoirs connected by a long tube, the small intestine. The first reservoir, the stomach, receives a large amount of food at one time and discharges it gradually into the intestine where the final stages of digestion occur. The second reservoir, the large intestine or colon, receives gradually the waste material left from the digested food and discharges it at one time. The tonic innervation of the colon is quite as important as that of the other parts. It is provided by nerves belonging to the sacral division of the autonomic system. Stimulation of these so-called "sacral visceral nerves" causes contraction of the muscles of the colonic wall. The extent of distribution of these nerves in the large intestine of man has not yet been determined.—Cannon, W. B. *Digestion and Health*. New York, W. W. Norton & Co. Inc., 1936.

THE OPERATIVE VERSUS THE MANIPULATIVE TREATMENT OF SLIPPED FEMORAL EPIPHYSIS

WITH A DESCRIPTION OF A CURATIVE OPERATION

SAMUEL KLEINBERG M.D.

AND

JOSEPH BUCHMAN, M.D.

NEW YORK

The treatment of slipped femoral epiphysis, sometimes called epiphysiolysis, epiphyseal fracture of the hip joint, epiphyseal coxa vara, or osteochondritis of the neck of the femur, is still perplexing and in a state of flux because of the poor ultimate results obtained by the present methods. The literature is replete with end result studies that are, to say the least, discouraging. It is because of these failures that a number of investigators have proposed new methods of procedure. It is not our purpose to enter into a clinical description of this condition but rather to consider certain features of the anatomy and physiology of the hip and of the symptomatology which have a bearing on the rationale that should guide the orthopedic surgeon in his therapy.

ANATOMY AND PHYSIOLOGY

With the approach of puberty several anatomic and physiologic features become manifest. 1 The epiphyseal plate between the head and the neck of the femur changes its position from the horizontal common in childhood to the oblique plane. 2 There is an increased growth activity in the epiphyseal region with a consequent widening of the epiphyseal plate. 3 There is a decrease in the thickness of the periosteum and of the retinacula of Weibrecht which supports the epiphyseal plate and holds the head firmly attached to the neck. 4 The femoral neck becomes longer and its angle with the shaft is lessened, while its size and the density of bone structure are increased. 5 There is a relative gain in body weight. 6 There is an increase of the general physical activity. The first four enumerated conditions produce a physiologic weakness at the epiphyseal area. The two latter conditions produce an increase in the stress and shearing strain on the epiphyseal area.

When these changes are within normal limits, the balance between the ability to withstand stress and strain and the stress and strain superimposed is maintained and no pathologic disturbance occurs. On the other hand when these changes are beyond normal limits this balance becomes disturbed and pathologic changes occur. Thus, if the plane of the epiphyseal line is so oblique as to be almost vertical or the thinning of the periosteal attachment of the femoral head is greater than normal, the ability of the parts to withstand normal stress and strain is reduced. Then too, if the rate of growth between the head and neck is abnormally fast, the epiphyseal plate would be wider than usual and consequently weaker and less able to withstand the usual superimposed forces. Furthermore, an unusual increase in body weight as in cases of endocrine dyscrasia (the obesity in cases of Fröhlich's syndrome) or excessive physical activity would impose a greater degree of stress and strain than the part can withstand. Finally, there may be a combination of these two groups of factors to produce a disturbance of the balance of opposing forces.

In the mechanism of the displacement, actual slipping of the femoral head may occur in one of three ways. It may be very gradual over a considerable period, may be very sudden, or may be gradual and then be completed by rapid displacement. The sudden slipping may have all the appearance of a fracture of the neck of the femur, but we cannot accept it as such for, as Mr Perkins¹ has pointed out, a fracture dislocation of an epiphysis always involves the metaphysis at one point or another. Furthermore Rammstedt² found experimentally that in producing a traumatic epiphyseal separation a fragment of the neck was broken off with the head. In the condition under consideration, the lesion is entirely through the epiphyseal plate.

Fig 1.—Section of epiphyseal plate ($\times 125$) showing mild changes from normal. *a*, the line of demarcation between cartilage and bone is relatively straight but definitely more irregular than normal. *b*, the columnar arrangement of the proliferating cartilage is only relatively normal. *c*, resting cartilage is well preserved. *d*, area of resting cartilage undergoing changes. *e*, split in resting cartilage invaded by blood vessels from metaphysis. *f*, fiber bone formation.

GROSS AND MICROSCOPIC PATHOLOGY

The gross pathology observed during an arthrotomy is definite and characteristic. The slipping of the head occurs downward and backward. The epiphyseal plate is wedge shaped with its base anteriorly and superiorly. The femoral head is firmly fixed to the neck and can be removed only by instrumentation. There is no line of solution of continuity. One gets the impression of a gradual wandering of the head downward and backward, resulting from a plastic change in the epiphyseal plate. The femoral neck bulges and appears longer.

Due to lack of space, this article has been abbreviated for publication in THE JOURNAL. The complete article appears in the authors' reprints.

anteriorly and superiorly. The periosteum in this region is markedly atrophied. The articular cartilage is normal in appearance. Anteriorly and superiorly, however, the border of the epiphyseal plate articulates with the acetabulum so that there is an incongruity of articulating surfaces. The ligamentum teres may be elongated and when sectioned is practically avascular or so poorly vascular that it never requires ligation. The acetabulum is normal in appearance. In old cases the capsule of the joint is thickened anteriorly and superiorly. The joint fluid is normal in appearance and in quantity.

A review of the resected epiphyseal areas, in which we were kindly aided by Dr. Sheldon Jacobson of the department of pathology of the Hospital for Joint Dis-

product of the ossification of connective tissue cells. Occasionally one may note areas of myxoid degeneration in this region. The osteoid tissue at the line of junction with the proliferating cartilage cells is irregularly disposed, and the newly formed lamellar bone is similarly irregularly disposed and in part replaced by fiber bone. The adjacent marrow in the femoral neck presents a moderate amount of fibrosis. Occasionally cartilage rests may be seen in the metaphyseal region.

In the moderately advanced stages the line of junction between the growing cartilage and newly forming bone, though still perceptible, is very irregular. The columnar arrangement of the proliferating cartilage cells is all but lost. The "resting" cartilage zone is poorly preserved. The newly formed bone is fairly well calcified and arranged in irregularly disposed trabeculae of fiber bone. Endochondral (normal) bone formation seems to be at a minimum. The fibrosis of the marrow is now increased.

In the severely advanced stages of this disorder the architecture of the growth zone is very confused (fig 2). The normal characteristics of the cartilage bone contact zone are entirely lost. The cartilage plate is very irregular and badly preserved and presents more increased areas of fiber bone and myxoid degeneration. From this zone, large irregularly shaped tongues of more or less degenerated cartilage extend into the bony zone. The arrangement of the newly formed bone trabeculae is confused and presents little of the normal topography. Endochondral bone formation is entirely replaced by the formation of fiber bone which is undergoing very active transformation. There is active osteoclastic resorption and osteoblastic deposition with a formation of large sheets of lamellar bone and osteoid. There are areas of localized bone necrosis while other areas present large dilated engorged blood vessels. The marrow is completely fibrous. The impression one gets is that of a completely chaotic arrangement of normally functioning cells interspersed here and there with areas of necrosis and areas of hypervascularity.

CURRENT FORMS OF TREATMENT

With these considerations in mind, one may analyze the various forms of treatment in vogue. There are several conservative methods of treatment of the slipped femoral head, but these concern themselves with the preslipping or very mild slipping stage. Rest in bed with interdiction of all weight bearing will in most instances produce excellent results. One must, however, bear in mind two considerations: that a sudden or gradual slipping may occur even in bed and that the period of rest in bed must extend over several years until the femoral head is definitely fused to the neck. The same considerations hold true for those mild or preslipping cases treated with plaster-of-paris spica immobilization, with traction, or with weight bearing on a well fitting Thomas hip brace.

The manipulative treatment as devised and advocated by Whitman is based on the assumption that this condition "is in reality an incomplete fracture of the neck of the femur. The exciting cause of displacement is apparently a superficial fracture at the superior portion of the junction of the head and neck, or possibly a less direct injury that weakens the immature bony structure on the diaphyseal side of the cartilage. Then follows gradual downward and backward displacement of the head on the neck."³ His primary indication for treat-

Fig 2—Section of epiphyseal plate ($\times 125$) showing most marked changes. *a* the normal characteristics of cartilage and the bone contact zone are entirely lost. *b* area of myxoid degeneration of cartilage. *c* area of fiber bone in cartilage plate. *d* split in cartilage plate. *e* lamellar bone. eases, revealed a changing microscopic picture, which varied with the severity of the lesion. In the early stages (fig 1) the line of demarcation between the cartilage and bone is relatively straight but definitely more irregular than normal. The columnar arrangement of the proliferating cartilage cells is evident but irregular and the number of cells per column is diminished. The "resting" cartilage is fairly well preserved and presents splits, some of which are invaded by blood vessels from the metaphysis while others are filled with granulation tissue. In other views one may see areas of fiber bone and osteoid surrounded by "resting" cartilage. This may be interpreted as a reparative process in the splits noted in the "resting" cartilage and the resulting fiber bone is not lamellar but is the

³ Whitman, Royal. *A Treatise on Orthopaedic Surgery*, ed. 9. New York: Lea & Febiger, 1930, p. 629.

ment is therefore to utilize natural leverage to reduce the deformity. The limb is manipulated into extreme abduction and internal rotation, thus utilizing the impingement of the greater trochanter against the upper rim of the acetabulum as the fulcrum and the capsule as the force acting on the displaced head to produce a reduction of the deformity.

The results of this method of treatment have on the whole been unsatisfactory, as is evident from the many statistical reports.⁴ In mild slippings perfect reductions do not result from these manipulations, even in those instances in which the postoperative x-ray studies show apparent correction of the deformity. The satisfactory appearances are illusory and the results of marked internal rotation, for subsequent x-ray studies in the same position as those in the preoperative studies show that reduction does not occur. This has been pointed out by Mau⁵ and is well exemplified in our case 1. Key⁴ stated that in advanced cases and in those instances of acute slipping of more than six weeks' duration, manipulation results in the forcing of the neck into the cancellous tissue of the head. Whatever correction is obtained is only apparent, for it is only the result of stretching of the capsule and not the replacement of the head. He further states that with the discontinuance of the fixation the deformity recurs.

In cases in which sudden complete slipping of the femoral head occurs, when treated shortly after the slipping, reduction as a rule is possible by the manipulative method. The early results are usually satisfactory but the late results are often disastrous in that ankylosis or marked limitation of motion supervenes. Later x-ray studies of these cases reveal a diminution of the joint space, irregularities of the outline of the femoral head and evidence of necrosis of the femoral head. In retrospect this is readily comprehensible when the surgeon realizes that no matter how gentle he may be with his manipulations the forces acting on the femoral head are tremendous because of the great leverage exerted through the extremity on a relatively small head thus resulting in considerable trauma to the head. Furthermore, once the reduction is completed, the possibilities for reestablishment of the circulation of the femoral head are rather meager. One must always consider that in a number of instances the circulation by way of the ligamentum teres, if it has remained uninjured as a result of the manipulation, is insufficient for the nourishment of the femoral head. On the other hand, in those instances in which the ligamentum teres is injured as a result of the manipulation, the circulation is in all probability nonexistent. The only other possible source of blood supply to the head is by way of the distal fragment. This, of course, is shut off by the deranged and excessively thickened epiphyseal plate that remains attached to the diaphyseal side of the neck. Thus, as a result of the various circumstances the possibility for survival of the head uninjured and as a normally functioning part of the hip joint mechanism is rather meager. The truth of this reasoning is well supported by the many end result studies available. The following case is illustrative of the sequence of events here described.

CASE 1—May D. aged 12 years seen by one of us (S. K.) in November 1933, had a typical seemingly mild slipping of the

right femoral head. November 10 the right hip was manipulated under an anesthetic. Considerable force had to be used for it was difficult to overcome the deformity. Despite the use of considerable manual force the attitude of outward rotation was only partially corrected. She was immobilized in a plaster-of-paris spica and was kept in bed in plaster for six months. She was then allowed out of bed walking with the aid of crutches, a canvas support for her hip and no weight bearing. She did not bear weight on the affected limb for sixteen months. Nevertheless there was continuously increasing deformation of the head. At the present time two years after the beginning of treatment, she has no pain, but she has 1 inch (2.5 cm.) of shortening of the limb, a marked limp, and severe restriction of all motions. The last roentgenogram shows great deformity of the head, flattening of its upper surface, and increased density of the head with areas of rarefaction and loss of definition of its articular surface. The upper border of the neck projects upward in the form of a triangular spike beyond the articular surface of the head and even beyond the acetabulum. The articular surface of the acetabulum is irregular in calcification and outline (fig. 3).

Fig. 3 (case 1)—Deformity of head and neck of the femur and irregularity of outline of the acetabulum and areas of sclerosis and rarefaction of the head and neck of the femur July 2, 1935, twenty months after manipulation.

In cases of marked slipping of prolonged duration, manipulation cannot, on the basis of our operative experience, be effective in reducing displacements, for we have always found the head firmly fixed and displaceable only by means of gouge and mallet. The only possible results of manipulations in this group of cases is the crushing of the head, as is evident from the following case.

CASE 2—Pearl W. aged 13 years complained of a deformity of the left lower limb and difficulty in walking Aug. 25, 1932. She stated that two years previously she fell and sustained an injury. Ever since that time she had had increasing difficulty with the left hip. She was manipulated by a leading orthopedic surgeon and then immobilized in a plaster-of-paris spica for from six to seven months. The result was unsatisfactory. The patient then submitted herself to the care of another orthopedic surgeon who repeated the same routine.

Examination revealed that she was overweight but in good general condition. She walked with the aid of crutches and a caliper brace on the left side and presented a marked limp on that side. The left lower limb was immobile at the hip joint at 120 degrees of flexion and 15 degrees of adduction. There was shortening of 1 inch. A roentgenogram revealed that the

femoral head was displaced downward in the acetabulum and disconnected from the neck. The upper surface of the neck was displaced upward and was in contact with the upper rim of the acetabulum. The joint space was diminished.

The hip was exposed by one of us (J. B.) through a Smith-Petersen incision. The capsule of the hip joint was found to be immensely thickened. The head and neck were united by thick fibrous tissue. This was severed and the limb was rotated outward. Notwithstanding that the manipulation was gentle, a supracondylar fracture occurred. The femoral head was found to be firmly "frozen" into the acetabulum and could not be budged. The distal surface was therefore curetted and the freshened neck was brought into contact with it. A Steinman pin was then inserted into the supracondylar region. The bone was so soft that the pin was readily passed through the bone without the use of a mallet. The wound was then closed and the limb was immobilized in a plaster-of-paris spica.

The patient made an uneventful convalescence. The end result was an ankylosed hip.

Fig. 4 (case 3).—Slight slipping of femoral head and loss of normal projection at the junction of the upper border of the head and neck, July 17, 1929. The epiphyseal plate is widened, laminated and irregularly calcified and is more oblique than on the opposite side.

This case demonstrates the danger of manipulation and prolonged immobilization in plaster-of-paris spicas. The manipulations produced a traumatic arthritis, which precluded any hope of a mobile joint, while the prolonged immobilization produced a marked atrophy, so much so that a fracture occurred on slight manipulation.

From the foregoing considerations, manipulative treatment in our judgment may possibly be useful and permissible in cases of acute slipping in which the elements of the manipulative reduction are executed deliberately and advisedly with the greatest gentleness. For all other forms the manipulative treatment is inadvisable for the following reasons: 1. The reduction may be impossible. 2. The reduction is often incomplete and illusory. 3. The circulation of the head is likely to be disturbed, as evidenced by late deformity of the head. 4. Traumatic arthritis and even ankylosis may ensue. 5. No change is effected in the pathologic epiphyseal plate.

OPERATIVE TREATMENT

Several operative methods have been devised to attack the deformity at the site of formation. Whitman advised the exposure of the hip joint through an anterior incision and the levering of the head into correct alignment by means of a chisel. The objection to this method is that there is no provision for the removal or the revascularization of the deranged tissue of the epiphyseal plate, which we believe essential to a cure.

Another more conservative operative procedure which has come in vogue for this and other conditions in recent years is that of drilling for the purpose of reestablishing circulation and causing premature ossification of the part. This method is naturally limited to the preslipping or mildly slipping stages. One of us (S. K.) has used this method in several cases with satisfaction. There are two objections to this method: 1. With our present technic one does not know whether the drill holes have actually traversed the epiphyseal plate and entered the femoral head. 2. There is the potential danger of the drill entering the joint, perforating the articular cartilage and introducing osteochondral particles into the joint cavity.

OPERATION ADVISED

It appears to us that successful treatment must include the following: 1. It must be as atraumatic as possible. 2. The deformity must be corrected. 3. The circulation across the epiphyseal area must be reestablished to produce an early fusion between the head and neck of the femur. This can be best accomplished by an operative resection of the epiphyseal plate, realignment and placing in intimate contact the cancellous bone of the head and neck of the femur.

With these points in mind one of us (J. B.) evolved the following technic. Through a Smith-Petersen incision the hip joint is exposed and the capsule is incised crucially. The femoral head is delivered into the wound. The ligamentum teres is disregarded and may be sectioned. The femoral head is then removed *en masse* with a curved chisel proximal to the epiphyseal plate. The epiphyseal plate, which is deformed and wedge shaped, is excised, exposing the healthy bone of the femoral neck. The removed section is wedge shaped, base superiorly and anteriorly. At times the periosteum on the posterior and inferior surfaces of the neck may remain attached both to the head and to the neck so that when the head is elevated it remains attached like a lid. The distal surface of the head is then curetted to remove all remnants of the epiphyseal plate and is shaped to fit the neck. The head is then replaced in the correct position and fixed to the neck by means of an ivory peg inserted through the fovea capitalis. The dislocation is then gently reduced, the capsule is closed with several interrupted sutures, and the wound is closed in layers. The limb is then immobilized in a plaster-of-paris spica in about 30 degrees of abduction, with the patella pointing forward.

The postoperative treatment consists of immobilization for four weeks in the plaster-of-paris spica. This is followed by several weeks in a suspension apparatus to allow mobilization of the hip. The patient is then supplied with a well fitted Thomas hip brace, the utmost care being taken that the weight is borne on the ischial tuberosity, and walking is permitted. No direct weight bearing is permitted until the roentgenogram shows that the femoral head has been completely revascularized as evidenced by smooth, even calcification similar in

density to the surrounding bone. This ordinarily takes about eight months, at the end of which period all restrictions are discontinued.

REPORT OF CASES

CASE 3—Marvin M. aged 12½ years, admitted to the service of Dr. Samuel Kleinberg July 20, 1929, complained of pain in the right knee and a limp on the right side. He stated that two weeks previously he was seized with a sudden pain in the right knee while walking. Since then the pain had been moderate but persistent, while the limp had become decided.

The general physical examination was negative, save that the patient was somewhat overweight and that he walked with a marked right-sided limp. The right limb was held in moderate external rotation. Extension at the hip joint was limited at 170 degrees, while all other motions were unrestricted. The right thigh was atrophied three-fourths inch (2 cm).

Roentgen examination of the right hip in external rotation showed a slight slipping of the femoral head with a loss of the normal projection at the junction of the upper border of the head and neck. The epiphyseal plate was widened and laminated and irregularly calcified (fig. 4). Another x-ray examination of the hip made at the same time with the limb in internal rotation did not reveal the slipping noted in the preceding film. The epiphyseal plate, however, showed the same changes previously described.

July 26 the limb was manipulated under deep anesthesia and brought into extreme abduction and internal rotation of 45 degrees.

The postoperative x-ray examination showed what appeared to be a satisfactory reduction. August 21 the plaster was removed and the limb was placed in a suspension apparatus for the mobilization of the hip. Further examination August 25 showed that all motions were unrestricted save extension which was now limited at 150 degrees. X-ray study at that time in external rotation revealed that the femoral head was not reduced and that its position was similar to that in the corresponding preoperative x-ray study. An open reduction was therefore advised.

Fig. 5 (case 3)—Perfect alignment and firm bony union of the head and neck of the femur Dec. 11, 1935, six and one-half years after operation. The outlines of the articular surfaces are smooth and the joint space is normal.

August 30 the operation outlined was performed by one of us (J. B.). The patient had an uneventful convalescence. One month later the plaster was removed and the limb was placed in a suspension apparatus to mobilize the joint and physical therapy was administered. Six weeks subsequently, i. e. ten weeks after the operation, the patient was discharged from the hospital walking in a well-fitting Thomas hip caliper brace.

Examination at that time revealed a complete range of motion at the hip joint, save for flexion, which was limited at 90 degrees.

The patient was then observed in the outpatient department at regular intervals. Six months subsequent to the operation the patient was permitted to walk without the brace for short periods, which were gradually increased, so that at the end of approximately eight months the brace was entirely discarded.

Fig. 7 (case 5)—Slipping of the femoral head April 19, 1933, before operation.

X-ray studies were made at regular intervals. The one made immediately after the operation showed a satisfactory alignment of the head and neck.

A roentgenogram made Dec. 11, 1935, approximately six and a half years after the operation, showed perfect alignment and union of the head and neck. The articular surface of the head was smooth. The joint space was normal. The neck of the femur was normal in size and conformation (fig. 5).

At that time the patient reported that he was leading an active life, indulging in all athletic activities. He was able to run up the stairs three steps at a time and was not conscious of any disability whatever. He had grown 6 inches (15 cm.) since the operation. There was a complete range of motion at the hip joint, save for flexion, which was limited at 80 degrees, and there was no shortening of the affected limb.

This case is of interest in that it demonstrates the illusion of reduction of the femoral neck by manipulation. The postmanipulative roentgenogram in external rotation gives the same appearance as that noted prior to the reduction with the limb in external rotation, while the postmanipulative roentgenogram in internal rotation gives a similar appearance to that taken prior to the stretching when the limb was in internal rotation. This case also demonstrates conclusively that there is no resultant progressive shortening because of the removal of the epiphysis between the head and the neck of the femur.

CASE 5—L. D., a girl aged 13 years, admitted to the Hospital for Joint Diseases in the service of Dr. Kleinberg April 19, 1933, complained of a limp on the left side and pain in the left hip. In August 1932 she fell from a hammock and on the following day began to experience pain in the left hip and a limp appeared on walking. Ever since that time the pain in the hip joint radiating to the knee was aggravated by activity and relieved by rest. The limp was similarly relieved by rest and aggravated by activity.

Physical examination revealed that the child was somewhat overnourished and was in good general condition, walking with

a marked limp on the left side and holding the limb in external rotation. Internal rotation at the hip joint was limited at the midline. External rotation was unrestricted. Abduction was possible to 20 degrees, while adduction was complete. Flexion was limited at 110 degrees and the limb rotated externally on flexion of the thigh. There was tenderness over the femoral head. Measurements revealed a shortening of the left lower extremity of one-half inch and atrophy of the left thigh of $2\frac{3}{4}$ inches (7 cm) and of the left calf of three-fourths inch.

X-ray examination (fig 7) showed that the left femoral head had slipped downward and backward. There was a rarefaction and widening of the upper femoral epiphyseal cartilage.

April 21, 1933, the left hip joint was operated on by one of us (J. B.). All the details of the technic described were carried out.

Fig 8 (case 5)—Complete bony union with normal calcification joint outlines and joint space Sept. 23, 1935, twenty-nine months after operation.

The postoperative x-ray studies showed a satisfactory alignment of the head and neck of the femur. May 29, five weeks subsequent to the operation, the plaster was removed. Several days later the patient presented a painless range of passive flexion of 150 degrees, abduction of 30 degrees and a free range of internal and external rotation. Active and passive exercises in a suspension apparatus and baking and massage were instituted. A few weeks later the patient was supplied with a well fitting Thomas hip caliper brace and was permitted to walk for short intervals with the aid of crutches. An x-ray study May 29 showed definite evidence of union between the head and neck of the femur. There were in addition resorptive changes in the peg uniting the head and neck of the femur. June 28, nine weeks after the operation, the patient was discharged and referred to the outpatient department.

One month later, June 26, thirteen weeks after operation, there was a complete range of motion and x-ray studies revealed bony union at the operative site. The eight months postoperative x-ray studies revealed that the architecture and ossification of the femoral head were similar to the surrounding bone areas. The patient was therefore permitted to discard the brace gradually. All support was completely removed the thirteenth month after operation. The patient was last seen Dec. 11, 1935, two years and eight months after the operation. At that time she presented a complete range of motion at the hip joint with no limp and no shortening notwithstanding the fact that she had grown 5 inches (12.7 cm) since the operation. X-ray studies, September 23, 1935, showed complete union of the capital epiphysis to the neck of the femur (fig 8).

CASE 7—Vivette G., aged $8\frac{1}{2}$ years, consulted one of us (S. K.) Aug. 8, 1934, for a right limp. Three and a half months previously, while she was standing on the rear plat-

form of a car, the tram started suddenly and she was twisted on her right lower limb. She began limping immediately thereafter. More recently she had a fall which increased the limp and disability. The examination showed that the right lower limb was fixed in flexion of 140 degrees and there was marked outward rotation. There was tenderness to pressure over the front of the hip and severe muscle spasm. A roentgenogram (fig 9) showed a marked downward slipping of the femoral head.

She was operated on, August 9. The typical operation was performed. A postoperative x-ray examination, September 24 (fig 10), showed an excellent alignment of the head and neck. The last roentgenogram made on March 22, 1936, shows fusion of the head and neck with a slight residuum of rarefaction of the upper part of the head, indicating that the femoral head is not as yet completely revascularized and reformed. Clinically the patient presents complete extension, 135 degrees of flexion, 40 degrees of abduction and free rotation. There is no shortening of the limb. She is still under treatment. Weight bearing has not as yet been allowed. It is believed that during the next few months when weight bearing is to be resumed there will be a more complete reformation of the head.

This patient was for special reasons immobilized in plaster for about six months and subsequently was allowed up with crutches without weight bearing. This was complicated by a sudden slipping of the femoral head on the opposite side, necessitating further restriction of weight bearing incidental to the treatment of that lesion. It is believed that the lack of physiologic stimulus resulting from walking on a Thomas hip brace is responsible for delayed reformation of the head.

The philosophy of this operation is based on the assumption that the described approach is the most atraumatic procedure possible, for there are no blind stretchings or manipulations. We further look on the replaced head as a free graft which must be given sufficient time to be revascularized. The approximation of the healthy bony distal surface of the head to a healthy bleeding proximal surface of the neck gives the greatest opportunity for the most rapid healing under the given circumstances. It is because of this that we are most emphatic that there must be no direct weight bearing until the femoral head has been completely reformed, as indicated by repeated x-ray studies. The course of treatment lasts approximately eight months to one year and is well worth the time and effort, in view of the practically perfect result obtainable as shown in our case reports.

CONCLUSIONS

Our experiences and studies of the management of slipped femoral epiphysis have led to the following conclusions:

1. Slipped femoral epiphyses are not fractures in the ordinary sense and therefore cannot be treated as such. This is supported by theoretical considerations as well as by clinical observations.

2. Treatment to be effective should be atraumatic, should correct the deformity and should establish a thorough circulation between the head and the neck of the femur.

3. Treatment in the preslipping or mildly slipping stage may be expectant and should consist of interdiction of weight bearing over a long period of time by rest in bed, preferably, or, if that is impracticable, by the use of a well fitted Thomas hip brace. The proviso must however, be made that further slipping may occur notwithstanding these measures. In this stage extra-articular drilling of the head and neck may be effective.

4. The most effective treatment for slipped femoral epiphysis as well as those cases in the preslipping stage is an operation which assures rapid and permanent healing by the removal of the epiphyseal plate and the direct

contact of the cancellous bone of the head and neck of the femur securely fixed by a bone peg

5 The operation described has been used in five cases with uniformly good results

1 West Eighth-Fifth Street.

ABSTRACT OF DISCUSSION

DR. JOSEPH BUCHMAN, New York I have very little to add, save to emphasize that one must be extremely careful in using this mode of attack that no direct weight bearing is borne until the head is completely revascularized and its structure has been replaced by new bone. Otherwise a traumatic arthritis will develop and a limitation of motion will occur. The operation is based on the principle that by removal of the epiphyseal plate healthy bone is approximated to healthy bone and thus good healing is assured. We regard the head as a free graft and protect it as such from weight bearing. Only under these conditions will one be able to get more satisfactory results

ROENTGEN THERAPY OF SOME INFECTIONS

FRED M HODGES, M.D.

AND

R. A. BERGER, M.D.

RICHMOND, VA.

It is our intention to present this paper not as a statistical analysis of a group of infections but as the report of accomplishments and conclusions obtained through seventeen years of experience and observations in the management of various infections.¹ It is hoped that this will bring before the medical profession and emphasize again that irradiation offers a potent ally for proficient and competent treatment in certain infectious states.

A survey of the literature relating to infections and irradiation may be found dated within six years after the discovery of x-rays by Roentgen. In the past twenty-three years numerous writings voice the opinions, theories and enthusiasms of writers both on this continent and abroad. Yet, with a firm theoretical basis and an absence of empiricism, one finds the use of roentgen rays sadly lacking in cases in which they might be of considerable benefit to the afflicted. Careful analysis of this situation discloses the fact that the use of radiation is employed where the radiologist is the best informed in this work and where he has familiarized practitioners in the other branches of medicine with this valuable therapeutic agent in many infections. To offer the patient the utmost that irradiation will give there must be complete and absolute cooperation between the co-workers. The radiologist must share in the responsibility and cannot expect to obtain results if he merely sees the patient gives a treatment and puts the record of the therapeutic dose in the files to forget from that moment such a patient has been treated by him. Prudent and careful observation we believe is the determining factor between success and failure of irradiation in the following acute subacute and chronic more or less localized infections.

We have arbitrarily grouped various lesions in two classes. These are not compiled according to etiologic or pathologic criteria but are collocated in accordance with their sensitivity or susceptibility to irradiation, complying with our observations and experience.

GROUP 1

- 1 Early localized erysipelas in adults
- 2 Furuncles and furunculosis
- 3 Granulomas
- 4 Infected hemangiomas
- 5 Cellulitis of certain types
- 6 Lymphangitis of certain types
- 7 Mikulicz's disease
- 8 Parotitis
- 9 Rhinophyma

GROUP 2

- 1 Carbuncles
- 2 Blastomycosis
- 3 Sporotrichosis

Group 1 comprises those infections which are sufficiently amenable to irradiation so that we feel no other form of therapeutics is necessary. The lesions under this classification respond so readily that one may predict an immediate amelioration or abortment, followed by rapid regression and healing.

Erysipelas chiefly the early localized form in the adult, is a commendable example. In this condition irradiation may be considered as a specific. Small early lesions are apt to disappear within twenty-four hours after treatment requiring no additional therapy. The temperature and toxicity are rapidly alleviated, while the edema and the erythema subside quickly leaving a wrinkled and exfoliating skin in from thirty-

Fig. 1—A extensive erysipelas involving most of the face. This lesion was twenty-four hours old, having started on the left side of the face. The patient received treatment April 19, 20 and 21, 1936. B appearance on discharge April 22 entirely well.

six to forty-eight hours. The dose required is small, from 100 to 150 roentgens (in air) with a voltage of 85 kilovolts of unfiltered rays. Administering this dose well beyond the apparent border of the lesion will prevent further streptococcal permeation of the corium.

Furuncles and furunculosis likewise lend themselves very favorably to the influence of properly applied roentgen rays, although in this instance the invading organism is most frequently a staphylococcus and the natural barrier is more apparent, being evidenced by the induration around the involved hair follicle or sweat gland. The early undeveloped lesion may be

Read before the Section on Radiology at the Eighty-Seventh Annual Session of the American Medical Association, Kansas City, Mo., May 15, 1936.

completely aborted in from twelve to twenty-four hours by a dose of unfiltered rays sharply delimited to the local area, while the more advanced lesion will have its course hastened to suppuration and drainage. On the other hand the chronic furunculosis so often seen on the back of the neck and in the axilla is best treated by using filtered rays of from 4 to 6 mm aluminum equivalent. Here the pathologic condition lies deeper and the connective tissue is more extensively involved. The treatment must be directed at the deeper lying lesions and at the same time toward the newly forming ones. A 125 roentgen, 125 kilovolt, 6 mm aluminum application at weekly intervals over several weeks has given almost uniformly good results.

The pathologic characteristics of infected angiomas and granulomas make them difficult to treat by other methods, especially when they are situated, which they so often are, where good cosmetic and functional results are desired. Where other forms of therapy have failed

Fig. 2—A granuloma treated June 10 and 12, 1935. B patient seen again nine months later having no recurrence. The scar is soft and there is no evidence of contracture.

irradiation has obtained admirable success. The abundant overgrowth of vascular and cellular tissue forming the tumor-like mass requires a large dose of from 700 to 900 roentgens of unfiltered rays, following which the lesions gradually regress and disappear within two to four weeks, leaving a small, soft and pliable scar. Every single case of this type has responded favorably to roentgen therapy.

Cellulitis of certain types, such as the type seen following an extracted tooth or in instances in which there has been a slight abrasion of the skin and in cases in which no portal of entry or etiologic factor could be determined, yields rapidly to the influence exerted by roentgen rays. The process is limited to the area, the probability of a serious complication is lessened and the reparative process is hastened. The lesions either point rapidly and discharge or gradually subside without evidence of drainage by small doses of from 100 to 150 roentgens of unfiltered rays.

Lymphangitis of certain types regresses quickly after they are subjected to a roentgen beam. The red streaks that one sees extending up an extremity radiating from a localized infected area usually disappear rapidly. In the later stage in which the lymphatic channels are rigid

and cordlike, with enlarged glands along the course of the system, these can as a rule be made to regress with small doses. When there is not a more or less rapid response to this treatment, of course other measures, such as blood transfusions from a normal or immunized donor or serums, should also be used by a consultant thoroughly experienced in this field.

Mikulicz's disease proper, due to a chronic inflammatory process of the lacrimal and salivary glands, responds more or less permanently to proper roentgen therapy. Differentiating the true Mikulicz disease from the Mikulicz syndrome is often difficult. The latter will also respond to therapy if its pathologic basis is due to one of the blood dyscrasias, such as leukemia, or is a manifestation of a malignant lymphoma, but the results are not permanent. Mikulicz's disease proper to be successfully treated requires larger doses than other inflammatory processes, because the pathologic picture is that of considerable connective tissue production infiltrated by lymphocytes and giant cells plus epithelial degeneration. The most effective dosage ranges around 400 roentgens, 200 kilovolts, 1 mm of copper and 1 mm of aluminum.

Parotitis, frequently seen as a complication of surgery of the lower part of the bowel and in patients requiring the presence of jute tubes and tube feedings, usually having a mortality of between 35 and 60 per cent, may have this mortality rate markedly lowered, and the percentage going to suppuration is far less. Whether one uses radium as reported by Rankin and Palmer² and Desjardins³ or the technic of roentgen irradiation that we employ the results are very gratifying, especially when one treats a very sick patient one day where the outcome appears hopeless and finds the same patient the next day sitting up in bed enjoying a meal and talking with his relatives.

In the chronic form that has persisted for months at a time and during which interval there have been numerous exacerbations and drainages, our results have been almost invariably good. In this condition it is not necessary for the patient to undergo repeated incisions with the production of numerous visible scars, and it is not necessary for the surgeon to undertake a difficult operation for the removal of the involved gland, as a series of filtered roentgen rays will produce the desired results, inducing a final result which is satisfactory to the physician and very gratifying to the patient.

The proof of the effectiveness and the ability of irradiation to produce results is readily demonstrated in infected rhinophyma. The pathologic nature of the lesion makes it difficult to manage by other means because the process consists of hyperplastic epithelium, ramified by a number of blood vessels and deeply situated infected glands. The appearance of the individuals and the obnoxious odor ostracize them from social and remunerative contacts. The lesion invariably responds to 300 roentgens of filtered rays and the final outcome is a nose of normal appearance, exhibiting little or no telangiectatic elements and a smooth natural skin. This entity is an ideal one for the radiologist to demonstrate his puissance, as they are quickly turned over by the clinician and is just as easily subjugated by properly applied roentgen therapy.

³ Desjardins, A. U. Radiotherapy for Inflammatory Conditions. *J. A. M. A.* 96: 401-408 (Feb. 7) 1931.

In group 2 we have placed those infections in which we feel that irradiation is an important auxiliary in the armamentarium for the management of these lesions

Carbuncles, although very similar to furuncles except for the extensive nature of the process, do not always respond as readily as furuncles. Irradiation alone in most instances limits the spread of the infection, lessens pain, increases drainage, shortens the course of the disease somewhat and undoubtedly, in our experience, lowers the mortality. We feel very strongly that roentgen therapy in combination with heat, especially poultices, offers more than any other form of treatment.

The early carbuncle, treated with a large dose of filtered rays, will often be completely aborted. Incision is rarely necessary. Extension into contiguous structures is impeded or entirely stopped. Carbuncles in later stages are best treated with small doses of unfiltered rays, repeated at short intervals if necessary.

It is surprising to note how soon after treatment the character of the discharge changes. From a watery and scanty exudate it becomes definitely seropurulent and copious, while the tough fibrous nature of the retained material is altered and the floor of the lesion is readily discerned. At the same time the hard induration softens and the multiple small draining sinuses coalesce, becoming one large abscess cavity in which the material readily loosens from the surrounding tissue to be discharged in from three days to a week, leaving a clean freely discharging wound. It is rarely necessary to employ surgical means to obtain a good cosmetic and final result, as the ultimate outcome leaves a smaller and more pliable scar than could be obtained otherwise.

The dermatomycoses, especially blastomycosis and sporotrichosis are frequently treated favorably and respond well to from 500 to 700 roentgens of filtered rays. Irradiation is supplemented by iodine therapy. On the other hand, many fungous infections of the hands and feet respond admirably to roentgen rays alone, and our best results are seen when the heavier filtration is used. Some radiologists object to the use of the shorter wavelengths on small structures such as the fingers and toes, but where we have failed with unfiltered rays we have been successful with the filtered. Our doses, however, never exceed two thirds of an erythema dose in a single series and therefore we do not feel that we are subjecting the patient to the danger of an obliterative endarteritis or to serious consequences.

COMMENT

Every infection, whether it appears trivial and unimportant or well localized and delimited in the beginning, is a harbinger of potential sequelae such as thrombophlebitis, lymphangitis and pyemia. We feel that irradiation plays an important role in diminishing secondary manifestations of the primary lesion. Rarely have we encountered complicating factors, and we are confident that irradiation has contributed much in preventing them.

Experimental data on laboratory animals have shown that, in lesions in which beginning destruction of tissue is taking place, irradiation hastens the disintegration of the tissue in the process of destruction with earlier and more profuse drainage of the area and more rapid recovery.

The changes produced by irradiation are apparently based on the sensitivity of leukocytes especially lymphocytes, which is well known to radiologists.

Heineke⁴ has conclusively demonstrated that roentgen rays per se have no subversive effect on pathogenic organisms in culture but that the destructive action which ensues following irradiation is due to a secondary manifestation following the effect of the rays on lymphocytes and leukocytes. In an incredibly short time after subjecting laboratory animals to the roentgen beam he was able to demonstrate lymphocytic changes in direct proportion to the dosage. The phenomenon is characterized by a liberation of chromatin material in the surrounding area. What takes place and what effects follow the manumission of the chromatin is not known. This material collects again and forms in clumps and balls, to be absorbed by adjacent reticular cells and carried away by them as collected material and debris.

Other experimenters suggest the liberation of ferments and the stimulation of antibodies, while some intimate an altered electrocolloidal and metabolic change within the cells.

Fig. 3—A cellulitis on the left side of the face following a slight lesion in the nose. Treated Jan. 18, 1936. B discharged well. January 22, when the photograph was made.

Different types of lesions and similar lesions in different stages of development react somewhat differently to roentgen rays. This is demonstrated in early carbuncles, in which we have seen rapid dissipation of the infection with these areas returning to normal without necrosis or drainage. The same effect is seen in erysipelas, while in abscesses and in well developed or late stage carbuncles a rapid breaking down of the tissues occurs with an ensuing copious drainage and early healing. The response of lesions is based on the type of disorder present. Lesions with considerable white cell invasion and small amounts of connective tissue are influenced more readily than lesions with much connective tissue and small numbers of leukocytes.

The technic employed is not empirical, but we are not led by a fixed dosage for a certain lesion. Every case is individualized and treated accordingly. It frequently happens that similar lesions receive identical doses coincidental rather than predetermined. We advocate smaller doses rather than dosages approaching erythemas. Rarely does a lesion receive more than

4. Heineke H. Experimentelle Untersuchungen über die Einwirkung der Röntgenstrahlen auf innere Organe. Mitt. a. d. Grenzgeb. d. Med. u. Chir. 14: 21-94, 1904-1905.

400 roentgens (in air) or two thirds of an erythema dose during a series. The interval between treatments is determined by the lesion and on no other basis. A working rule which is apparently adaptable to most forms of infections may be expressed in the terms of the disorder present, i. e., the greater the lymphocytic and leukocytic infiltration, the smaller the dose with softer x-rays, and the more chronic the condition the larger the dose and the harder the ray.

In cases in which roentgen therapy is an auxiliary in the armamentarium against infection, we insist that if hot dressings are to be applied they be made to fit the lesion and not to include the surrounding area. We feel that the latter produces an unnecessary edema and swelling, especially around the eyes, which can be prevented. When poultices, usually flaxseed, are advised careful instructions are given that the compress shall not be large and cover only the lesion and not extend beyond. Supportive measures are also utilized when necessary to give to the patient as much comfort as possible. Concomitant systemic disorders are treated as necessary by a consultant experienced in the special field of medicine involved.

Fig. 4—A beginning carbuncle on the left side of the neck in a case of chronic furunculosis one furuncle showing in the middle of the neck just below the hair line. Numerous scars are present following previous furuncles. Treated Feb. 26 and 28 1936. Discharged eleven days later. B after filtered and unfiltered therapy there has been no recurrence of furuncles or carbuncle. In the area of the last carbuncle there is only a slight scar not visible in this view.

We believe that there is no question of the great value of roentgen therapy in certain infections. In our experience clinicians and surgeons have cooperated fully with us in this work. This method of treatment will, we believe, be generally adopted in many infections when the radiologists throughout the country familiarize the general profession in their respective communities with its value.

1000 West Franklin Street

ABSTRACT OF DISCUSSION

DR EDWARD H. SKINNER, Kansas City, Mo. There are only two situations in which I have any additional points to offer. One is with regard to the treatment of hair follicle infections and furunculosis of the nose, ears and arm pits. I have had cases of these types which have responded beautifully just as Hodges and Berger report. It seems to me this is a nice problem for some ambitious young radiologist. Certain tissue studies are required with cytologic evidence, including the career of these tissues following the x-irradiation.

DR F. F. BORZELL, Philadelphia. I believe that certain phases of the present status of treatment of infection by radiology require a word of caution. We are all getting beautiful striking results but we are at the present moment decidedly empirical. Our results in inflammatory conditions may probably be due to certain cellular influences perhaps on the reticulo-

endothelial cells, rather than to any bactericidal effects. This may probably be true in these gangrene cases. It might be well for those who meet an occasional gas gangrene case to use every effort to establish the diagnosis from the standpoint of the organism involved and to make careful clinical records and correlate them. It might be well to refer these records to Dr. Kelly for his continued investigation.

DR J. JAMES DUFFY, Denison, Iowa. In dealing with the type of staphylococcal infections it has been my experience that if one gives a maximum dose the first time one sees them one has much more success. I saw five years ago a case of Ludwig's angina, the patient having a high temperature and the infection in the neck extending down to the suprasternal notch. There was no evidence of fluctuation and no evidence of localization. Hot packs had been used at home. The patient was in a grave condition. The patient was given a maximum dose at about 104 kilovolts and the next day there was a definite localization. It is most peculiar that better coordination does not exist between the roentgenologist and the surgeon.

DR L. R. SANTE, St. Louis. With reference to the administration of a large dose of radiation at a single sitting I would say that I am aware that it does not sound reasonable and that it is not done universally. I got into the habit of doing this primarily because I was called on to treat certain carbuncles that were very rapid in their spread. With a feeling of helplessness I crowded the dose and found that it did no harm at all, and the effect was much more rapid. I am at a loss to understand that and cannot explain it. It has been my experience when the infection is in the fascial planes and not in the skin proper that the effect is not the same; it is less pronounced. This reaction has always occasioned considerable thought. I have on certain occasions obtained cultures of the organism that produced the carbuncle and have found that radiation applied to the organism in culture does not have any effect at all. Thus of course is a common observation. Why then do the x-rays applied to the organism that is infecting the skin produce a different result? There must be an influence of the rays on the organism, in close intimate contact with the tissue elements and the result must be due to the development of certain substances in the tissue of the skin.

DR W. EDWARD CHAMBERLAIN, Philadelphia. I have used carefully calibrated thimble chambers, calibrated at the particular voltage that Dr. Sante has used, against the Bureau of Standards chambers. It was within 0.1 per cent. With eight minutes, 400 milliamperes, at a distance of 16 inches, it was found that various x-ray tubes vary all the way from something like 160 roentgens up to a maximum of about 400 roentgens more than a hundred per cent variation. The answer is that in this work one must calibrate the beam and must remember that especially with an unfiltered beam the variation from one tube to another is tremendous on account of the wall thickness of the tube. The space charge effects are different but with the unfiltered beam just the changes from one x-ray tube to another make a big difference. I have demonstrated that a carbuncle will get well very much more quickly with a large dose than with a small dose, but there is an element of danger. I have seen two cases of pyemia that were fatal following 600 roentgens over a carbuncle in one case and 700 roentgens in another. I have not seen the development of pyemia when the smaller doses were used.

DR LEO G. RIGLER, Minneapolis. In 1924 Platon and I reported a series of fifty cases of erysipelas. It was probably the first list of cases of erysipelas treated with x-rays in this country. We used as a criterion of a good result a drop in the temperature within twenty-four hours after the institution of the x-ray treatment, only one dose being given and that rather a large one. The dose was not carefully measured although we thought we were approaching the skin erythema dose using unfiltered radiation. We used this criterion, the drop in temperature in twenty-four hours and the number of days that the patient had to remain in the hospital as compared to a control series which was entirely unselected. That is we took the previous year's fifty cases. It appeared evident that one single fairly large dose would have a very favorable effect on erysipelas. It was strikingly illustrated by the fact that the temperature dropped in a high percentage of cases in twenty-four hours. Some time later Dr. Walter Ude who

succeeded me at the General Hospital in Minneapolis, felt that certain risks were being taken by using \times radiation in large doses and he changed to the use of ultraviolet radiation. Since then they have collected a large series of cases treated both by \times rays, ultraviolet rays and, independently, serum. It would appear from a critical analysis of their cases that the results with large doses of ultraviolet radiation were as good as with \times rays. The method of choice would certainly be the ultraviolet radiation. It is much more available, the risk is infinitely less, and it is much more easily applied.

DR. SANTE. I am aware that the the output of \times -ray tubes changes. It is obvious that the thickness of the walls of different tubes makes a difference in output. But after all the biologic effect on the skin of the patient always will remain the ultimate criterion of superficial therapy. For skin dosage my associates and I have found for practical purposes that the ordinary factors are perfectly satisfactory for treatment, once the full output of the tube is established. This is checked up at regular intervals by our physicist. At the City Hospital, where we use a machine constructed for higher voltages, the output is smaller. At St. Mary's Hospital the output is greater, but once the output for a tube is measured it remains fairly constant. After all, dosage measured in this way never varies from 30 to 100 per cent as Dr. Chamberlain's statement might lead one to believe.

DR. ROLLIN H. STEVENS, Detroit. I wonder whether any one has had the experience I have had with cervical parotitis. The few cases that I have treated have responded well when treated in the first twenty-four hours. If those cases run much over twenty-four hours, say two or three days, they go on to suppuration and form retropharyngeal abscess and blood infection and the patient dies. The patients that it was possible to treat in the first twenty-four hours got well. I refer to a series of seven cases seen last fall. Our setup previous to this series of seven was 100 kilovolts and 4 millimeters of aluminum, from 85 to 100 roentgens at a dose repeated once or twice every twenty-four hours. In the series of seven cases we used 200 kilovolts, 2 mm of copper and 100 roentgens. We did that, trying to see if there was very much difference in the time factor of treating infections. Of course it probably does not matter whether one uses the short or the long wave, but I do believe that the time consumed in giving a treatment does make considerable difference. We have treated carbuncles in the same way. We have treated them with the long wave and the short wave, with high filtration and low filtration but using only about 100 roentgens, around 80 to 100 roentgens in either case either method of treatment and we find that they seem to do equally well.

DR. WILLIAM H. SARGENT, Oakland, Calif. I have treated a number of cases of surgical parotitis with \times -rays with gratifying results. None of them were treated within the first twenty-four hours and yet none went on to suppuration, even though some of the patients were very ill. One patient with extreme swelling recovered more promptly than some of the less ill ones. The dosage in all cases has been from 200 to 240 roentgens usually given in two doses occasionally three were used, with an interval of from two or three days between treatments. Three millimeters of aluminum filtration was used but 1 mm of aluminum and no filtration has been used with apparently the same results. It has been my impression that in this condition as well as other inflammatory conditions suppuration is the result of the stage of the pathologic process rather than any particular feature of the \times -ray treatments. It is no doubt preferable to treat these cases early.

DR. R. A. BERGER, Richmond, Va. In inflammatory lesions we are not governed by a fixed dose in any single instance. Our doses are usually empirical. We have found however that the more acute the infection the smaller the dose. In carbuncle we employ a small dose rarely exceeding 100 roentgens with either 4 mm. aluminum or no filter at all. Dr. Hodges has found that treating carbuncles with a massive dose, anything approaching a skin erythema, does what he terms "freezing the lesion." After receiving such a dose the lesion usually remains stationary for some time. Although drainage is present it is not of the copious seropurulent type obtained with smaller doses. In acute parotitis we have been fortunate in having no cases go on to suppuration.

THE CLINICAL DIAGNOSIS OF PERIARTERITIS NODOSA

MILTON B. COHEN, M.D.
BENJAMIN S. KLINE, M.D.

AND
ANNA MAY YOUNG, M.D.

CLEVELAND

Periarteritis nodosa is more of a pathologic than a clinical entity, and the diagnosis is more frequently made after the autopsy than at the bedside.

Our experience with this condition has led us to the conclusion that it is a manifestation of clinical allergy of so severe a degree that irreversible and destructive lesions occur in the blood vessels and lead to disturbances in the function of the organs supplied by the involved vessels. This opinion is based on the study of the following cases, a review of the literature and an experimental study of induced allergic reactions in man.

REPORT OF CASES

CASE 1—I. M., a woman, aged 25, was admitted to Mount Sinai Hospital complaining of pains in the arms and legs, swelling of the wrist, elbow and knee joints, itchy red spots on the legs and arms and asthmatic attacks. The asthmatic attacks had been recurring at intervals of from two to four weeks winter and summer for two years, the other symptoms had been present for two months.

The past history was irrelevant, as there had been no earlier allergic manifestations and no rheumatic fever.

The family history was positive for allergy.

The patient was thin and asthenic and she appeared to be older than her 25 years. The mucous membranes were pale and showed a slight degree of cyanosis. The eyes, ears, nose and throat showed no significant abnormalities.

The chest was slightly emphysematous in type. The heart was not enlarged, the sounds were clear, there were no murmurs. The lungs were slightly overdistended without evidences of infiltration. Many fine sibilant rales were present.

The abdomen was flat and showed no physical signs of abnormalities of its organs.

The extremities were thin. The wrist, elbow, knee and ankle joints were painful to touch and on motion and were slightly swollen. The skin showed numerous urticarial lesions, many of which were surrounded by areas of hemorrhage. There were also occasional areas of subcutaneous hemorrhage.

Urinalysis revealed a normal urine. The blood contained 12,000 leukocytes and 3,000,000 erythrocytes with 65 per cent hemoglobin. The differential count showed 30 per cent eosinophils. The Kline test for syphilis was negative. The bleeding and clotting time were within normal limits. The stool showed no ova or parasites. X-ray examination of the chest showed only slight overdistention of the lungs with an increase in the bronchial markings.

The provisional diagnosis was bronchial asthma, urticaria, purpura and hydrarthrosis of allergic origin, hypochromic anemia.

During a ten day period of hospitalization the only additional subjective complaint was that of abdominal cramps.

The patient was discharged from the hospital and study from the allergic standpoint was begun. This study revealed positive intradermal reactions to extracts of *Mav* fly, house dust, orris root, maple elm and sorrel pollens. There were suspicious reactions to several foods.

While these studies were being made there was a constant increase in the severity of the joint manifestations and the abdominal pain. There was practically no asthma. Within two weeks areas of hyperesthesia followed by anesthesia were present over the peripheral nerve supplies of both arms and legs and foot and wrist drop developed. The patient was readmitted to the hospital where consultations were had with all services that might have been useful. No additional facts

From the Asthma and Hay Fever Clinic and Mount Sinai Hospital.
Read before the Section on Pathology and Physiology at the Eighty-Seventh Annual Session of the American Medical Association, Kansas City, Mo., May 15, 1936.

of importance were noted. She died on the eighth day of her second hospitalization without a satisfactory clinical explanation of her condition.

Autopsy revealed innumerable severe inflammatory lesions involving the arteries in practically all the organs and tissues of the body. In addition to edema and cellular infiltration of the wall, most marked in the adventitia many arteries showed severe degenerative and necrotic changes involving one or more

Physical examination on admission to the hospital revealed a waterlogged condition, with areas of purpura scattered over the body surface. Except for chronic infection of both antrums, the head and neck showed no abnormalities. Some enlarged glands were palpated in the axillae. The heart was enlarged in all dimensions, there was gallop rhythm, no murmurs were heard. The blood pressure was 200 systolic and 120 diastolic. There was fluid in the chest and in the abdomen. The liver and spleen were both markedly enlarged.

The urine contained albumin. Blood chemical examination revealed nonprotein nitrogen 40, sugar 90, creatinine 2. The Kline test was negative. Blood count revealed 25,000 leukocytes, 81 per cent neutrophils, 6 per cent eosinophils, 5,230,000 erythrocytes and 90 per cent hemoglobin. The electrocardiogram showed a PR interval of 0.22 second with low voltage. X-ray examination of the chest, May 9, 1934, revealed a left pleural effusion.

The provisional diagnoses were malignant hypertension, cardiac failure, Hodgkin's disease, eosinophilic leukemia.

During an eleven day period of hospitalization there was no significant change in the condition and the patient was sent home, where appropriate treatment for the cardiac failure was continued.

It was at this time that one of us (M. B. C.) had the privilege of seeing him again in consultation with Dr. H. H.

Fig 1—Section of skin under low magnification. Normal reaction thirty minutes after injection of histamine showing congestion, edema and few wandering cells.

coats. The lesions were characteristic of periarteritis nodosa. In places parenchymatous organs and voluntary muscles showed areas of inflammation.

The most severe arterial lesions were present in the voluntary muscles, liver, gallbladder, heart, lung, alimentary canal and kidneys. The spleen, pancreas, adrenals, bladder and internal genitalia showed less severe arterial lesions than the other organs.

CASE 2—L. H., a man aged 31, was seen by one of us (M. B. C.) in consultation with Dr. M. H. Fineberg, Aug. 22, 1932. At that time he had an infection of the upper respiratory tract complicating an attack of bronchial asthma caused by the inhalation of ragweed pollen. He had had attacks of bronchial asthma during the fall hay fever season for ten years. Except for the asthma and the signs of bronchial infection there were no significant manifestations. The blood pressure was 120 mm. of mercury systolic and 80 diastolic.

In May 1934 the patient returned to Cleveland from his home in New York City. He had not had treatment for his allergy. At this time he presented the picture of marked cardiac failure and was hospitalized. Since the fall of 1933 he had had continuous asthma which began with very marked conjunctival and moderate nasal symptoms. In November he began to have severe abdominal pain, swelling and pain in various joints and purpuric spots in the skin and subcutaneous tissues. Anasarca developed in March 1934.

Fig 2—Section of skin under low magnification. Reaction in a person hypersensitive to ragweed thirty minutes after injection of allergen showing edema, congestion and eosinophil exudate.

Schweid. In view of our experience in case 1 a diagnosis of periarteritis nodosa was made. Biopsy of a tender area in a muscle confirmed this diagnosis.

CASE 3—A. K., a woman aged 27, was admitted to St. Alexis Hospital, Aug. 9, 1934, complaining of pain and cyanosis of the left arm, forearm and hand. The condition began three months before admission with numbness and tingling in both hands. Two days before admission severe pain developed in the left hand and discoloration followed. Coincidental with

the onset of the symptoms in the arms there was an attack of abdominal pain with vomiting. The abdominal symptoms persisted in mild form. There was a loss of 40 pounds (18 Kg) during this three months period. Early in adolescence there had been periodic attacks of typical bronchial asthma, and winter cough with occasional wheezing had persisted. The patient was emaciated. The result of physical examination was essentially negative except for the cyanosis of the

33, who has signs of intermittent claudication and severe abdominal cramps. There is diffuse tenderness in the calf muscles, but as yet no nodules have developed that could be removed for histologic study.

CASES DESCRIBED BY OTHERS

Middleton and McCarter¹ have recently reviewed the literature on periarteritis nodosa and have added to the approximately 200 cases in the literature three of their own. They agree with the generally accepted opinion that, while the disease is of unknown etiology, its occurrence in rheumatic subjects justifies its inclusion among the rheumatic diseases. It is pertinent to this discussion that one of their patients had attacks of asthma. Curtis and Coffee² described a case in which the diagnosis was made ante mortem from a biopsy and was confirmed at the autopsy table. The history of nasal polyps and asthma in this man was considered incidental and was casually mentioned. These authors have charted the symptoms and signs in thirty-eight cases from the literature, including their own. It is significant that four of the patients had

Fig 3—Section of bronchus under low magnification. Reversible allergic inflammation (bronchial asthma): mucus, Curschmann's spirals, leukocytes (many eosinophils) in lumen, leukocytic infiltration of mucosa (reversible).

left hand with beginning gangrene of the thumb and the tips of the index and little finger. The blood count was within normal limits. The urine showed no abnormalities, the serologic tests for syphilis were negative.

A diagnosis of Raynaud's disease was made and a left periarterial sympathectomy was performed. The increase in temperature in this arm was so striking that bilateral cervical sympathectomy was deemed advisable and was performed in two stages a few days later. At the same time the left thumb was amputated and gangrenous tips of the index and little finger were removed.

Within a day or two after the second operation, severe asthma began and one of us (M B C) was privileged to see her in consultation.

At this time the patient was very asthenic. She was in acute status asthmaticus which was not relieved by repeated doses of epinephrine.

A consideration of this case led us to explain all the symptoms on the basis of periarteritis nodosa. Death occurred six hours later from bronchial obstruction. Autopsy revealed the typical vascular signs of the disease.

In addition to these three cases we have seen one case at autopsy in which there was a definite history of a bronchial cough with wheezing and have under our care at the present time an asthenic asthmatic woman, aged

Fig 4—Section of voluntary muscle under low magnification. Reversible and irreversible allergic inflammation. Periarteritis nodosa. Degeneration and necrosis of adventitia of artery (irreversible). Eosinophil mononuclear round cell infiltration (reversible).

sufficiently severe asthma to be called to the attention of the clinician in the presence of more alarming and severe symptoms, and two others had cough. This incidence of asthma is well above that in the general population or among hospitalized patients. Very recently

Motley³ described a case in a man with severe bronchial asthma. The signs were typical but the significance of the asthma was overlooked.

PERIARTERITIS NODOSA AS A SEVERE MANIFESTATION OF CLINICAL ALLERGY

Our conception of periarteritis nodosa as a severe manifestation of clinical allergy is based on the following considerations:

When cells in the allergic state are brought into contact with an antigen to which they are sensitive, a characteristic reaction occurs. This reaction is vascular in nature and results in the outpouring of fluid into the reacting area followed by the extravasation of leukocytes. Reactions vary greatly in severity, depending on the degree of sensitization of the tissues and the doses of the antigen. Most of them disappear without permanent tissue change. For these we use the term reversible. Some, however, are so severe that tissue death results with healing by scar tissue formation. For these we use the term irreversible. The wheal produced by a skin test is an example of a reversible reaction, the Arthus phenomenon is an example of an irreversible one.

Our studies of the histology of induced allergic reactions in man showed that the body response was the same for all plant and animal foreign proteins and histamine, and that the reaction could be identified histologically if examined between thirty and sixty minutes after its inception.⁴ The reaction represents inflammation in which the predominating cell is the eosinophil. In some of the more severe reactions there were small areas of tissue necrosis. The Arthus phenomenon is merely an accentuation of this reaction in which there are well defined areas of tissue necrosis associated with areas in which ordinary allergic inflammation is present. Allergic reactions then may be entirely reversible or may represent varying degrees of both reversible and irreversible changes.⁵

If one examines sections of the vessels in periarteritis nodosa, one finds lesions which are indistinguishable histologically from those mentioned. There are areas of scarring alone, areas in which there is only reversible allergic inflammation and every conceivable combination of allergic inflammation and repair.

Cases can be classified into four general types:⁶ (1) fever, splenomegaly, leukocytosis, severe anemia, marked emaciation; (2) polyneuritis and polymyositis; (3) renal symptoms; (4) epigastric pain, vomiting and diarrhea. Clear cut types are not seen as often as those in which combinations of symptoms occur, as is well shown in the case histories cited. The most important point in the diagnosis of periarteritis nodosa is to think of the disease. The clinical diagnosis is not difficult to make if the clinician will consider every patient having severe allergy as presenting a potential case of periarteritis nodosa and will watch for symptoms and signs which may be explained on the basis of a temporary or permanent disturbance of the blood supply to any organ. Biopsy of a skin nodule or of a tender area in a muscle will usually confirm the diagnosis, as the histologic picture is characteristic and easily recognized.

10616 Euclid Avenue

ABSTRACT OF DISCUSSION

DR. HENRY C. SWEANY, Chicago: I would like to ask Dr. Cohen and his associates whether they made a search for sensitization in these cases of periarteritis nodosa and whether they were able to connect that up with the formation of this type of lesion. Also, have they any idea of the connection between this type of phenomenon and that described by Dr. Schwartzman?

DR. MILTON B. COHEN, Cleveland: We have had the opportunity to study several of these patients from the standpoint of allergy. They all give reactions to the common antigens or allergens that are usually associated with clinical allergy. We do not feel that this lesion has any direct relation to the Schwartzman phenomenon. Perhaps all these things are types of hyperimmunity or hypersensitivity, but we feel that that is a peculiar and specific one separate and distinct from the type seen in the Schwartzman phenomenon.

REPORT OF CASE

History—J C, aged 28, an Italian presented himself for operation. The history states that last January while at work he developed a large right indirect inguinal hernia. Gradually becoming incapacitated he was prevailed on to attend a clinic for an injection treatment. One injection of a tincture of

was uneventful and the patient left the hospital in satisfactory condition ten days later.

Pathologic Report—A small section of muscle tissue showed marked degeneration of the fibers and absence of nuclei, with necrosis and beginning gangrene. Other sections showed extensive thrombosis of the blood vessels hemorrhage into the muscle fibers and surrounding tissue with generalized necrosis.

COMMENT

From the foregoing it is possible to learn that the repair of hernias by the injection of materials must depend on destruction of the healthy tissue first and subsequent replacement with fibrous tissue that solutions however apparently harmless may cause considerable destructive damage that thrombosis of the vessels has definitely been observed and proved, that the vas deferens may be pathologically altered, that the pain

Fig 2—Thrombosis of the blood vessels with necrosis of the adjacent tissue elements

thuja solution was given into the region approximating the right internal inguinal ring. A truss had been fitted, and the patient sent home with instructions to return for a second injection. That evening the entire right lower quadrant of the abdomen became discolored. Intense pain developed which radiated down into the testicle. The scrotum swollen and painful confined the patient to his bed and extreme discomfort forced him to discard the truss. Several days passed before he was able to walk. The ecchymosis and swelling having gradually disappeared, he requested operation.

Two weeks elapsed before it was considered safe to attempt surgical repair. Under ether anesthesia, an inguinal incision was made through the presenting structures including the aponeurosis of the external oblique. All appeared healthy. When the fibers of this fascia were separated however, and the canal with its contents exposed, a green, gangrenous strip including fibers of the internal oblique and cremasteric muscles the upper portion of the pampiniform plexus and the greater part of the cord was found. The vas deferens looked blanched swollen and tortuous running directly through the gangrenous appearing spots. The hernial opening situated midway between the internal and external rings as such and adjacent to Poupart's ligament, offered an unusual position for injection. The sac made its exit here, ascending first under the cord structures then laterally following them into the scrotum. A small section of the greenish tissue was removed for histologic examination. The hernial opening was repaired by a purse string suture without opening into the sac. The rent in the transversalis fascia closed and the aponeurosis of the external oblique imbricated above the cord structures constituted the essential steps of the operation. Convalescence

Fig 3—Destruction of the muscle fibers absence of nuclei and gangrene of adjacent tissue elements

and inconvenience are greater than ordinary herniotomy, and that the site of hernias can be mistaken even by experienced men and injection fluid impregnated into healthy tissue.

CONCLUSION

Herein is reported a detailed early picture of tissue changes found at operation immediately subsequent to injection of supposedly innocuous solutions for treatment of reducible hernias.
30 North Michigan Avenue

TUBERCULOSIS AND CANCER

J. K. MILLER, M.D., INGLESIDE, NEB.

A consideration of the interrelation of tuberculosis and cancer presents a mass of contradictory observations. It is generally agreed that tumor cachexia as a nonspecific process will favor the development of tuberculosis, reactivate an old focus or accelerate the course of the disease. However, difference in the age incidence of the two diseases offers little opportunity to exercise such an influence.

That tuberculosis favors the development of cancer is supported by no less an authority than Ewing.¹ In such malignant processes as the leukemias, lymphosarcomas, carcinoma of the

Fig. 1—The malignant cells in the center of a typical tubercle. High power.

lung and epithelioma on a subsoil of lupus vulgaris, it seems highly probable to Ewing that a tuberculous process is often the excitant. Along the same trend is Esperance's work on Hodgkin's disease as an atypical form of tuberculosis. Experimentally, Cherry² has found a greater incidence in mice tumors concurrently inoculated with tubercle bacilli. With the exceptions noted by Ewing, it is still debatable whether tuberculosis is a precancerous disease.

Pearl,³ in a series of 7,500 autopsies, found active tuberculosis twice as frequent in the noncancerous group as in the cancerous class. This greater frequency in the nonmalignant cases is noted also in the necropsy studies of McCaskey,⁴ Landis and Broders. However, it must be recalled that tuberculosis takes its greatest toll before the age of 40 and cancer after the age of 40. Contrary to Cherry's work, Centanni and Rezzesi⁵ and also Teutschlaender⁶ found that tuberculosis hindered the production and retarded the growth of mouse tumors. In general, it is admitted that those organs most frequently the recipient of malignant growths are seldom infected by the tubercle bacillus, a fact observed as early as 1841 by Rokitsky.⁷

Cooper⁸ has collected 247 cases in which the two diseases coexist in the same organ. Carlson and Bell,⁹ from 11,000 general autopsies, find no statistical evidence supporting an antagonism between tuberculosis and cancer. They believe that the relation is incidental. Fischer found that the tubercle bacilli in a tissue culture of Rous sarcoma did not injure the cells that were subcultured many times.

Hueper¹⁰ finds the statistics on hereditary interrelations of cancer and tuberculosis too meager to offer any aid. He observes that the Negro race, while it is especially susceptible to tuberculosis, shows less cancer of the lung than the white

race. Eggers,¹¹ in his review of the etiology of cancer, says "The validity of the relation [tuberculosis and cancer] would appear to be one that can be settled only by continued and comprehensive statistical study."

The following case of concurrent tuberculosis and cancer of the descending colon is reported as an example of a most intimate association of these two diseases. Cooper has collected forty-nine cases in which the gastro-intestinal tract has harbored cancer and tuberculosis side by side. Of these, four were in the sigmoid colon. Hamperl has reported a series of twenty-two additional cases, of which one was in the colon.

REPORT OF CASE

History.—J. W., a white man, aged 62, admitted Dec. 12, 1932, had pleurisy fifteen years previously. The onset of the present illness was in December 1931, with productive cough, dyspnea and a loss of 18 pounds (8.2 Kg.) during the year. He had suffered from constipation for the past five years.

Physical examination revealed emaciation, medium moist rales in both upper lobes and suppression of breath sounds and dullness over the entire left lung field.

X-ray studies during hospitalization showed productive motting throughout both lung fields, with an excavation 6 cm. in diameter of the right upper lobe. Sputum was persistently positive. The diagnosis was pulmonary tuberculosis far advanced.

The patient was under pneumothorax and rest therapy but became progressively worse and died May 26, 1934.

Autopsy.—There was an empyema of the right side of the chest. The lung parenchyma showed a caseopneumonic tuberculosis of both lungs with cavitation of the right upper lobe.

Scattered throughout the terminal ileum and entire colon were infrequent old tuberculous ulcers. In the midportion of the descending colon was a mass measuring 7 by 6 by 6 cm., which partially occluded the lumen. The walls of the colon were from 4 to 5 cm. thick in the region of the tumor mass. The lymph nodes draining this area and the periaortic chain were enlarged, some being 1.5 cm. in diameter.

Fig. 2—Infiltrating cords of cells from the carcinoma of the rectum and two typical tubercles (a, b), one of which contains cancer cells in its center (b and figure 1). Low power.

Microscopic Examination. There was a caseopneumonic pulmonary tuberculosis with associated miliary tuberculosis of the liver, spleen and kidneys. The lymph nodes draining the tumor site showed only typical tubercles.

Section of the colonic mass showed an adenocarcinoma, grade III. The malignant process had invaded the submucosa and muscularis. In one portion, two adjacent tubercles were seen. The one presented the typical histologic features. The center of the other tubercle showed a nest of cancer cells similar to the more anaplastic cells of the main tumor.

SUMMARY

Cancer and tuberculosis were found in such intimate relation that cancer cells from an adenocarcinoma of the colon were seen in the center of a tubercle, part of a tuberculous process of the same area. Hueper has observed that some tubercles found in connection with a malignant growth may be pseudo-tubercles of the cancer stroma and that acid-fast bacilli present are nontuberculous saprophytic organisms. However, the presence of a typical tubercle containing Sternberg-Reed cells adjacent to the cancerous tubercle, justifies a claim of true tuberculosis. From the literature, little impression of an antagonism between cancer and tuberculosis is gained and their coexistence appears incidental.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS
HOWARD A. CARTER, Secretary

EVEREADY TWO-BED CARBON ARC LAMP, MODEL A-22, ACCEPTABLE

Manufacturer: National Carbon Company, Cleveland

According to the company, the Eveready Two-Bed Carbon Arc Lamp has been designed to meet the need of the small institution where two adults or four children may be exposed to carbon arc lamp radiation at the same time. It is designed to use different types of carbon electrodes thereby producing different types of radiation.

The lamp is automatically controlled, the throw of a small snap switch being required for starting and stopping. It is provided with a motor that brings the carbons together, establishes the arc and maintains uniformity until the lamp is stopped by another throw of the switch. The mechanism for controlling and operating this arc is of the same general principle as that used in the Eveready Professional Model and Solarium Lamps.¹ It is adapted for operation on 60 cycle

115 volt alternating current. A transformer is used to secure maximum arc efficiency from the power supplied the 10 amperes or 1,100 watts drawn from the electrical supply being converted by the transformer to 25 volts at 40 amperes. The lamp requires 1,100 watts, the transformer efficiency is approximately 49 per cent, under two hours' full load the transformer temperature rise is approximately 40 degrees C.

The carbon holders in this lamp are so arranged that they use copper coated carbon electrodes 6 mm in diameter and 9 inches long. Each trim of carbons lasts about two and

one-half hours in this lamp. Eveready Sunshine C and E carbons can be used, giving erythema-producing ultraviolet and substantial amounts of infra red radiation respectively. At a distance of 42 inches with Therapeutic C Carbons, without filter, a minimum perceptible erythema is produced in about four minutes.

Substantial casters are provided so that the unit may be easily transported from place to place. The heavier parts of the lamp are built into the base, thereby giving it stability. The electrical parts of the lamp are constructed of transformer iron, bronze, stainless steel, copper and other materials suited to the functions of the particular parts. The exterior of the lamp is constructed of stainless steel, polished aluminum and chromium. Doors are provided in which one can place wire screens or filter panels or special glass as desired.

This lamp is offered to the medical profession for use in its professional application of carbon arc lamp radiation in the

general fields of pediatrics, internal medicine, dermatology and a few other specialized fields.

The unit was investigated in a clinic acceptable to the Council. From a physical standpoint it was found to be not unlike the professional model already accepted by the Council. The evidence presented concerning the spectral energy distribution of the lamp was declared acceptable.

The Council on Physical Therapy therefore voted to accept the Eveready Two-Bed Carbon Arc Lamp, Model A-22, for inclusion in its list of accepted apparatus.

PROMETHEUS INFRA RED LAMP PORTABLE MODEL #201 ACCEPTABLE

Manufacturer: The Prometheus Electric Corporation, New York

This unit is recommended for home use on the prescription of a physician. The reflector is 11 inches in diameter and is mounted on a flexible rod that may be adjusted from a height of 35 inches to 66 inches. It has a 13 inch base telescopic tubes and the reflector is chromium plated. The burner is of the refractory type with the resistance wires embedded within the ceramic material.

The physical measurements indicate that it requires about 550 watts to operate the lamp.

This unit was tried out in a clinic acceptable to the Council and found to be reliable.

The Council on Physical Therapy voted to include the Prometheus Infra Red Lamp Portable Model #201 in its list of accepted devices.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEXCH, Secretary

SCARLET FEVER STREPTOCOCCUS TOXIN

(See New and Nonofficial Remedies 1936, p. 388)

Lederle Laboratories, Inc., Pearl River, N. Y.

Scarlet Fever Streptococcus Immunizing Toxin—Also marketed in packages of one 2 cc vial containing 80,000 to 100,000 skin test doses of scarlet fever streptococcus toxin for supplementary treatment of those patients who fail to become Dick negative after receiving the full five dose series of scarlet fever streptococcus immunizing toxin.

SILVER NITRATE (See New and Nonofficial Remedies 1936, p. 421)

The following dosage form has been accepted:

Ampoule Solution Silver Nitrate 1 Per Cent Sharp & Dohme—Solution silver nitrate 1 per cent, approximately 0.2 cc, is contained in ampoules composed of beeswax. For use a pinhole is made at one end of the ampoule and after suitable preliminary cleansing of the eye two drops are placed in each eye of the newborn.

Prepared by Sharp & Dohme, Inc., Philadelphia, Pa. No U. S. patent or trademark.

HALIBUT LIVER OIL (See New and Nonofficial Remedies, 1936, p. 459)

I. V. C. Halibut Liver Oil, Plain.—A brand of halibut liver oil N. N. R.

Manufactured by International Vitamin Corporation, New York. No U. S. patent. U. S. trademark 314,818.

CASTOR OIL—Castor Oil is the fixed oil obtained from the seed of *Ricinus communis* Linne (Fam. Euphorbiaceae). U. S. P.

For standards see the U. S. P. under *Oleum Ricini*.
Actions, Uses and Dosage—See *Useful Drugs*.

McNeil's Emulsion of Castor Oil (Emulsion Olei Ricini McNeil's)—Castor oil 50 per cent by volume with acacia as an emulsifying agent and sodium benzoate 0.1 per cent as a preservative. Cinnamon is used as a flavoring agent.

Prepared by McNeil Laboratories, Inc., Philadelphia. No U. S. patent or trademark.

EFFECT OF FAT ON GASTRIC TONUS

The idea that fats retard digestion is an ancient one. Aristotle had evidently observed evidence for this before he expressed the opinion "Now the best digestion is in the bottom of the stomach because the fat descends not there, such as eat fat meat are very sleepy, by reason that digestion is hindered." This observation has been repeatedly confirmed in more modern studies of gastro-intestinal function. The researches of Cannon¹ are particularly clear in demonstrating the delay in emptying time of the stomach following a fat meal, as compared to the rate of passage of food from the stomach after protein or carbohydrate ingestion. The introduction of x-ray technic made it possible to observe, under normal conditions, both gastric peristalsis and the exit of food through the pylorus. Although the earlier studies emphasized the effect of fat on motility of the stomach and on the control of the pylorus, it was soon demonstrated that fat in the duodenum is of profound importance in influencing gastric tonus. In his classic work on hunger, published in 1916, Carlson² observed that oil as well as other substances introduced into the small intestine inhibited gastric hunger contractions and gastric tonus. This observation has been substantiated and expanded, notably by the researches of Ivy and of Lim.³ These investigators have conducted numerous experiments, the results of which are interpreted to indicate that a humoral mechanism is responsible for the inhibition of gastric motility. They suggested that the inhibitory substance is for the most part present in normal intestinal mucosa in an inactive state and that after exposure to oil a certain proportion of the inactive substance is activated. The name "enterogastrone" was proposed for the agent. Intravenous injections of extracts of

this substance, prepared from the upper part of the small intestine, inhibited gastric motility in dogs.

A major portion of the experiments designed to study factors influencing gastric tonus have involved surgical technic of various types, usually applied to the stomach. This is particularly true of attempts to determine the possible importance of a nervous mechanism or of the pancreas in modifying the motility of the stomach. It has been desirable to investigate this question by a method in which the stomach and its nerve supply are undisturbed by any surgical procedures and which produces as nearly normal physiologic conditions in the stomach as possible. This goal has been achieved recently by Waugh,⁴ and his data therefore assume added significance. This investigator worked with trained animals under controlled conditions and by means of fluoroscopic examination determined the time of appearance of the routine barium sulfate meal in the duodenum and the emptying time of the stomach. The preparation of a jejunal fistula made it possible to study the effect of various materials introduced into the jejunum on gastric motility and emptying. Under proper care of experimentation, fairly uniform and consistent results could be obtained for the time required for the barium sulfate to appear in the duodenum and for the period necessary for the emptying of the stomach. Physiologic solution of sodium chloride in the jejunum had little effect on gastric motility and emptying. However, the introduction of fat in the form of undiluted cream into the jejunum immediately produced marked atony of the whole stomach with no peristalsis for periods of from thirty to ninety minutes. This resulted in a considerable delay in the time of appearance of the barium sulfate in the duodenum and in a prolongation of the emptying time of the stomach. A study was also made of the gastric inhibitory action of fat placed in the stomach, and this was found to be much less pronounced than that of fat put into the jejunum. In the latter study, fat administered orally appeared to be without effect until it had reached the upper part of the small intestine.

The experimental results of Waugh permit the conclusion that the site of initiation for the gastric inhibitory mechanism is not in the stomach but in the upper part of the small intestine. The main mode of action is apparently an atony of the stomach with an absence of peristalsis, although an actual closure of the pylorus may also be concerned in the gastric inhibition produced by fat. It seems evident that a similar technic may be employed for the assay of various materials prepared from duodenal tissue and should be of considerable aid in further purification and chemical studies of the apparent humoral agent activated by fat and of importance in the regulation of gastric tonus.

PROBLEM OF NUTRITION

The committee of the League of Nations¹ formed to investigate the problem of nutrition found the subject too extensive for the presentation of a comprehensive report to the 1936 assembly of the league. The preliminary report of the committee consists of four volumes: 1 An Interim Report of the Mixed Committee on the Problem of Nutrition, embodying the suggestions made by the committee to the assembly and giving a general idea of the problems involved; 2 A report on the Physiological Bases of Nutrition drawn up by the Technical Commission of the Health Committee and forming the starting point of the scientific aspect of the nutrition problem; 3 A Report on Nutrition in Various Countries, which gives the substance of the actual data received by the committee, including the essential portion of the information contained in the replies of certain governments to the secretary-general's circular letter of Nov. 30, 1935, and the available statistical material concerning the consumption of foodstuffs; 4 Statistics on Food Production, Consumption and Prices. The first two volumes are now available. The first volume contains a general survey of the nutrition problem, including some of the latest dicta regarding optimal and minimal standards of human diet. The specific problems of child health, general and professional education, economic considerations, the agricultural and national nutrition policies and social welfare are discussed in the first chapter. The special dietary needs of different classes and age groups, including expectant and nursing mothers, infants, children of various ages and adults, are considered briefly in the second chapter. Energy requirements and the specific role of various foodstuffs in the dietary form the subject of considerable discussion. Perhaps the most important conclusion was that milk is the nearest approach to a perfect and complete food and that no other single food is known that can be used as a substitute. Since, however, different foods are available at lower costs in some areas than in others, the possibilities of substitutions are important. Concerted international action would greatly stimulate the development of rational nutrition. An enormous mass of information on nutrition is available in the world, but it is fragmentary, heterogeneous and frequently devoid of scientific basis. In short, the conclusion is obvious that the gaps between general knowledge on nutrition and the application of this knowledge in legislative practice are wide. The main problem is to bridge this gap.

A number of recommendations are made in this report, including the encouragement and support in every possible way of further scientific study of nutrition problems; vigorous policies of education in public nutrition; special consideration of the means of meeting the nutritional needs of the lower income sections

of each community, the setting up of standards of reference and specifications for grading food according to quality, and consideration of the degree and method by which national supplies and consumption of individual foods might be improved.

The analysis of the physiologic bases of nutrition, contained in the second volume of the report, results in the following general recommendations: 1 Although a simplified diet may be so constituted from a few protective foods as to be satisfactory, it is a general principle that variety in diet tends to safety, provided it contains a sufficiency of the protective types of food materials. 2 Since white flour in the process of milling is deprived of important nutritive elements, its use should be decreased and partial replacement by lightly milled cereals should be encouraged. 3 Milk should form a conspicuous element of the diet at all ages. 4 Fresh vegetables and fruits should always be constituents of the normal mixed diet. 5 The need for provision of extra vitamin D wherever and whenever sunshine is not abundant is especially emphasized.

MASKED ALLERGENS

The protean manifestations of the allergic state and the apparent infinitude of substances to which the human being may become sensitized have made us more conscious of the importance of knowledge in this field. Reports of new agents as sensitizers are encountered with increasing frequency. Recently a starch-splitting enzyme has been shown to be the causative agent in untoward gastro-intestinal symptoms following its administration. Certain constipation correctives of plant origin produce similar results. Many of these events cannot be foreseen. When products already marketed and of known composition are concerned, much needless inconvenience and not infrequently even dangerous reactions may be avoided by investigation previous to use. The more adequate labeling of these materials will prevent much unnecessary distress. No group of individuals is more aware of its environment, is more careful of its food, its drugs, its very milieu, than those who are allergic. Unless forewarned by their physicians or by the label of the manufacturer, these otherwise conservative and wary folk must learn by grievous experience. It makes considerable difference whether vitamin preparations (now in seasonally increased usage) are put up in fish oil, maize oil or peanut oil. The palatability and digestibility of potato chips may depend entirely on whether they are cooked in lard, cottonseed oil or linseed oil. The small fraction of wheat in a supposed "all-rye" bread may spell the difference between a happy or a miserable few hours. The unlabeled bromide sedative, phenolphthalein laxative or iodide compound may cause more discomfort than the conditions they allegedly correct. The memory of any practitioner could multiply these examples many times.

¹ The Problem of Nutrition. Vol. 1. Interim Report of the Mixed Committee on the Problem of Nutrition. Vol. 2. Report on the Physiological Bases of Nutrition. Distributed by World Peace Foundation, 8 West Fortieth Street, New York.

Proper labeling of such commodities should set forth not only their principal ingredients but every substance contained in them or of significance in their preparation. The ready response of the public to such a plan would be manifested by the increased use and prescription of products so marketed. There would be no need for compulsion to bring the usual stand-patters and conscientious objectors into line, for, once the advantages of such a program were seen, they would be quick to follow, and an informed public would enjoy the benefits of this new protection.

Caveat emptor was never meant to apply to the purchase of commodities that affect the health of a nation. The need for such a warning will automatically disappear with the unmasking of our commercial labels. Education and experience have made the allergic patient, cosmetic conscious, food and drug conscious, and household conscious. To remove the cloak of obscurity from articles in common use is a decided step toward making self preservation less difficult for an increasingly large proportion of our population.

Current Comment

INEFFECTIVENESS OF CONTRACEPTIVE METHODS

The reproductive life histories of 30,949 women form the basis for a recent report by Pearl.¹ Of the white women in the sample, 10,806, or 42.7 per cent, and of the Negro women 925, or 16.4 per cent, had practiced contraception up to the time of record. An analysis of the mean and median age of women not practicing contraception, married only once and having no form of gynecologic disease, shows that under these conditions the median pregnancy rates of white and of Negro women are identical in each quinquennial age period of exposure to the risk of pregnancy. The same is true also for the age specific mean pregnancy rates, except for two age periods in which the racial differences are probably statistically different. The analysis of the age specific mean and median pregnancy rates of white women practicing contraception regularly and steadily throughout their married lives, without intermission of any sort, married only once and free of gynecologic disease, showed that this type of contraceptive practice led generally to a reduction of median pregnancy rates below those of noncontraceptors in the same age period. This reduction in pregnancy rates, however, averaged only from 20 to 30 per cent. This low average may probably be interpreted as an expression of the relative lack of intelligence and effectiveness of these women with the methods employed. Among Negro women in the same category the reduction of pregnancy rates was insignificantly slight. The latter fact demonstrates the extremely inexact nature of ordinary birth control methods when employed by Negro women.

CULTURAL METHODS FOR THE DIAGNOSIS OF GONOCOCCIC INFECTIONS

Many mediums and procedures have been described for the cultivation of *Neisseria gonorrhoeae* since Bumm in 1885 first successfully grew the organisms on coagulated human serum. Difficulty heretofore has been experienced in isolating the gonococcus from purulent discharges teeming with other species of bacteria. Most significant information on the growth requirements was contributed by McLeod and his associates¹ in England. They observed that autoclaved peptones inhibited the growth of the gonococcus but that by incorporating heated blood in the medium this untoward effect was eliminated. The British investigators also proved that a reinforcement of the atmosphere with approximately 10 per cent carbon dioxide favored the isolation of the organism, while such an atmosphere was unnecessary to propagate stock strains. In this country, Leahy and Carpenter² not only confirmed these observations but reported that 15 per cent of the strains of gonococci failed to grow unless the atmosphere in which the cultures were incubated contained 10 per cent carbon dioxide. Furthermore, they observed that the temperature of incubation was an essential factor in the routine isolation of cultures. Some races failed to grow at 37 C but developed at 34 C, and vice versa. This information suggests that more positive cultures may be obtained when lower temperatures, such as 35 or 36 C, are employed. Another most useful adjunct to the cultural method is the "oxydase test" described by Gordon and McLeod.³ It is used to identify colonies of *Neisseria* in mixed cultures and is especially valuable in differentiating such colonies from those of streptococci and diphtheroids, which macroscopically appear very similar. Several workers⁴ in this country and abroad have reported that by its use in conjunction with the cultural method from 15 to 50 per cent more positive diagnoses were made than by the examination of stained smears for gram negative diplococci. The cultural method also serves as a reliable test for cure, in which role it is perhaps of greatest value. Its use overcomes the difficulties encountered in examining smears in chronic cases of gonorrhea when secondary infection has changed the clinical picture and few gonococci are present in the inflammatory exudate. The isolation of *Neisseria gonorrhoeae* therefore removes the shortcomings of the "smear" method and renders an unmistakable diagnosis. Furthermore, it constitutes medicolegal evidence that is acceptable in court. Although further research will undoubtedly contribute toward the simplification of the cultural method and make it more practical, the more extensive use of the present procedure in public health laboratories will immeasurably aid in the control of gonococcic infections.

MEDICAL AND HOSPITAL CARE FOR DEPENDENT FAMILIES

A Government Problem as Met in the City of Rochester, N Y

S J APPELBAUM, M D
ROCHESTER N Y

Medical care of the indigent as a government obligation in the past few years has become an increasingly greater problem. This is due to two factors (1) the large increase in the numbers who are not able to purchase their medical needs, and (2) the increasing inability of private agencies to supply the necessary medical needs.

The old state Poor Law, which was in effect until 1930, was rather vague with reference to medical care. Medical care, while implied in the old Poor Law, was not definitely mandatory. The Public Welfare Law of 1930 under article IX section 77, however, definitely states that 'It shall be the duty of public welfare officials insofar as funds are available for that purpose, to provide adequately for those unable to maintain themselves. They shall, whenever possible, administer such care and treatment as may restore such persons to a condition of self support, and shall further give such service to those liable to become destitute as may prevent the necessity of their becoming public charges.'

Article X, section 83 as later amended and effective April 25 1935 made the responsibility of the public welfare districts for providing medical care, not only for persons unable to provide such care, but also for persons not otherwise in need of relief. Section 83 reads "The public welfare district shall be responsible for providing necessary medical care for all persons under its care, and for such persons otherwise able to maintain themselves, who are unable to secure necessary medical care. Such care may be given in dispensaries, hospitals, the person's home, or other suitable place."

In order to provide for such care, the welfare district is empowered under section 84 to appoint physicians to care for sick persons in their homes. 'In a county welfare district such physician or physicians shall be appointed by the county commissioner. In a city such physician or physicians shall be appointed in accordance with the provisions of the general or local law, relating to such city. In a town, such physician shall be appointed by the town board. Where no physician or physicians is so appointed, the public welfare official shall employ a physician or physicians to visit sick persons in their homes whenever necessary.'

Under section 85 the present Public Welfare Law makes counties and cities responsible for providing hospital care. Under the old Poor Law, towns provided hospital care but now have no responsibility for such care. The law also provides a definite procedure for securing acceptance as public charges in emergency cases. These cases are of increasing importance. The old Poor Law made no provisions and had no procedures for this group. Under the foregoing laws the principle is definitely established that the state, through its various political units, has a definite obligation to provide not only food, shelter and clothing but also medical care to those in need.

As relief increasingly became a major problem in the past few years, the state through the Temporary Emergency Relief Administration stepped into the picture to share in the cost and make possible a fuller and more adequate service than was possible through unassisted local funds.

The Emergency Relief Act setting up the Temporary Emergency Relief Administration was passed in 1931. As amended

in 1933 it reads as follows: "'Home Relief' means shelter, fuel, food, clothing, light, necessary household supplies, *medicine, medical supplies*, relief to veterans under existing laws and *medical attendance* furnished by a municipal corporation or a town, where home relief is a town charge, to persons or their dependents in their *abode or habitation* whenever possible and does not include old age relief or allowances made to mothers for the care of dependent children or *hospital or institutional care*.'

The state, then, through the Temporary Emergency Relief Administration does not participate in the cost of hospital or institutional care and furthermore under its regulations will not approve claims for expenditures by municipal corporations in cases

"1 Where necessary hospital or institutional care has not been provided, or has been unduly delayed, and

2 Where full use has not been made of all existing public facilities for providing free medical services"

To provide for the orderly administration of its activities, the Temporary Emergency Relief Administration has set up rules and regulations under which it functions. On March 3, 1933, the Temporary Emergency Relief Administration adopted "Rules and Regulations Governing Medical Care to Home Relief Clients" in the form approved by the Special Temporary

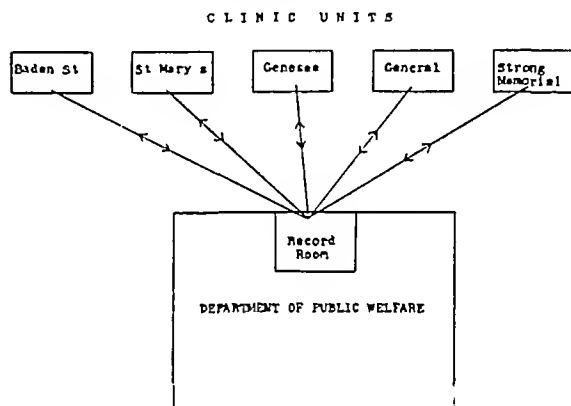

CHART 1—Contact between clinic units and record room of Department of Public Welfare. Direct telephone connections for verification of status of case.

Emergency Relief Administration Advisory Committee of the Medical Society of the State of New York, and the State Commissioner of Health. These are the rules and regulations revised from time to time, the last revision being in March of this year and in effect April 1, 1936, under which medical care is administered in the various political units of the state so far as the state assumes the responsibility for medical care.

With the preceding as a general background, the facilities and regulations created in the city of Rochester to meet the problem of medical care of the indigent may now be discussed.

The private hospitals in the city of Rochester had been operating for the past several years with increasing deficits over and above allotments made by the Community Chest. In response to the needs of the hospitals, it was determined in consultation with and with the approval of, the State Department of Health and the Temporary Emergency Relief Administration, to institute an experiment whereby the hospitals would be reimbursed for clinic care given to the Department of Public Welfare clients in the outpatient departments of the hospitals.

For the two fiscal years April 1933-1934 and April 1934-1935 the combined operating deficits of the four private hospitals participating in the Community Chest respectively were in round numbers \$200,000 and \$225,000. In each year the Community Chest granted these hospitals about \$157,000, with a resulting net deficit of about \$42,000 and \$69,000 for the respec-

five years The respective figures for 1935-1936 were \$222,000, \$182,000 and \$40,000 In recognizing that it is a municipal obligation to pay for the medical needs supplied to the clients of the Department of Public Welfare by these hospitals, just as the Department of Public Welfare pays for the food shelter and clothing supplied to its clients, it was expected that these deficits, either in full or in a large part, would not recur

As a by-product of the need for medical direction and supervision for this particular activity, the municipal authorities

Chart 2—Routing of medical supply forms from clinic units to Medical Service Division

deemed it desirable to consolidate the entire question of medical care to the indigent, including medicines, medical supplies and hospitalization with this outpatient program I was requested in June of last year to take over the directorship of the Medical Service Division of the Department of Public Welfare with that end in view A medical unit had existed in the Department of Public Welfare Its supervision of these medical activities however, because of the lack of competent medical advice, was not considered adequate.

An analysis of the medical needs of clients of the Department of Public Welfare and of individuals otherwise indigent indicated the following desirable activities in such a division of the Department of Public Welfare.

- 1 Medical care supplied in homes of patients and offices of physicians
- 2 Dental care—treatments extractions repairs and dentures
- 3 Clinic care in outpatient departments of hospital or dispensary
- 4 The supplying of medical needs such as
 - (a) Medicines on prescriptions
 - (b) Medical appliances, eyeglasses orthopedic needs, special belts, braces, corsets and shoes, and so on
- 5 Hospitalization
 - (a) Private hospitals
 - (b) Municipal hospital.
 - (c) County hospital
- 6 Placement of individuals in
 - (a) Monroe County Home.
 - (b) Private homes

Let me briefly dispose of several of these simpler problems and then take up more fully the major problems such as arrangements for medical care through the dispensaries the supplying of medical needs and the large question of hospitalization.

Medical care in the homes of patients and the physicians office is furnished through a staff of about twenty city physicians working under the supervision of the Health Bureau These physicians also have responsibility for medical activities in the public schools Requests for such services are made at the Medical Division The requests are then passed on to the

Health Bureau There are no provisions in accordance with the Public Welfare Law for payment for medical care to private physicians

Dental care is provided through the dental clinics of the dispensaries and several dentists located in different parts of the city, in accordance with the regulations and schedules of the Temporary Emergency Relief Administration

Admission of individuals into the County Hospital and Home, either direct or on transfer from a general hospital, is arranged for through the office of the County Commissioner of Public Welfare.

The problem of assuming financial responsibility for clinic care for families on the relief rolls of the Department of Public Welfare was a new project something in the nature of an experiment This demanded the creation of an organization and the formulation of regulations, schedules and procedures

Five clinics were selected four attached to hospitals and one unattached dispensary in a section of the city without a hospital One clinic having less than 20 000 visits a year was not included In each of these five clinics was established a unit of the Medical Service Division consisting of a trained social service worker with medical experience or a graduate nurse with social service experience and one or two clerical aids, depending on the size of the clinic The units were opened successively, from four to seven days apart, beginning with the smallest The first unit was opened with two staffs, one, which remained at the first clinic and the second which was utilized as a traveling training unit for each of the succeeding units Each succeeding clinic was then opened with its unit and the training unit When this training unit arrived at the fourth clinic, the staff for the fifth and last clinic was also brought into the fourth unit for its training A direct telephone connection was established from each unit to the record room of the Department of Public Welfare for the verification of the statements of patients who claim to be on the relief rolls of the Department of Public Welfare Records are maintained of each patient, with daily and monthly reports on the work of each clinic.

Regulations and procedures governing the authorization of patients as a city charge, the authorization of expensive medica

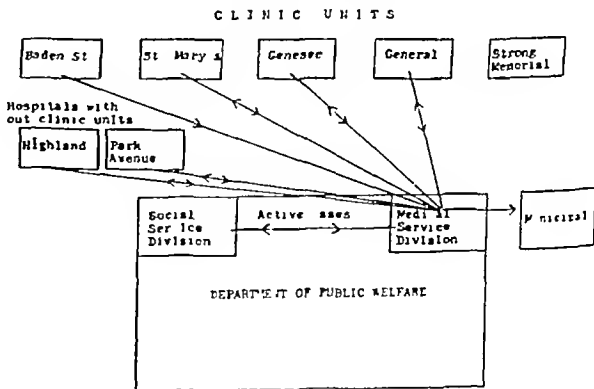

Chart 3—Routing of referrals for hospitalization Cases active with the department are referred to the visitor in charge of the family for guidance. Cases inactive with the department are investigated by the staff of investigators attached to the Medical Service Division Cases active and inactive in accordance with regulations are referred to the Municipal Hospital

tions and x-ray examinations and treatments were prepared These were discussed at a conference with representatives of the clinics and had their approval With but minor changes, these regulations and procedures are in use at the present time

A fee of \$0.50 is paid by the department for each clinic visit All medication costing the clinic less than \$0.50 is supplied without any additional charge. An authorization includes visits

to all clinics to which the patient may be referred on the day of authorization, including physical therapy, the usual laboratory tests and ordinary surgical dressings. Expensive drugs costing more than \$0.50, x-ray examinations and other medical needs are separately authorized. The care of acute and chronic cases is regulated in accordance with the procedures established by the Temporary Emergency Relief Administration.

The schedule of costs for expensive medication, x-ray examination and therapy is a schedule approved by the Temporary Emergency Relief Administration.

Because of anticipated other provisions, the care of venereal disease is not authorized through this set up. Because of the existence of other facilities neither prenatal nor postnatal well baby and tuberculosis clinics are authorized.

The amount paid to the hospitals for this service to welfare clients over the period from July 1, 1935 to Jan. 1, 1936, was \$37,174.82, approximately one half of the combined hospital deficits of the previous year. However this income is offset by an additional expenditure on the part of the clinics for medication supplied to these patients. This innovation of payment to the hospitals for clinic care given to clients of the Department of Public Welfare is an experiment. How long it will continue with state aid, or at all we do not know.

MEDICAL SUPPLY NEEDS

In order to conform with rules and regulations governing medical care as issued by the Temporary Emergency Relief Administration which of necessity conform with regulations of the Federal Emergency Relief Administration it is necessary to supervise with considerable care all requisitions that come to the Medical Division for medicines, medical supplies, dental work, orthopedic supplies, special shoes, eye glasses, corsets, belts, trusses and the like.

This supervision is indicated both in the interest of economy and with the view of securing state reimbursement. Reimbursement can be secured only as our procedures conform with state regulations. Excepting in very unusual conditions, prescriptions are restricted to medicines and mixtures listed in the latest editions of the United States Pharmacopeia and the National Formulary. A small list of additional remedies which have been accepted as approved in New and Nonofficial Remedies by the Council on Pharmacy and Chemistry of the American Medical Association may be authorized with a view to reimbursement.

Requests for medicines and medical supplies come to the Medical Service Division from two sources: the outpatient departments of the hospitals and city and private physicians. Such requests originating in the outpatient departments are routed on a medical supply form, first through the social service worker of the particular clinic unit for notation of pertinent facts and secondly through the Assistant General Case Supervisor with reference to social and financial factors and then to the Medical Service Division for final action. In evaluating these requisitions the age, the apparent degree of necessity, the relationship of need to continuing at or securing work and other significant factors are taken into consideration. Although the article requested is indicated to correct an abnormality, nevertheless the request is not always granted. The deviation from the normal may be quite minor. The age and general condition of the patient may be such that the requested article would have no bearing on the individual's activity. In general, then, the principle is observed not to authorize such needs which the average taxpayer would not purchase for himself out of his own private funds.

The problem of hospitalization is a large financial problem. In Rochester we have three distinct means of meeting this need for the dependents. There is a Municipal Hospital operated by contract by the University of Rochester in conjunction with the Strong Memorial Hospital, both units in turn being

affiliated with the medical school of the university, five private hospitals, and a county hospital under the supervision of the county commissioner of public welfare. The operation of the Municipal Hospital costs the city about \$400,000, care authorized in the private hospitals about \$175,000, and care authorized in the County Hospital about \$200,000. The private hospitals are paid a per diem rate of \$4 with no extras. The County Hospital rate is about \$15 a week. The per diem cost at the Municipal Hospital of course varies with its occupancy, less when the occupancy is high and more when the occupancy is low.

From the foregoing it can readily be seen that there are three important factors involved in the problem of hospitalization:

- 1 The problem of keeping the Municipal Hospital reasonably full. This involves a question of economy.

- 2 The problem of minimum interference with the intake of city cases by the private hospitals. These hospitals are an asset to the community. They fulfil a need in the community.

- 3 The problem of the care of the chronic cases, both by direct admission to the County Hospital and by transfer there from the private hospitals.

The attempt is being made to solve this rather complicated and conflicting problem under the following regulations. These regulations were approved by the hospital directors before they were put into effect.

- 1 Urgent cases are accepted at any hospital on arrival. If authorization is requested, authorization is given if warranted.

- 2 Cases that are not urgent, but which have been worked up in the clinics, are referred to the Medical Service Division before admission to the hospital. Authorization, if warranted, is made to the hospital or clinic where the case was worked up.

- 3 Cases that are not urgent and new to the clinic for the condition requiring hospitalization are referred in person to the Medical Service Division for investigation and disposition. The disposition usually is reference to the Municipal Hospital.

A distinction is made in cases referred for hospitalization between those active on relief and those inactive. In the active case the request is referred to the welfare visitor of the patient or family for guidance, but in the inactive case the investigation is made by a staff of investigators attached to the Medical Service Division. In the inactive group, however, no investigation is initiated until application has been made by the patient or a responsible member of the family for payment of the hospital bill by the Department of Public Welfare.

In certain cases, application for hospitalization is not accepted:

- 1 The Veteran group—these are referred to the respective organization.

- 2 The tuberculosis group—because of other existing facilities.

- 3 The tonsil and adenoid group of children under 16 years of age—because of other existing facilities.

- 4 The maternity group—also because of other existing facilities.

The hospital referral form is carefully considered in the disposition of the request for authorization of hospitalization. If the patient is already admitted to the hospital and the referral indicates no apparent emergency, the hospital is requested to explain what emergency indicated admission prior to authorization. No further action is taken on the referral until after the requested information is given. If the family does not make application for hospitalization within thirty days after admission the hospital is so notified. Applications are not accepted sixty days after hospitalization. If the family can make partial and deferred payment of the hospital bill, the case is not accepted and the hospital is so notified. Compensation liability and legal residence factors are also given careful consideration.

When authorization is requested for an acute exacerbation of a chronic condition, the authorized stay is usually limited

to the period of the exacerbation and arrangements are made for the transfer of such cases to the County Hospital if further hospitalization is indicated

COMMENT

The foregoing, in a rather sketchy form, outlines the facilities and procedures followed in Rochester in the effort to provide for medical and hospital care for dependent individuals. Of course, the need is not met 100 per cent. The burden of the average small taxpayer cannot be overlooked any more than he can overlook the inability of our voluntary health agencies to raise sufficient funds to meet the calls on them for adequate service. There is, however, a growing sense of public responsibility for meeting the health needs of our dependents. These health needs are beginning to be recognized as a public health problem. An individual case of illness, an illness which involves only personal health and which is not a menace to public health usually is not considered a public health problem. However, an accumulation of such conditions does become a matter of public health. It then does become a matter of public responsibility. Our aim has been to coordinate our medical resources and to utilize these resources most efficiently and economically, having in mind the needs of the dependent and the ability of the community to meet these needs.

Our program in Rochester does attempt to meet in a reasonable measure the medical needs of the dependent. Quite naturally, it does not meet all the demands that are made for service. A number of requests are refused either because the condition is deemed relatively trivial or because means of satisfying the demands exist in responsible members of the family. The problem of relief is so great that relief funds, either state or local, should not be expended on those individuals able to finance their own needs. This restriction should apply to medical and hospital care at public or private expense just as it does to other basic needs. Neither clinics nor hospitals should be expected to supply medical service to those who are able to pay reasonable professional fees for such service. Such a policy is essential in order to conserve the facilities and funds both public and private so as to make it possible to give more adequate service to those who are dependent.

This entire question of meeting the medical needs of the dependent through public and private funds is in a state of transition. How great will this problem continue to be? What effect will the recent social legislation have? I refer to legislation respecting old age security, retirement pension provisions, and unemployment insurance. At the same time there has developed in various parts of the country for the medium income group a variety of voluntary plans for the payment for medical service, such as group prepayment or insurance, deferred and partial payment, and group insurance to provide for hospitalization. It is yet too early to evaluate these new schemes. Without question some of these plans have value and will become recognized and approved facilities for securing medical and hospital care. Also, the entire scheme of state aid under the Temporary Emergency Relief Administration in our state in a short time will be transferred to a reorganized State Department of Public Welfare. All these and many other factors have a bearing on this question. Consequently, the problem is quite complicated. However, the realization in advance of these many complicating factors should help in the proper solution of the problem.

Of one thing I am certain: local facilities both public and private are unable to give adequate medical care to their dependents. Local funds are inadequate to meet the need. The state through one agency or another will continue to share the responsibility of meeting this problem if the problem is to be met adequately.

277 Alexander Street

Association News

ANNUAL CONFERENCE OF STATE SECRETARIES

The Annual Conference of Secretaries of Constituent State Medical Associations will be held in the American Medical Association Building, 535 North Dearborn Street, Chicago, November 16 and 17.

The program will be as follows:

MONDAY NOVEMBER 16 10 A. M.

Call to Order Rock Sleyster, Chairman of the Board of Trustees of the American Medical Association.

Address Charles Gordon Heyd, President of the American Medical Association

Basic Science Laws Mr J W Holloway, Bureau of Legal Medicine and Legislation, American Medical Association

The Michigan Filter System L Fernald Foster, Secretary of the Michigan State Medical Society

The Public Health League of California Glenn Myers Los Angeles

12 30 p m Luncheon

MONDAY NOVEMBER 16 3 P. M.

Address J H J Upham, President-Elect, American Medical Association

The United States Public Health Service and the Social Security Act Thomas Parran, Surgeon General, United States Public Health Service.

The Children's Bureau and the Social Security Act. Miss Katharine F Lenroot Chief, Children's Bureau, United States Department of Labor

Practical Hints on the Preparation of Manuscripts and Illustrations Richard M Hewitt, Rochester, Minn

MONDAY NOVEMBER 16 6 30 P. M.

Dinner Conference of Editors of State Medical Journals Holman Taylor, Secretary-Editor, State Medical Association of Texas, presiding

TUESDAY NOVEMBER 17 9 30 A. M.

Insurance Against Alleged Malpractice. Mr Thomas V McDavitt, Bureau of Legal Medicine and Legislation, American Medical Association

The Scientific Exhibit at Annual Meetings of State Medical Associations Thomas G Hull, Director, Bureau of Exhibits, American Medical Association

REFERRED FOR DISCUSSION BY HOUSE OF DELEGATES

Consultation and Correspondence with Bureau of Legal Medicine and Legislation

Violation of Laws Pertaining to Narcotics

RADIO BROADCASTS

The American Medical Association and the National Broadcasting Company are presenting the second series of dramatized health broadcasts under the title *Your Health*. The first broadcast in the new series the thirty-second dramatized cooperative broadcast under the title *Your Health*, was given October 13. The theme for 1936-1937 differs slightly from the topic in the first series, which was medical emergencies and how they are met. The new series is built around the central idea that 100,000 American physicians in great cities and tiny villages who are members of the American Medical Association and of county and state medical societies stand ready, day and night, to serve American people in sickness and in health.

The program will go out on the Blue network instead of the Red as originally announced. The announcement cards that were sent out when the program was planned for the Red network can be changed simply by substituting the word "Blue" for Red where it occurs.

The topics are announced monthly in advance in *Hygeia*, the Health Magazine and three weeks in advance in each issue of *THE JOURNAL*. The topics and speakers for the next three programs are:

November 10 Noise Paul A Teschner M.D.
November 17 Football Injuries Morris Fishbein M.D.
November 24 Be Thankful W W Bauer M.D.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES NEW HOSPITALS EDUCATION AND PUBLIC HEALTH)

CALIFORNIA

State Association News—The council of the California Medical Association is holding a special meeting November 7 to consider the inauguration of a voluntary hospital insurance plan, which would be statewide in scope and under medical control.—The annual conference of county society secretaries will be held in San Francisco February 6

The Lane Lectures—Dr Eugene F Du Bois, professor of medicine, Cornell University Medical College, and medical director of the Russell Sage Institute, New York will deliver the Lane Lectures at Stanford University School of Medicine San Francisco, April 5, 9, 1937 The subject of the lectures will be "Mechanism of Heat Loss and Temperature Regulation"

State Board Reelects Officers—At the annual meeting of the California State Board of Medical Examiners in Sacramento, October 19, the following officers of the board were reelected Dr William R Molony, Los Angeles president Dr Clark L Abbott, Richmond and Dr Charles B Pinkham, San Francisco, secretary Dr Pinkham has held his position for twenty four years

Society News—At a meeting of the Alameda County Medical Association, October 19, the speakers were Drs Theodore C Lawson on "Tumors of the Colon", William Whitfield Crane "Surgical Aspects of Jaundice" Don D Weaver, "Acute Intestinal Obstructions," and Dexter N Richards, "Problems in Gastric Surgery." All are from Oakland—Dr Roger Anderson, Seattle addressed the Hollywood Academy of Medicine, October 29, on "An Ambulatory Method of Treating Fractures of the Lower Extremity"—At a meeting of the Los Angeles County Heart Association October 21 Dr Morris H Nathanson, Los Angeles, discussed "The Pathology and Pharmacology of Cardiac Syncope and Sudden Death"

CONNECTICUT

Personal—Dr Carlton K. Heady has been appointed town health officer of Milford, and Dr Robert M Taylor health officer of East Haven, succeeding Dr Paul H Brown—Dr Wilmar Mason Allen has been appointed director of Hartford Hospital, it is reported He has been a member of the staff for several years

University News—At a meeting of the Yale Medical Society in the Sterling Hall of Medicine, Yale University, October 14 Dr John P Peters, Anna J Eisenman, Ph D and Pauline N Hald, B A, discussed "Osmotic Exchanges in the Blood", Abraham White, Ph D, and Kurt G Stern, Ph D, "Studies on the Physiologically Active Group of Insulin" William W Greulich, Ph D, "A New Syndrome Associated with Testicular Tumors in Cryptorchid Dogs" and Alfred Z Gilman Ph D and Dr Louis S Goodman, "Secretion of an Antidiuretic Hypophyseal Hormone in Response to the Need for Renal Water Conservation"

DELAWARE

State Medical Election—Dr Charles P White, Wilmington, was chosen president of the Delaware State Medical Society at its recent annual meeting in Rehoboth Vice presidents are Drs Charles G Harmonson, Smyrna, and John Roscoe Elliott Laurel Dr William H Speer, Wilmington was reelected secretary

FLORIDA

New Tuberculosis Bureau—The state department of health has established a tuberculosis bureau with Dr Arthur J Logic, Chattahoochee as director One of the first activities of the bureau will be a survey to determine the need for clinics throughout the counties A mobile laboratory will be operated in sections not cared for by county health units

Personal—Dr Harold D Van Schaick, Jacksonville, has been named a member of the state board of medical examiners succeeding Dr Simon E Driskell, Jacksonville—Dr Arnold S Anderson, St. Petersburg has been appointed a member of the state tuberculosis board—Dr Joseph S Spoto, Tampa, has been appointed director of the Hillsborough County health unit.

GEORGIA

Appointments to State Board—Drs Horace G Huey, Homerville, has been appointed a member of the state board of medical examiners for a term of six years Dr Harold F McDuffie, Atlanta, has been named to fill an unexpired term on the board

Dr Boyd Addresses Pathologists—Dr William Boyd, professor of pathology University of Manitoba Faculty of Medicine Winnipeg, delivered the annual lecture of the Georgia Association of Pathologists, October 19, in Atlanta His subject was "Bronchogenic Carcinoma"

Crawford W Long Prize—The *Journal of the Medical Association of Georgia* for October announces that five copies of all papers read before the 1936 annual meeting of the association, which contain original work by their authors, should be submitted to the chairman of the Crawford W Long Memorial Prize committee, Dr William R Dancy, 102 West Jones Street, Savannah The features of each article which the writer claims to be original should be stated in a letter addressed to the committee and submitted with copies of the paper

ILLINOIS

Society News—Dr Leroy H Sloan, Chicago, discussed "Differential Diagnosis of Common Causes of Coma" before the Bureau County Medical Society, October 13—The Carroll County Medical Society was addressed in Savannah, October 13 by Drs John W Powers, Milwaukee, and Harry M Hedge, Chicago, on diseases of the skin and compound fractures respectively

Chicago

The Plan for Hospital Care—A new low cost hospitalization program, known as the 'plan for hospital care,' has been adopted by the Chicago Hospital Council Contracts have been sent to Chicago's hospitals Individuals may become subscribers to the plan, but all subscribers must make application in groups of ten Each contract is executed individually and not by group, but subscribers may make payments through their companies by payroll deductions or having a company remitting agent In small firms where such procedure is not practical, payments will be made either in full at the beginning of the contract or in quarterly remittances The annual fee is \$9.60 In addition, each subscriber may designate a dependent for whom he may purchase half coverage After designating the first dependent for an annual fee of \$4.20, the subscriber may for another \$2.20 cover in a group all the other members of his family who qualify as dependents All contracts become effective ten days after the date of the certificate, except that in case of accident or emergency illness hospital care will be provided immediately The contract does not cover pulmonary tuberculosis after diagnosis, or any care provided under the workmen's compensation laws of any state or the United States If a subscriber requires emergency or accident treatment outside Chicago his bill is paid to the extent of \$6 a day so long as he selects a hospital which maintains a standard of care and scale of rates satisfactory to the corporation and the Illinois State Department of Public Welfare Major benefits under this plan include twenty-one days of hospital care covering board and room in semiprivate accommodations general nursing service, operating room and auxiliary services delivery room and obstetric service for a subscriber in good standing more than twelve months, anesthesia when the services are rendered by salaried employees of the hospital ordinary drugs, medications and dressings, pathologic and laboratory services, and x-ray examinations when considered necessary by the attending physician Incorporators of the Hospital Service Corporation, which will carry out the project, include Mr Charles H Schweppe, president, St. Luke's Hospital Dr Arthur C Bachmeyer, director of the University of Chicago Clinics, Rev John W Barrett, director of Catholic hospitals in Chicago, Dr Irving S Cutter, dean, Northwestern University School of Medicine, J Dewey Lutes, superintendent, Ravenswood Hospital, and Taylor Strawn, president of Grant Hospital

INDIANA

State Medical Election—Dr Herman M Baker, Evansville, was chosen president-elect of the Indiana State Medical Association at the recent annual meeting in South Bend and Dr Edmund D Clark, Indianapolis, will take over the duties of president January 1 The next annual session will be held in French Lick

District Meetings—At the meeting of the Union District Medical Association in Rushville October 22, the speakers included Drs Walter U Kennedy, Newcastle on state

medicine, Ezra V Hahn, Indianapolis, results of collapse therapy in tuberculosis, and Mason B Light, Indianapolis, bronchoscopy as a diagnostic aid—The Eleventh District Medical Association held its fall meeting in Huntington, October 28, speakers included Drs Jesse O Arnold, Philadelphia, George J Garceau, Indianapolis Paul W Ferry, Kokomo and Charles P Emerson, Indianapolis

IOWA

Dr Peterson Named Professor of Surgery—Dr Frank R Peterson associate professor of surgery, State University of Iowa College of Medicine, Iowa City has been appointed professor and head of the department of surgery succeeding the late Dr Howard L Beye. Dr Peterson is 42 years of age. He graduated from the State University of Iowa in 1918 and from the school of medicine in 1920. He has been affiliated with the faculty of the university since 1921.

Society News—Dr Milo G Meyer, Marshalltown addressed the Jasper County Medical Society in Newton, September 1 on "The Irritable Colon"—At a meeting of the Johnson County Medical Society, October 7, Dr Ruben Nornland Iowa City, discussed "Classification and Treatment of Eczema and Dermatitis"—Wilber J Teeters Ph C, Iowa City addressed the Washington County Medical Society in Kalona, September 29, on "Chemistry in the Detection of Poisons"—The Southeastern Iowa Medical Society was addressed in Mount Pleasant October 15 among others by Drs Mazyck P Ravenel on immunization against infectious diseases, and Marcus Pinson Neal, cancer viewed as a preventable disease. Both are of Columbia Mo.

KENTUCKY

District Meetings—At a meeting of the tenth councilor district of the Kentucky State Medical Association in Lexington September 18, the speakers included Drs Thomas M Marks, Lexington, on "Early Diagnosis of Brain Diseases in Children", David M Cox, Louisville, "Endocrine Function and Dysfunction in Gynecology" and Ernest B Bradley Lexington "Insulin Protamine"—The Seventh District Medical Society met in Lancaster in September with the following speakers: Drs John W Scott, Lexington pneumonia Ellis S Allen Louisville, fractures of the long bones, Robert F Monroe, treatment of occipital posterior positions and Harry S Andrews, Louisville birth injuries—Among the speakers at a meeting of the Third District Medical Society in Hopkinsville September 16 were Drs Guthrie Y Graves, Bowling Green, on "Gas Gangrene Following Sacral Anesthesia" and Beverly Douglas Nashville "Plastic Procedures of Interest to the Practitioner."

LOUISIANA

Charity Hospital to Be Rebuilt.—Eight million dollars will be expended in a building program at Charity Hospital New Orleans. The main building of this unit which was erected in 1832 has been condemned and will be replaced with a twenty story modern hospital, newspapers report. Part of a PWA grant of \$3,600,000 recently given to the state will be used to finance a part of the construction. The group will ultimately provide facilities for 2,470 patients it was stated.

Society News—The Orleans Parish Medical Society was addressed October 12, by Drs Daniel N Silverman, New Orleans on "Continuous Drip Blood Transfusion" Theodore J Dimitry "The Introduction of Leprosy into Louisiana" Dr Eleazar R Bowie gave a demonstration of simplified projection of x-ray films Mr Archibald H McIndoe, London England, addressed a special meeting of the society October 5 on plastic surgery—At a meeting of the Bi-Parish Medical Society in Jackson recently speakers were Drs Hiram W Kostmayer New Orleans and Lionel F Lorio Baton Rouge, on endocrinology and diseases of the mastoid.

MARYLAND

Marihuana Farm Found Near Baltimore—A marihuana farm described as one of the largest ever found in this country was discovered on the eastern edge of Baltimore October 3 newspapers reported. The leaves of the 3,000 drug plants were estimated to be worth \$1,000,000 on the retail market. Most of the leaves of the marihuana plants, which were in the center of the field and concealed by tomato plants pumpkins and cornstalks were still green and unfit for immediate use. A police guard was posted at the farm until the plants could be dug up and burned.

MASSACHUSETTS

Personal—Dr Walter B Cannon, George Higginson professor of physiology Harvard University Medical School, Boston, has been elected a corresponding member of the National Academy of Medicine of Buenos Aires Argentina.

Harvey Society Lectures—The William Harvey Society of Tufts College Medical School, Boston announces the following lectures at the Beth Israel Hospital:

- Dr Henry E Sigerist Welch professor of the history of medicine Johns Hopkins University School of Medicine December 11 "The Social Problems Confronting Medicine Today"
- Dr Siegfried J Thannhauser associate professor of medicine at Tufts January 15 "The Development of Our Knowledge of Metabolism"
- Dr Richard C Cabot Cambridge professor of clinical medicine emeritus Harvard University Medical School February 17 "The Wisdom of the Body"
- Dr John M Wheeler professor of ophthalmology Columbia University College of Physicians and Surgeons New York March 5 "Various Types of Grafts Used in Plastic Surgery About the Eyes"
- Dr James B Collip professor of biochemistry McGill University Faculty of Medicine Montreal, Que April 16 "Significance of Recent Studies on the Anterior Pituitary and Related Glands"

MICHIGAN

The Wayne County Programs—The Wayne County Medical Society held a public meeting, October 26 with Dr Victor G Heiser, New York, as the speaker on "Medical Adventures During Sixteen Trips Around the World" Dr Thomas Archibald Malloch, librarian, New York Academy of Medicine, New York, spoke November 2. A joint meeting of the medical section with the Detroit chapter of the American Association of Social Workers, November 9, will be addressed by Dr John H J Upham Columbus, Ohio President-Elect, American Medical Association, on "The Relation of the Social Worker to Medical Practice" Dr James Burns Amberson Jr, New York will speak at a general meeting November 16, and on November 30 the surgical section will be addressed by Dr Morris Fishbein Chicago, editor of THE JOURNAL, on "New Forms of Medical Practice."

Features of Medical School Opening Exercises—Honorary degrees of master of science and doctor of science, respectively, were conferred on Drs Russell S Rowland, Detroit and Reuben Peterson, Ann Arbor, September 26, by the University of Michigan at the eight-seventh annual opening exercises of the medical school. Dr Peterson retired from the faculty of the medical school in 1931 as emeritus professor of obstetrics and gynecology. A portrait of the late Dr Albert Moore Barrett was presented to the university by Dr Robert H Haskell medical superintendent of the Wayne County Training School, Northville. It was executed by John Koch Ann Arbor. Dr Barrett at the time of his death in April was professor of psychiatry at the university and director of the state psychopathic hospital. The Sternberg Medal for outstanding work in preventive medicine was presented to Dr Homer Allen Howes Coldwater now an intern at the University Hospital.

MINNESOTA

Special Meeting of House of Delegates—The House of Delegates of the Minnesota State Medical Association held a special session at the Hotel Lowry St Paul November 1. The meeting was called to formulate and define principles and policies of organized medicine for submission to the interim committee of the state legislature which is now engaged in shaping legislation to be introduced at the next session for the uniform and coordinated handling of social security relief and welfare activities in the state. The committee was created by a resolution adopted at the 1935-1936 special session of the legislature.

NEW HAMPSHIRE

Medical School News—Dr Hermann Burian formerly assistant to the director of the eye clinic of the University of Bern, has been appointed visiting research fellow in the department of physiologic optics at Dartmouth Medical School Hanover. Dr Nathan T Milliken Canandaigua N Y., superintendent of Oak Mount Sanitarium Holcomb N Y., has been appointed instructor in physical diagnosis.

NEW JERSEY

Society News—Dr William P Murphy, Boston will address the Academy of Medicine of Northern New Jersey November 19 on "Clinical Findings and Treatment of Pernicious Anemia." Dr Paul Klempner New York addressed the academy October 15 on "Newer Aspects of Liver Pathology." Dr Foster Kennedy New York gave a public lecture

at the academy, October 29, on "The Organic Background of Mind"—Thomas Cook, D.D.S., Philadelphia, addressed the Burlington County Medical Society, Burlington, September 9, on "Diseases of the Mouth and Their Importance to the Physician"—The Passaic County Medical Society held an "Interns' Night" at its meeting in Paterson, September 10, the speakers were Drs David Doktor, Burnert Memorial Hospital, Paterson, on "Anemia in Association with Achlorhydria", Seymour Scholtz, St Joseph's, "Hodgkin's Disease", Irving W Ariel, Paterson General, "Lymphogranuloma Inguinale", Rochelle Burstein, Passaic General "Childhood Eczema" and Oscar H Cohen, St Mary's, "A Case of Liver Abscess"

NEW YORK

Society News—Dr Russell M Wilder, Rochester, Minn., addressed the Rochester Academy of Medicine, October 1, on "The New Insulin"—Dr Howard T Langworthy, Brooklyn, addressed the Medical Society of the County of Nassau, Mineola October 27, on "Carbuncle of the Kidney"—Dr Wilbur Ward, New York, addressed the Medical Society of Westchester County, Grasslands, on obstetric technic and Dr Arthur W Bingham, East Orange, N J, on a maternal welfare program in progress in New Jersey—Dr Charles A Perry addressed the Medical Society of the County of Albany, October 28, on "Coronary Heart Disease"—Dr Anton W Solhrweide Jr Syracuse addressed the Seneca County Medical Society, Willard, October 8, on treatment of diseases of the skin

District Meetings—At a meeting of the Third District Branch of the Medical Society of the State of New York in Albany, September 22, the scientific program was presented by Drs Daniel M Brumfiel, Saranac Lake, speaking on "Diagnosis and Significance of Silicosis", Herbert M Bergamini New York. Fundamentals in the Treatment of Fractures" John J Ramey, Troy, "A Review of Nasal Accessory Sinuses" Dr Edward S Godfrey Jr, state commissioner of health discussed plans for using federal appropriations to the department of health Drs Floyd S Winslow Rochester president of the state society, Peter Irving, New York, secretary and David J Kaliski, New York, chairman of the committee on workmen's compensation spoke on state society activities—Among speakers before the Fourth District Branch of the Medical Society of the State of New York at Plattsburg, October 23 were Drs James B Collip, Montreal on hormones and Lewis M Hursthal, Boston, congestive heart failure Drs Floyd S Winslow, Rochester, and John B Wheeler, Burlington, Vt were speakers at a dinner at the Hotel Cumberland—The Fifth District Branch of the Medical Society of the State of New York met at the Rome State School, Rome, October 1 Guest speakers included Drs Donald Guthrie, Sayre Pa, on "Surgical Aspects of Peptic Ulcer" and Edwin P Maynard Jr, Brooklyn, "Cardiovascular Syphilis"

New York City

Friday Afternoon Lectures—Dr Russell S Fowler delivered the Friday afternoon lecture of the Medical Society of the County of Kings, October 16, on "Diagnosis of Abdominal Tumors." Dr Charles A Gordon spoke October 23 on "Everyday Obstetrics" and Dr Herman O Mosenthal October 30 on "Surgical Emergencies in Diabetes and Their Treatment." Dr Sam Z Levine spoke November 6 on "Water Metabolism in Normal Infants"

Personal—Dr George Henry Fox for many years a member of the faculty of the College of Physicians and Surgeons Columbia University, celebrated his ninetieth birthday October 8 Dr Fox was clinical professor of diseases of the skin from 1881 to 1904 and professor of dermatology from 1904 to 1907 He also taught at various times at the Woman's Medical College of New York Infirmary, the old Starling Medical College, Columbus, Ohio, and the New York Post-Graduate Medical School He was president of the Medical Society of the State of New York in 1895 He is the author of numerous publications on diseases of the skin

Staff Appointments Available—Three appointments in the general service of the Hospital for Joint Diseases to begin July 1 1937 and three to begin Jan 1, 1938, will be made by an examination to be held December 29 at the hospital Registrations for the examination must be received by December 15 The appointments are for two years' rotating service. Graduating students and graduates (unmarried men) of class A medical schools are eligible. The hospital provides maintenance and uniforms. Applications should be addressed to the director of the hospital, Madison Avenue and One Hundred and Twenty Third to One Hundred and Twenty-Fourth streets

NORTH CAROLINA

Specialty Society Meeting—The North Carolina Eye, Ear Nose and Throat Society held its second annual meeting in Durham, October 8 Among the speakers was Dr Angus L MacLean, Baltimore, on "Etiology of Iritis from an Experimental Standpoint" Dr James M Lilly, Fayetteville, was elected president and Dr Franklin C Smith, Charlotte, secretary

Symposium at Duke University—The third annual symposium at Duke University School of Medicine, Durham, was presented October 15-17 on diseases of the heart, circulation and kidneys The speakers were Drs Stewart R Roberts, Atlanta Soma Weiss, Boston, William B Porter, Richmond and James Edwin Wood Jr, Charlottesville, Va William de B MacNider, Chapel Hill, Frank N Wilson, Ann Arbor, Mich Herrman L Blumgart, Boston Charles C Wolferth, Philadelphia Claude S Beck and Carl J Wiggers, Cleveland, James C White, Boston, Mont R Reid Cincinnati, William F Braasch, Rochester, Minn, Warfield T Longcope, Louis Hamman and Hugh H Young, Baltimore

OHIO

Personal—Dr Gertrude Felker, Dayton, recently received the honorary degree of master of arts at Rockford College, Rockford Ill—Dr Albert F Green, Cleveland recently celebrated his fiftieth anniversary in the practice of medicine.

State Medical Election—Dr John B Alcorn, Columbus, was named president-elect of the Ohio State Medical Association at the annual meeting in Cleveland October 8, and Dr Edwin M Huston, Dayton was installed as president. The next annual meeting will be in Dayton

Postgraduate Day in Akron—The Summit County Medical Society will present its fifth Postgraduate Day at the Mayflower Hotel November 11 The guest speakers will be Drs Fred H Albee, New York, who will discuss surgery of the knee and fractures of the neck of the femur, Arlie R Barnes, Rochester, Minn diagnosis of gastro-intestinal disease and fitting the diet to the patient, and Martin H Fischer, Cincinnati, diabetes and coma

OREGON

State Medical Election—Dr Charles T Sweeney, Medford, was chosen president-elect of the Oregon State Medical Society at the annual meeting at The Dalles, October 10, and Dr Thomas W Watts, Portland, was installed as president The following were elected vice presidents Drs Charles E Sears, Portland, John C Vandeventer, Bend, and William W Baum Salem Dr Morris L Bridgeman, Portland, was reelected secretary

PENNSYLVANIA

Society News—Dr Walter J Larkin, Scranton, was elected president of the Pennsylvania Association of School Physicians at the annual meeting in Pittsburgh in October, Dr Henry R Steadman, Erie, vice president, and Dr Mary J Baker, New Castle secretary

State Medical Election—Dr Frederick J Bishop, Scranton, was chosen president-elect of the Medical Society of the State of Pennsylvania at the annual meeting in Pittsburgh October 7 Dr Maxwell J Lick Erie, became president and Dr Walter F Donaldson Pittsburgh, was reelected secretary The 1937 meeting will be held in Philadelphia, October 4-7

Philadelphia

Medical College News—Dr Thomas A Shallow, professor of surgery, Jefferson Medical College delivered the address at the opening exercises of the school September 21 on "Medical Progress"—Temple University School of Medicine opened its thirty-fifth session September 23 with an enrolment of 447 The freshman class of 100 was selected from 1,093 applicants

Fund for Study of Digestive Disorders—The bulk of an estate estimated at more than \$200,000 was bequeathed to the University of Pennsylvania by the late Frances T Kinsey to support and develop the Gastro-Intestinal Clinic at the University Hospital under the direction of Dr Thomas Grier Miller or for such other activities in this field as he may desire After Dr Miller severs his connection with the university hospital the income is to be used for such similar activities as the professor of medicine may desire. The fund will be known as The Kinsey-Thomas Foundation for the Study and Treatment of Diseases of the Digestive System" It is to be a memorial to two sisters and a brother-in-law of Miss Kinsey

Pittsburgh

Hospital News—Dr Henry A Christian Hersey professor of the theory and practice of physic at Harvard University Medical School Boston, spoke on "Diuretics at the annual celebration of "West Penn Day" at the Western Pennsylvania Hospital October 20

Society News—At a meeting of the Allegheny County Medical Society, October 20 acute appendicitis was the subject of discussion Dr William W Briant Jr, Mount Lebanon, spoke on the disease as seen in children Dr Harold G Kuehner, in adults, and Dr Harry E Feather, in the older patient—The last of three pediatric institutes sponsored by the state department of health and the Medical Society of the State of Pennsylvania in Pittsburgh was held at the Western Pennsylvania Hospital October 28 Dr Henry C Flood presided, and the speakers were Drs Edmund R McCluskey on respiratory diseases Carl L Ruder blood dyscrasias, and Minor D Silberberg, allergy and endocrinology

SOUTH CAROLINA

Society News—Dr Robert W Ball, Columbia addressed the York County Medical Society, September 24, on "Maternal Preventive Medicine."—At a meeting of the Seventh District Medical Association in Kingstree September 17, the speakers included Drs Hal McCluney Davison, Atlanta on Nonspecific Treatment of Allergic Diseases Hamilton W McKay, Charlotte, N C "Pyelocystitis Complicating Pregnancy", Frank K. Boland Atlanta, "Surgical Treatment of Pulmonary Tuberculosis", and Oscar D Baxter, Sumter, Exaltation of Symptoms" Dr Robert C Bruce, Greenville, president of the South Carolina Medical Association, made an address on medical economics

TENNESSEE

Fined for Violation of Medical Practice Act—Filmore Shoun, Greeneville, was recently fined \$175 and costs for violation of the medical practice act The evidence showed that Shoun applied a salve containing zinc chloride to the nose of a man in Chuckey, to remove a mole The application of the salve resulted in destruction of a portion of the nose leaving a complete perforation

Health at Nashville—Telegraphic reports to the U S Department of Commerce from eighty-six cities with a total population of 37 million for the week ended October 24 indicate that the highest mortality rate (23.8) appeared for Nashville and that the rate for the group of cities as a whole was 11.3 The mortality rate for Nashville for the corresponding week of 1935 was 12.2 and the rate for the group of cities was 10.7 The annual rate for the eighty-six cities for the forty-three weeks of 1936 was 12.1, as compared with 11.4 for the corresponding period of the preceding year Caution should be used in the interpretation of these weekly figures as they fluctuate widely The fact that a city is a hospital center for a large area outside the city limits or that it has a large Negro population may tend to increase the death rate

Society News—Dr Tinsley R. Harrison discussed the "Treatment of Congestive Heart Failure" before the Nashville Academy of Medicine, October 13, Dr Joseph T Gilbert presented a case report on Meningitis Complicated with Gas Bacillus Infection—Drs John W Hocker and Samuel H Long, Chattanooga, addressed the Hamilton County Medical Society November 5 on "The Status of Immunization in Pediatrics" and "Maxillary Sinusitis" respectively—At a meeting of the Hardin Lawrence Lewis, Perry and Wayne Counties Medical Society September 29 the speakers were Drs Dexter L Woods, Waynesboro on Compensation (Industrial) in General Practice Jere L. Crook Jackson "Radium and Its Uses" John W Simpson Nashville A New Conception in the Treatment of Senile Vaginitis and William E. Boyce, Flat Woods "Hemophilia"—Dr Frank H Krusen Rochester Minn, addressed the Memphis and Shelby County Medical Society, Memphis, September 1 on "The Relationship of Physical Therapy to General Practice" and James B Mitchell Jr PhD, Memphis, spoke on Pharmacologic Aspects of Dilaudid"

TEXAS

State Public Health Meeting—Dr Ernest W Prothro Temple was elected president of the Texas Public Health Association at the annual meeting at Kilgore in October Dr Reginald M Atwater New York secretary of the American Public Health Association was among the speakers discussing the future of public health work The next meeting will be in El Paso

Society News—Drs Frank H Newton and Edwin L Rippy addressed the Dallas County Medical Society Dallas,

September 24, on "Injuries to the Eyes" and "Physical Constitutional Types and Their Relationship to Disease" respectively—Drs Cecil S E Touzel and McKinley H Crabb, Fort Worth addressed the Tarrant County Medical Society in Fort Worth, September 15, on "Childhood Tuberculosis" and "Typhoid Carriers" respectively—Drs Carroll M Pounders and Charles P Bondurant, Oklahoma City, addressed the Wichita County Medical Society, Wichita Falls, October 13 on nervous disorders of children and treatment of common skin diseases, respectively

WISCONSIN

Dinner in Honor of Dr Sleyster—The Medical Society of Milwaukee County will give a dinner at the Wisconsin Club, Milwaukee, Saturday evening November 14 in honor of Dr Rock Sleyster, Wauwatosa, chairman of the Board of Trustees of the American Medical Association Dr Arthur J Patek is chairman of the committee in charge and members are Drs J Gurney Taylor Eben J Carey, Frederick J Gaenslen and William L Herner Dr Sleyster is a past president of the State Medical Society of Wisconsin

ALASKA

Outbreak of Scarlet Fever—It is reported that the schools at Snag Point and Clark Point were closed indefinitely, October 27, due to an outbreak of scarlet fever

PUERTO RICO

Medical Association Election—Dr Juan H Font, San Juan, was elected president of the Puerto Rico Medical Association at a meeting August 30 Others elected were Drs Manuel Pujadas Diaz, San Juan, vice president, Dolores M Pinero Rio Piedras, secretary, and David E Garcia, Rio Piedras, treasurer

GENERAL

Bequests and Donations—The following bequests and donations have recently been announced

Michael Reese Hospital Chicago \$100,000 to endow not less than six beds for needy children under the will of the late Mrs G T Smith Hospital and Home for Crippled Children Newark \$500,000 by the will of the late Clark P Williams

Homeopathic Medical and Surgical Hospital and St Joseph's Hospital, Reading Pa \$1,500 and \$1,200 respectively under the will of D Willington Dietrich

Ohio State University College of Medicine, Columbus \$200,000 by the will of the late Mariette Comly for medical and surgical research and the residuary estate for aid to needy students Children's Hospital Columbus also received \$10,000

Methodist Episcopal Hospital Philadelphia \$10,000 Chestnut Hill and Germantown hospitals \$5,000 each by the will of the late John Ervin Vail

Presbyterian Hospital New York \$20,000 by the will of the late Mrs S Augusta Mora

Yale University New Haven \$15,384 for fellowships and research in the medical school

Changes in Status of Licensure—The Virginia State Board of Medical Examiners recently reported the following action

Dr Walter F Hartman Swoope license restored at the June meeting it had been revoked at the meeting of December 1935 because of narcotic violation

Dr Mars L Madsen formerly of Paia Hawaii license reinstated July 22 License revoked Dec 28 1935 because of violation of statutes

The Massachusetts Board of Registration in Medicine announces the following

Dr Julius Saipe, Somerville license suspended for three months October 8 for deceit in connection with an accident insurance case

The Illinois State Department of Registration reports the following action

Dr Joseph M Blakemore Chicago license restored
Dr Milton M Glascoe Jacksonville license revoked for violation of the Harrison Narcotic Act

Dr Russell R. Craft Chicago license revoked for his conviction of a felony

Dr Edward E Rohrabough, Peoria license revoked for his conviction of violation of the Harrison Narcotic Act

The Connecticut State Department of Health reports the following

Dr Gaetano G Petrocelli Waterbury license revoked August 13 having been found guilty of manslaughter

Society News—Dr Cassius H Watson medical director of the American Telephone and Telegraph Company, New York, was reelected president of the National Safety Council at its annual congress in Atlantic City October 5-9—The Pacific Coast Surgical Association will meet in Seattle Wash and Victoria B C Feb 24-27 1937—Dr Robert D Mussey, Rochester Minn was chosen president-elect of the Central Association of Obstetricians and Gynecologists at the eighth annual meeting in Detroit October 15-17 and Dr Jean Paul Pratt Detroit was inducted into the presidency Dr Calvin R. Hannah Dallas, Texas was named vice president and

Dr Ralph A Reis, Chicago, reelected secretary. The next annual meeting will be held in Dallas in November. — Dr Chester T Brown, Newark, N J, was elected president of the Association of Life Insurance Medical Directors of America at the forty-seventh annual meeting in New York, October 22-23. Drs Samuel B Scholz Jr, Philadelphia, and Henry W Cook, Minneapolis, were elected vice presidents and Dr Edwin G Dewis Newark, secretary. — Mr Robert E. Neff, superintendent, State University Hospitals, Iowa City, was chosen president elect of the American Hospital Association at its annual meeting in Cleveland recently. Dr Claude W Munger, medical director of Grasslands Hospital, Valhalla, N Y, was installed as president. — Dr Henry W T Woltman, Rochester, Minn, was elected president of the Central Neuropsychiatric Association at its annual meeting, October 10, Dr George B Hassin, Chicago, was named vice president, and Dr Karl A Menninger, Topeka, Kan, secretary.

Southern Medical Association—The thirtieth annual meeting of the Southern Medical Association will be held at the Fifth Regiment Armory, Baltimore, November 17-20, with the Baltimore City Medical Society acting as host. Tuesday evening there will be a general public session with the following speakers: Dr Jonathan C Meakins, professor of medicine, McGill University Faculty of Medicine, Montreal, on "Heart Disease Versus Longevity"; Dr Thomas Farrar, surgeon general, U S Public Health Service, Washington, D C, "Syphilis as a Public Health Problem," and the Rev Alphonse M Schwitalla, SJ, dean, St. Louis University School of Medicine, St. Louis, "Medical Education and Medical Practice." Presidents' Night will be observed Wednesday evening. Tuesday will be devoted to general clinical sessions on medicine, surgery and otolaryngology, while Wednesday morning will be given over to general clinical sessions, meeting concurrently, representing all the specialties. The remainder of the program will be devoted to sectional presentations. The annual golf tournament will be played during the meeting and the annual trap and skeet shooting tournament will be held at the Oriole Gun Club, November 18. The woman's auxiliary to the Southern Medical Association will meet November 18-19, at the Lord Baltimore Hotel. Other organizations meeting at the same time include the southern branch of the American Public Health Association, National Malaria Committee and regions one and two of the American Academy of Pediatrics. An allergy clinic and round table will be held November 19 at the armory with Dr Hal M Davison, Atlanta, as chairman.

Annual Report of the Red Cross—Preceding its annual roll call, which begins November 11, the American Red Cross issued its report of activities during the fiscal year ended June 30 1936. In the twelve months covered by the report the Red Cross rendered aid in 105 domestic disasters to 400,000 persons. In addition there were thirty-nine disasters in insular possessions and six in foreign countries. These included the floods in New England, Pennsylvania, southern New York and Ohio, tornadoes in Georgia and Mississippi, hurricanes in Florida, earthquakes in Montana and epidemics in Kentucky, Missouri, Colorado and Oklahoma. Under a policy adopted the previous year, Red Cross chapters participated in various health projects in cooperation with local health agencies including typhoid and diphtheria immunization, malaria control, oral hygiene and tuberculin testing of school children. Seventy-seven chapters carried on programs of education on food and nutrition. Public health nurses made 1,070,000 visits during the year. The course in home hygiene and care of the sick was presented to 68,677 students, 25,000 more than in 1932. First aid instruction certificates were issued to 222,693 persons. During the year 867 highway emergency first aid stations were established and 3,617 have been provided for, to be opened as fast as personnel can be trained. The Red Cross expended \$7,682,821.20 during the fiscal year. An appeal for funds after the storms and floods of March of this year resulted in gifts amounting to \$7,955,963.38. Expenditures for relief in those disasters had amounted to \$3,789,408.62 by June 30 and the remainder was being held to cover the balance needed to finish the relief program.

Council of Research in Child Neurology—Appointment of a council to administer the Friedsam Foundation's program of research in child neurology was announced October 17 by Dr Bernard Sachs, New York, who is director of the new project. Announcement of a grant from the foundation to finance the new work was made in *THE JOURNAL*, July 11 page 139. Members of the council are Drs Louis Hausman, Foster Kennedy, Frederick Tilney, Stanley Brady, Howard Reid Craig and Lewis Clark Wagner, Mr William E Grady, associate superintendent of public schools in New York and Mr Nathan Straus. In addition an advisory committee has

been appointed with the following members: Drs Walter B Cannon, Boston, Harvey Cushing, New Haven, Conn., Adolf Meyer, Baltimore, Edward A Strecker, Philadelphia, Lewis J Pollock and Harold Douglas Singer, Chicago, Ernest Sachs, St. Louis, Walter T Schaller, San Francisco, Frederick Peterson, Charles R Stockard, Herbert B Wilcox and Alfred Wiener, New York, Georges Guillain, Paris, Samuel Alexander Kummer Wilson, London, and Otto Marburg, Vienna. The research program will include studies of (1) organic and functional diseases of the nervous system in children, (2) neuroses and psychoses in early life, and (3) social personality and home problems. It will be carried out through grants and scholarships to research workers all over the world. The council will consider only original work that promises to be fruitful of results, and the applicant must state distinctly the problem under investigation and the methods to be pursued, it was said. Results of the work will be recorded in volumes to be issued by the council from year to year. This program is distinct from a similar program begun at the Neurological Institute, New York, two years ago through a grant of \$100,000 from the Friedsam Foundation, it was explained.

CANADA

Society News—Dr James R. Corston, Halifax, was elected president of the Nova Scotia Medical Society at the annual meeting in Halifax, August 31-September 5. In his official address, Dr Robert M Benvie, Stellarton, retiring president, discussed sterilization of the mentally unfit. Drs Herman M Robertson, Victoria, B C, and Thomas C Routley, Toronto, president and secretary, respectively, of the Canadian Medical Association, discussed unification of the provincial societies as component parts of the dominion organization. — The Canadian Physiological Society, organized in 1935, met at Queen's University, Kingston, October 24. — Drs Austin B Schinbein and William Elliott Harrison, Vancouver, B C, addressed the Vancouver Medical Association, October 6, on "Surgical Treatment of Pulmonary Tuberculosis." — Sir Albert James Walton, London, addressed the Toronto Academy of Medicine at a special meeting October 15 on "Some Aspects of Peptic Ulceration." At a special meeting, October 9, Dr Charles Hill, deputy medical secretary of the British Medical Association, London, spoke on health insurance.

FOREIGN

Cancer Prize Awarded—Prof Ernest L Kennaway, director of the Research Institute of the Cancer Hospital, London, and J W Cook, research chemist at the institute, received a prize of 50,000 Belgian francs and 50 mg of radium offered by the International Cancer Union for scientific work on cancer, *Science* reports. The award was made at the recent Second International Congress on Cancer in Brussels. The prize was made available by the Union Minière du Haut Katanga, a Belgian company that produces a large proportion of the world's supply of radium.

Large Fund for Research at Oxford—Lord Nuffield, British motor car manufacturer, has offered to the University of Oxford the sum of £1,250,000 for the promotion of medical research. It is his plan to provide graduate training in modern methods of investigation in a special research center under the direction of full time university professors and cooperating with existing hospitals to obtain the necessary clinical facilities. The organization suggested is the establishment of clinical departments of medicine, surgery, gynecology and anesthetics to be followed by other departments as they seem desirable as extensions in scope of the medical school and of the Nuffield Institute for Medical Research, which Lord Nuffield gave to the university in 1935. The present gift is said to be the largest ever given by a single donor to any British university.

Personal—The Weber-Parkes Medal and Prize of the Royal College of Physicians has been awarded to Sir St. Clair Thomson, emeritus professor of laryngology and consulting surgeon for diseases of the throat and nose in King's College Hospital, London, for his work on cancer of the larynx. The Moxon Medal was awarded to Dr Edward Mellanby, Sheffield, for his work on the problems of nutrition. — Mrs Irene Joliot-Curie, Paris, has resigned as undersecretary of state for scientific research in the French cabinet. — Dr John W McNee, at one time associate professor of medicine, Johns Hopkins University School of Medicine, has been appointed regius professor of the practice of medicine at the University of Glasgow, succeeding Prof Thomas K. Monro, resigned. — Sir Grafton Elliot Smith has retired as professor of anatomy at University College, London, and Dr Herbert H Woollard, professor of anatomy at St. Bartholomew's Hospital Medical School, has been appointed to succeed him.

Research in Radium Therapy

The Report of the Radium Institute for 1935, just published, contains some important advances in technic.

RODENT ULCER

During 1935, 191 cases of rodent ulcer were treated. They are classified into (1) hypertrophic, (2) superficial ulcerating, (3) superficial cicatrizing and (4) deep ulcerative. Many of the cases were postoperative recurrences and a few were recurrent after x-ray and radium treatment elsewhere. The majority of the cases in the first three groups were treated by unscreened radium by means of flat applicators for from one and one-half to two hours. For the most extensive superficial hypertrophic and ulcerated varieties, radon seeds with a filter of 0.3 mm. and containing 15 millicuries were used. The usual treatment of the deep ulcerative type was gamma radiation by means of radium tubes mounted on stent and Columbia paste wax molds, but needling was done in a few cases. During the past two years a new method has been used for the treatment of rodent ulcers in certain situations mainly extensive ulcers over bone, as in the frontal region over the malar bones and in the mastoid region. The lesion is measured and a rectangular figure is marked on the skin with the lesion in the center and 1 cm. of normal skin between each of its sides and the edge of the lesion. A lead tube with a cross section of 8 mm. and walls of 2.5 mm. containing radon is used for treatment. The active length of the tube is equal to one side of the rectangle and its linear intensity is 10 millicuries. Parallel to the side concerned lines are drawn 8 mm. apart. The tube is covered with strapping and applied along the side of the rectangle. The next field to be treated is the space between this line and the next and so on for the others. For most lesions the exposure is two hours for each field, except the two outer ones for which it is two and one-half hours. After every third exposure the radon tube is made up to its original intensity. The results are good and the technic has the following advantages: 1. The tube, since it contains radon, can be made of any length required. 2. The patient can be treated in two or three days without hospitalization. 3. The reaction is slight and does not keep the patient from work.

THE BLADDER IN CARCINOMA OF THE CERVIX

Valuable information may be gained from inspection of the bladder in carcinoma of the cervix. Since 1933 cystoscopy has been done on the first application of radium. The following appearances in the order of their development as the growth extends to the bladder wall have been observed: (1) bulging and distortion of the base of the bladder, (2) dilatation of vessels, (3) transverse striation, (4) bullous edema and (5) growth in the bladder. Distortion does not necessarily indicate invasion of the bladder wall. It may be due only to pressure when palpation of the anterior vaginal wall will show that the mucous membrane of the bladder moves freely over it. Cystoscopic abnormalities were found in forty-five of 100 cases. Since distortion is regarded as of no significance as regards spread of the disease to the bladder thirty-eight cases may be said to have shown significant abnormality. Dilatation of the vessels in the bladder base proved to be a bad prognostic sign.

RADIUM BEAM THERAPY RESEARCH

In January 1934 an organization entitled Radium Beam Therapy Research was established in Great Britain to investigate the treatment of cancer by radiation from large quantities

of radium at a distance. The Radium Institute placed at its disposal a treatment room and wards. The organization has its own staff of surgeons, a radium therapist and physicists. In January 1934, after the installation of the first 5 Gm. radium unit and again in January 1936, after the second 5 Gm. unit was installed, an exhaustive series of measurements was made on the intensity of the radiation in the treatment and adjoining rooms. As a result it had been possible to make adequate provision for protecting the staff from radiation. The radiation received by nurses is checked daily by condenser measurements. No ill effects have been observed. Each application of the unit is made by a medical officer. After the unit has been placed in position the patients are under continuous observation by a nursing sister from an observation room at a distance. This is made possible by using a system of mirrors between the observation and treatment rooms. Microphones and loud speakers enable the patients under treatment and the nurse to communicate at will. The apparatus used to contain the first 5 Gm. unit was designed by Sievert of Stockholm. The second was designed at the Radium Beam Therapy Research and has several new features. In the interests of protection the new dense tungsten alloy developed here has been freely used and a rotatable eccentric screen has been provided to secure the maximum protection for the patient. An important advance is perfection of pneumatic transference, so that the radium holder is blown by air pressure to and from the storage safe to the unit. The position of the radium is indicated by lamps on a control panel in the observation room. The system reduces exposure of the staff to zero.

Efforts have been made to devise a scientific scheme of estimating dosage. An instrument designed at the research has enabled extensive investigations into tissue dosage to be made. Before constructing this instrument it was not possible to determine tissue doses either in such detail or with such accuracy. These investigations have proved of inestimable value in developing the treatment and, by placing it on a more scientific basis, in advancing telerradium therapy. Many cases that could not have been treated by any other method have been accepted. The results of the treatment have been sufficiently encouraging to justify the continuance and extension of the research.

Industrial Accidents and Diseases

An increase of factory accidents notified in 1935, amounting to an excess of 9 per cent over those for 1934 and 32 per cent over those for 1933 is reported but can be largely accounted for by increased industrial activity. In 1935 there were 149,696 accidents of which 843 were fatal. Substantial progress in accident prevention has been made in some directions. A comparison of the years 1934 and 1924 shows a reduction of 20 per cent both in the total number of accidents and in the fatalities. The chief inspector of factories is impressed by the active desire of employers' associations to combat the accident menace, especially in the dangerous industries. The principal opportunity for improvement lies in the education of the smaller employers. The returns again show the high rate of accident risks among young workers.

With regard to industrial diseases the chief inspector finds disconcerting the continued high incidence in certain industries of severe epitheliomatous ulceration. He expects little improvement until periodic examination with a view to early detection becomes prevalent. The rapid displacement of sand and flint grit by steel grit and other innocuous abrasives in the dangerous operation of sand blasting is expected to diminish the incidence of silicosis. Some apprehension is expressed as to the effects of speed which is the essence of present day industry. This is exemplified by the conveyor system such as exists in the clothing trade wherein a single operation is performed minute in and minute out throughout the working

day It remains to be seen whether the mental make up of the present generation is such that work of this nature is detrimental or not

Catalogue of Type Cultures

The new catalogue of the National Collection of Type Cultures, containing 2,000 entries, has been issued by the Medical Research Council. These cultures are maintained by the council at the Lister Institute of Preventive Medicine in London. Not only has the number of types increased, but through the cooperation of other scientific institutions it has become possible to include important groups of organisms at present conserved by specialists elsewhere. The following examples show the extraordinary variety and sources of the cultures all over the world. *Actinomyces dasonvillei* Underground. Isolated by J. Graham Forbes from dust of London Tube Railway. *Alternaria* species Ireland. Isolated by Miss Lorain Smith from rotting tent canvas. *Salmonella Derby* Isolated from tank water and from pork pies (cause of thirty-seven cases of pork poisoning). *Verticillium cinereascens* Isolated from wilting carnations in England. *Vibrio El Tor* Amsterdam. Isolated by Dr. Doorenbos from Mekka pilgrims. *Helmintosporium maequale* Isolated from cranberry by C. L. Shear of Washington, D. C.

The Examination of Elderly Taxicab Drivers

There is an elaborate system of examination to ensure that the drivers of taxicabs who are advancing in life are physically fit. A satisfactory medical certificate is demanded of all original applicants for a license of all licensees who have reached the age of 50, and at each sixth year afterward until the age of 65. After that a certificate is required in the fifth year until the age of 73. After this age medical certificates must be produced every year. In addition to these regular certificates the commissioner of police may, if he thinks fit, call for the production of a further certificate at any time. The proportion of licenses withdrawn from elderly drivers on grounds of health is not large.

PARIS

Sept. 26, 1936

Changes in the French Medical Curriculum

In the July 1936 bulletin of the Association pour le développement des relations médicales appears an abstract of the changes recently made in the attempt to bring the curriculum in the French medical schools abreast of the times. Before citing the essential features of these changes, it may be stated that the association has been highly successful, under the leadership of its president, Prof. Henri Hartmann, in attracting a large number of graduates to the manifold advantages of Paris and other large medical centers (Lyons, Bordeaux, Strasbourg and Montpellier) from a clinical standpoint. The office of the association is in charge of Miss Alice Hure, who speaks English fluently and is thus able to give the necessary information to those who do not speak French. The office is located in the main building of the Paris Medical School (Faculté de médecine).

As to the changes that go into effect this fall, the requirement for admission to the medical school for those who wish to practice in France or its many colonies remains the same, viz., a bachelor of arts degree from a French university. A student who simply wishes to take the courses in the medical school without the license to practice can obtain a "diplôme universitaire" instead of a "diplôme d'Etat," or state license. The latter of which requires a French bachelor of arts degree. In several communications published last year in THE JOURNAL, some recent requirements were cited to the effect that only those born in France or its colonies or those who have been

naturalized can practice here now. Fortunately, the law was not made retroactive, so that physicians and dentists practicing at the time of passage of the law in France can continue to do so.

Every first (preliminary or P. C. N.) year medical student is obliged to devote this period to a course in basic sciences (physics, chemistry and biology) at the University of Paris, which is close to the medical school. The medical course has been extended to seven years (including the preliminary basic science or P. C. N. year). As in the past the clinical work occupies a major part in the program of the medical curriculum in France. In order to emphasize this, those students who are not able to pass the examinations for externships or internships at the large public hospitals must remain attached to some approved hospital during their final or sixth clinical year. The student can elect to spend this year in a service or hospital which specializes in some field so as to begin work as a specialist if he desires.

A noteworthy feature of the medical curriculum which surprises many who visit France is that the mornings are spent by the first and second year students at the various large public hospitals and the afternoons are devoted to anatomy, histology, embryology, physiology, medical physics and chemistry. The claim is made that the student finds that such subjects as anatomy and physiology are of more interest if he has the daily opportunity of observing the clinical application of these fundamentals of medicine. This conception of medical teaching, the report states, is less criticized now than formerly. In a number of foreign countries the question is already being discussed as to whether it is wise to wait until the third year of the curriculum before the student is given bedside instruction.

During the third and fourth years in France the curriculum now includes general and surgical pathology, bacteriology, parasitology, obstetrics, surgical anatomy, operative surgery and experimental medicine, and that of the fifth year includes hygiene, legal medicine, pharmacology and therapeutics. Attendance during periods of two or three months at clinics in general surgery, obstetrics, dermatosyphilology, psychiatry, neurology, pediatrics, contagious diseases, ophthalmology and otolaryngology is compulsory during the third, fourth and fifth years. The effort is made to have the student devote as much time as possible to those of these subjects which will be of the greatest service for general practice. The sixth or hospital year will be spent at hospitals attached to medical schools or approved institutions not so attached or even in a hospital situated in a foreign country.

The system of examinations here differs from that employed in the United States. Intermediate examinations, i. e., during the school year, are not required in any of the clinical subjects, but every student must pass an oral test and, in a few subjects, a written one, at the end of the school year (June or July). At the end of the sixth or hospital year, oral examinations before a "jury" of three professors, as well as those at the bedside, must be passed by every student. In addition, he or she must submit and be ready to defend a thesis based on research or clinical work, before a jury of three members of the faculty. After the second year, every student is eligible to take part in an examination for externships in the many large public hospitals of every large city in France. The successful candidates serve as clinical clerks but are required to pass all final examinations. In addition, an extern can become an intern with added privileges and responsibilities by passing a second competitive rigid series of written examinations. Interns must agree to remain in a hospital for four years. They can select the service which they desire to enter according to their rank in the examinations. As a rule, the internship is a stepping stone to higher positions (also obtainable by competitive tests) such as chief of clinic, associate professor and professor. Thus the majority of interns become

specialists because the opportunities for work in a special field are not to be excelled, by reason of the large number of beds in each service and the well attended outpatient departments.

In the department of the Seine there are 35,000 beds in the various public medical institutions, so that about 800 externs and interns can be selected annually during the second to sixth years of the medical school curriculum. This seems a rather high percentage, but it must be recalled that there is only one medical school in Paris and that the student body averages well over 4,000 annually. Every effort is made here to create a general practitioner and not a specialist or research worker. Perhaps in the future a greater effort will be made to simplify still further the present overcharged curriculum.

The teaching personnel of the various medical schools in France must pass competitive examinations in which the ranking is based not only on the results of the written tests but also on the clinical and research work of the candidate. The same system is used for all appointments on the staffs of the public hospitals. "Agreges," or associate professors, who thus secure their appointment by competitive examination must remain in this rank for nine years. They are then eligible to promotion to a professorship by election, after submission of a list of previous positions they have occupied and work done. Retirement is compulsory for associate professors at the age of 62 and for professors at the age of 70 years. Diplomas as specialists have been bestowed up to the present time by only a few medical schools in France and these specialties have included only physical education, hygiene, radiology and public school medicine.

Regulations for Public and Private Sanatoriums

According to a law passed by the French senate and chamber of deputies recently every sanatorium for the treatment of pulmonary tuberculosis will be obliged to possess grounds which will suffice to permit the patients to take walks without leaving the premises under control of the institution. Such an area will be in proportion to the number of beds in the sanatorium. A private sanatorium cannot be opened without special permission of the government. This applies also to any changes in construction and increase in the number of beds. Tuberculous patients whose sanatorium costs are paid by the social insurance authorities can be treated only in institutions that are regularly licensed and not indiscriminately in any villa, hotel, boarding house or private resort.

The Increase in Diabetes Mellitus

Bertram, the Hamburg internist, recently pointed out the need for a systematic prophylaxis since diabetes is on the increase throughout the world. According to his interpretation there exists in addition to the apparent increase in the incidence of the disease, namely, that due to the prolongation of the life span and to better diagnostic and therapeutic methods an absolute increase as well. He visualizes as responsible for this absolute increase a greater consumption of fat, the migration of the population to the cities and the decrease in bodily movement due to modern means of transportation. Almost all cases of diabetes are based on a congenital inferiority of the endocrine system (demonstrated in from 25 to 46 per cent of the cases). Bertram takes the stand that a renunciation (compulsory if need be) of procreation should be required of diabetes mellitus sufferers. For the time being however he discontemplates sterilization although he goes so far as to advocate the prohibition of the marriage of any diabetic persons in whom a hereditary familial predisposition is demonstrable even among collateral relatives. He further believes that a like prohibition should apply to persons presenting fairly severe diabetes even

if the familial history is negative. In cases of bilateral hereditary taint, marriage should be interdicted even if neither prospective marriage partner has as yet presented diabetes. Imperiled persons, namely, members of diabetic families, persons who experience occasional elimination of sugar, persons with renal diabetes and certain cases of obesity, should be subjected to continuous supervision. The alimentary functional test with dextrose is recommended as a test of pancreatic function.

For persons threatened with diabetes, prophylactic measures consist in regulation of the habits of life—a regimen of milk and vegetables, abstention from alcohol and tobacco and, on the other hand, participation in sports. A regular leave of absence is necessary as well as vocational guidance. Of paramount importance is the avoidance of a heavy consumption of fats. In the restriction of fat consumption lies the cause of the disappearance of diabetes during the World War. Persons in danger of diabetes should be spared any sort of mental excitement. Infections may frequently induce a diabetes as well as disorders of the gallbladder. In the latter event early operation is indicated, particularly in patients with hereditary predisposition.

Arteriosclerosis is far more likely to be presented by diabetic persons than by those whose metabolism is normal. Bertram sees the cause of this in the generally prevalent carbohydrate-deficient and fat-rich diet that leads to a permanent increase in the cholesterol content of the blood (Aschoff's imbibition theory of arteriosclerosis). The first problem in combating diabetes mellitus particularly in the fight against acidosis, has been solved by insulin. The second problem, prevention of those arteriosclerotic changes so much more prevalent among diabetic patients than among persons of normal metabolism, can be solved according to Bertram's theory, by a general introduction of a diet rich in carbohydrates and deficient in fats. Accordingly he administers daily at least 150 Gm. of carbohydrate and a maximum of 100 Gm. of fat. It can hardly be supposed that the enormous increase in diabetes depends on an increase in the hereditary predisposition. It appears logical and is generally assumed that the tendency to diabetes mellitus is extremely widespread and that this high incidence may be attributed to exogenic influences, principally to a diet rich in fat and deficient in carbohydrate, and to the underexercised condition of dwellers in civilized lands. If the foregoing factors are well comprehended, the outlook for a preventive attack on diabetes will appear more promising.

In discussing these observations which were made before the Medical Society of Hamburg one should mention the fact that Bertram's opinion with reference to the authorization of eugenic measures was by no means concurred in by a majority of his hearers or at least the sentiment was general that judgment be reserved pending further investigation. Bertram's evaluation of excessive consumption of fat in prediabetes is by no means acceptable. The increased fat with diet can be interpreted as a general expression of prediabetic polyphagia and should not be considered unqualifiedly as the cause of the pathologic development. Finally, one must think of the substantial increase in the consumption of sugar as a possible etiologic factor in the greater prevalence of diabetes. As Dr. Scholderer explained pure sugar probably exercises an influence on metabolism entirely disparate from that of carbohydrate as with the latter assimilation first slowly takes place after the decomposition of vegetables.

Recent Developments in Treatment of Thyrotoxicosis

The Berlin Medical Society recently discussed the recent developments in the treatment of thyrotoxicosis from a variety of angles. Professor Siebeck who spoke as an internist pointed out that in those conditions of poisoning from the thyroid substance which are called thyrotoxicoses the basal metabolism

erves as a criterion neither of the quantity of these substances nor of the severity of the illness. Likewise there exists no proportionality between the basal metabolism and the iodine content of the blood. The interrelation of diseases of the central nervous system and the hypophysis must be considered as well as the reciprocal effect of the hormone storage in the thalamencephalon. Exophthalmic goiter is no true hyperthyreosis but a disease of another character from thyrotoxicosis. It should be diagnosed only on the basis of a completely developed triad of symptoms. Important in the manifestation of exophthalmic goiter is the constitutional factor, which often presents itself in anomalies of the premorbid personality. Although no specific psychogenic factors are present in exophthalmic goiter, frequent appearances of the illness subsequent to psychic traumas, and especially after those of an erotic nature, have been observed. In the introduction of therapeutic measures a general preliminary treatment and a specific therapy must be differentiated. Of the greatest importance are an adequate psychic quieting, a nonfattening diet rich in carbohydrates with fruit days interpolated and, in addition, phenobarbital. Siebeck observed no particular benefit from administration of vitamin A, though a decrease in the iodine content of the blood and the basal metabolism can frequently be obtained by use of vitamin C. These preliminary measures form the basis of any therapeutic approach and in the milder cases they alone will suffice. The quieting of the patient helps to correct the abnormal activity of the thyroid body. Siebeck considers iodotherapy as the specific treatment. In the coma of exophthalmic goiter, improvement, although manifestly not steady, is observed after large dosages of iodine. The success of iodotherapy depends not on the amount of the dosage but on the preliminary treatment. Individual reactions to iodine vary. Diiodotyrosine, in corresponding doses, produces virtually the same reaction as inorganic iodine and this leads Siebeck to doubt that diiodotyrosine possesses an antagonistic action toward thyroxine. A further parallel to iodine is to be found in the unreliability of the result. Still, diiodotyrosine is innocuous as a therapeutic substance. Digitalis exercises a beneficial effect on the circulation only if administered in large doses and subsequent to the introduction of the general preliminary treatment and iodotherapy. Continued use of quinidine may even do away with pronounced arrhythmias. The permanently successful results of internistic therapy cannot be favorably compared with the results from operative therapy. Surgical intervention is indicated in all quite severe or reasonably severe cases, the patient's general condition being considered the criterion. The operation is dangerous only if the preliminary treatment has been inadequate. The effects of roentgen irradiation are uncertain and even dangerous, favorable reports notwithstanding. Radiotherapy is an innocuous but extremely protracted procedure.

The work of the surgical clinic (Sauerbruch) appears of particular importance in this connection. The preliminary measures correspond roughly to those outlined, the most favorable results are obtained in cases of diffuse, soft, pulsating goiter. Sauerbruch himself discussed some innovations in the surgery of the thyroid body. The results of operative treatment are unquestionably more satisfactory than formerly. In contrast to hyperthyreosis, exophthalmic goiter is a disease of the entire personality which commences with disturbance of the nervous system. Sauerbruch does not perform operations on patients newly come down with exophthalmic goiter. To be differentiated from the psychic form of exophthalmic goiter is thyroid disease induced by a primary disturbance of the endocrine system. The so-called secondary types, toxic thyroid adenomas and thyroid hyperplasias, which frequently appear subsequent to a thyroiditis, are not to be regarded as genuine exophthalmic goiters. Of paramount importance in true exophthalmic

goiter is the determination of the optimal time for operative intervention. As a rule operation should be performed from two to three months after the psychic trauma. Early operative treatment can still heal exophthalmic goiter, since it acts before the changes have become permanent. Moreover, operation for exophthalmic goiter never can be considered a causal therapy. The operation itself is not dangerous if performed under local anesthesia after suitable preliminary psychotherapy, although it gradually has tended to become more radical. The mortality for 294 operations on patients presenting fully developed exophthalmic goiter performed at the Sauerbruch clinic has sunk below 6 per cent, for operations on patients with hyperthyreosis it amounts to only 1 per cent. Irradiation renders the eventually necessary operation more difficult by inducing hyperemia of the capsule, moreover, it is responsible for a mortality of from 14 to 18 per cent. Finally one should remember that there is also a type of hyperthyroidism without goiter; in such cases there is a retrosternal struma.

Opposition to Women in Competitive Athletics

The commission that has been studying the question of feminine participation in sports has just published a report which may be summarized as follows. Like men, women should be adequately trained to participate in sports by a course of preliminary physical education beginning in childhood. They should be subjected to a rigorous process of classification together with prudent measures for individual orientation. Furthermore, before, during and after the training period and the athletic contest a woman participant should submit voluntarily to medical supervision. A woman may, without danger, undergo the training procedures of a majority of sports. Yet there is no question that those fiercely competitive athletic contests wherein the contestant seeks to make the maximum effort, *per fas et nefas*, may prove harmful to the female athlete since she lacks the muscular force of the male and her organism cannot endure maltreatment with the same impunity as that enjoyed by the male. The female is less able than the male to undergo severe physical and nervous strain, the risk of certain traumas, notably of the thorax and of the abdomen, and the harsh rough and tumble inseparable from certain types of jumping and from certain games.

We consider therefore that only when the greatest precautions have been taken should women participate in high speed racing events (such as foot, swimming, rowing, cycling and skating races). Women should avoid those sports which demand the utilization in a relatively short time of all the organism's reserves, they should not participate in violent and rough jumping in which the fall cannot be broken, nor should they habitually engage in exercises that involve suspension by and leaning on the arms.

There is no doubt that at present all these questions are far from being definitively solved. It is to be hoped that women themselves will undertake to investigate the varied and complex effects of different types of physical exercise and that sportswomen, women athletes and women in general (be they teachers, physicians or professors of physical education) will further interest themselves in these questions so fundamental both for themselves and for the race.

From the standpoint of hygiene, we continue to be opposed to the participation of women in competitive games. We believe, however, that because of its benefit as general propaganda for physical education a certain amount of such participation should be tolerated. But we repeat the importance of a con-

stant and strict medical supervision cannot be overestimated. The observations made at the time of these medical examinations shall permit the assembly in the near future of sufficient material on which to base more exact opinion with regard to which sports should be approved for women and which interdicted. Meanwhile the following division may be accepted as tentative. Sports in which women should not participate are boxing, wrestling, exercises with dumb-bells, football, ice hockey, bicycle racing, pole vaulting, foot racing and ski jumping. Sports in which women may participate are tennis, handball, basketball, cricket, swimming, boating, equitation golf, lacrosse, field hockey, fencing, skiing (without the jumps) skating and javelin hurling.

New Regulations for the Preparation of Bottled Drinking Water

A new ordinance concerning the preparation of drinking water has just been passed. It is an attempt to regulate the delivery pipes, conduits, water tanks and reservoirs so that all possibility of contamination will be excluded. The flow from the conduits must be in proportion to the actual supply used. The working premises shall be reserved exclusively for the manufacture, preparation, placing in receptacles and disinfecting of the utensils and receptacles. These premises as well as the place of storage of the finished products must not communicate directly with any stable or barn, or with any toilet pits for manure cesspool or place of deposit for decomposing organic matter. The working premises shall be well lighted and well ventilated, kept in suitable condition and arranged so as to permit the rapid efflux of the water. The walls shall be constructed of tile or redecorated with waterproof plaster. The apparatus and the premises shall be washed and cleaned out each day with abundant water immediately following working hours. Even for washing, none but sanitary water shall be used. Carbonating appliances that employ pressure shall be subjected, previous to being placed in use, to a test pressure 50 per cent greater than that which would be required in the ordinary course of operation. They shall, in addition, be equipped with a device calculated to prevent the limit of pressure from being exceeded.

In the preparation and bottling of table waters destined to be placed on sale, and in the commercial manufacture and preparation of ices and lemonades, the following are forbidden: 1. Any apparatus, utensils or receptacles that are soiled or in which the parts in contact with the product are made of wood or contain substances that are poisonous or injurious to the health. 2. Bottles or other receptacles that have not been, immediately prior to filling, thoroughly cleansed or sterilized, rinsed with water pure enough for drinking purposes and emptied again. The washing of receptacles both outside and inside must take place before every filling and in such a way as to remove all impurities and deposits. This washing process must be followed by an abundant flushing with constantly renewed pure water. The bottling shall be immediately followed by the stoppering and capping. These processes must be effected by means of a device that is not in direct contact with the receptacles.

Persons employed in the preparation of drinking waters must be free from infectious disease; they must further be properly attired and scrupulously clean, above all with reference to the hands and nails. It is forbidden to prepare or to place in receptacles for marketing any water that does not come from a spring, a reservoir, a well or a public water main. The same prohibition applies to the commercial manufacture and preparation of ices or lemonades. Water must not be brought to the preparation and bottling plant except by an air-tight channel connecting directly with the reservoir, well or stream. In the commercial preparation of table water and lemonades and

in the manufacture of ices the use of the following is forbidden: (1) poisonous substances, (2) substances that have been declared noxious by the proper supervisory authorities, (3) antiseptics, (4) saponins, (5) mineral acids and (6) carbonic anhydride containing nitrogen, sulfur and hydrocarbon derivatives.

Silicosis Among Glassmakers

Drs. Courtois and Leclercq have reported to the Belgian Society for Tuberculosis Research the results of their observation of glassmakers in the Charleroi region. The nature of the work and the working conditions are described. Among the plants investigated was a glass factory at Jumet in which the old procedures of gathering and blowing were still employed for the manufacture of colored glass. As a matter of fact, the entire report resolved itself into a consideration of the manufacture of glass in the old way, the workers examined being for the most part elderly persons who had learned their métier before the advent of machine-made glass.

The atmosphere of the glass works seemed to contain only a small quantity of dusts and gas, except in the drying room, where conditions appeared more unhealthful. The lesser degree of active combustion in the ovens in this room made it possible that incompletely burned gases such as carbon monoxide might be inhaled together with sooty dusts. It was further observed that the beating process involved an exposure to inhalation of sand particles.

An exhaustive analysis of these dusts showed the particles to be relatively large, so large in fact that only 14 per cent of the particles were less than 10 microns in diameter (the maximal dimension of any object that could find its way into the lower respiratory passages).

An examination was made of eighteen workers, including five glass-blowers (representing forty-one, forty, thirty-six, twenty-seven and twenty-six years of work), three gatherers (thirty-six, thirty-five and twenty-five years of work), five cutters (thirty-six, thirty-six, twenty-three, twelve and ten years of work), two grinders (twenty-four and twenty years of work), one storekeeper (fifty years of work), one gas man (twenty-five years of work), one beveling assistant (fifty years of work). The investigation disclosed only one case of silicosis and this was in a man aged 61, who presented the classic clinical, physical and radiologic syndrome: cough, expectoration of mucus, dyspnea, and scattered dry and sibilant rales; the roentgenogram showing the entire pulmonary region studded with extremely fine nodular opacities. The authors, however, still found it necessary to make reservations with regard to this single case, since diagnosis must be 'etiologic' as well as clinical and radiologic and here strangely enough, the apparent victim of silicosis was the storekeeper who for fifty years had worked in the least unhealthful spot of the glass factory (the warehouse).

Silicosis then may possibly occur as an occupational disease among glassworkers although such cases are extremely rare. The fact evidenced by statistics that many glassworkers die prematurely cannot therefore be attributed to silicosis but quite decidedly to the cardiopulmonary disorders to which their métier particularly exposes them and with which they appear so frequently to be afflicted. Tuberculosis, like silicosis, is seldom encountered among this group. One should remember that glassworkers formerly constituted a sort of aristocracy among the working class, they were well paid, well fed and well housed. Hence the social background fails to present the pathogenic factors that underlie the manifestation of infectious bronchopulmonary diseases.

In concluding their discussion, the authors emphasize the complexity of the diagnostic problem in silicosis research, even when the disease is definitely recognized as occupational in origin.

Marriages

ROBERT EDWIN WRIGHT, East Orange, N J to Miss Marjorie Eloise Coffman of Orange at Glen Ridge, August 22

EARL S HALLINGER JR Wildwood, N J to Miss Sylvia Hoffman of Cleveland at Harrison N Y, September 23

WILLIAM K. SENNETT, Macy, Ind, to Miss Gladys Baxter of Shelbourne in Indianapolis, September 17

FRANK HART PETERS to Miss Madeleine Henriques, both of New York, in Princeton, N J, September 5

ROBERT JEROME PARSONS, New York, to Miss Fannie Bach of New Canaan, Conn, September 12

JAMES GRAHAM SHAW, Columbia, S C to Miss Marie Lee Keiley of Richmond, Va, August 28

PAUL ANTHONY O'CONNOR to Miss Katherine Fissell both of Newark, N J, August 22.

CARL M PORTER, Jansenville, Ind, to Miss Rosalind English of Clay City recently

Deaths

James Clifford Perry ♂ Medical Director U S Public Health Service, San Francisco, University of Maryland School of Medicine, Baltimore, 1885, was appointed assistant surgeon in 1889, passed assistant surgeon in 1893, surgeon in 1904 senior surgeon in 1915, assistant surgeon general in 1918 and since 1930 medical director of the U S Public Health Service organized a protective quarantine at Hongkong, China, in 1899 governing vessels for the United States ports organized quarantine service in the Philippine Islands and was chief quarantine officer from 1900 to 1903 served as chief quarantine officer on the sanitary staff of the Isthmian Canal Commission from 1905 to 1914, was health officer of the City of Panama from 1909 to 1914, later made special investigations in Chicago, Richmond Ind and Columbia, S C, and served as chief medical officer at Ellis Island member of the American Public Health Association and the Society of Tropical Medicine and Hygiene of London, aged 73, died suddenly, October 19, on the steamship *District of Columbia*

Frederick William Marlow, Toronto Ont, Canada Trinity Medical College Toronto 1900 L.R.C.P., London, and M.R.C.S., England, 1902, F.R.C.S., England, 1903, in 1913 was appointed associate professor of gynecology, and from 1903 to 1906 demonstrator of anatomy at the University of Toronto Faculty of Medicine, past president of the Ontario Medical Association and the Academy of Medicine, one of the founders and fellow of the American College of Surgeons, served with the Canadian army during the World War, senior attending gynecologist to the Toronto General Hospital, member of the surgical staffs of St Johns and the Wellesley hospitals, aged 59, died, August 22 at Knollview, his farm in Scarborough

Homer Dupuy ♂ New Orleans, Tulane University of Louisiana Medical Department, New Orleans, 1897 professor of otorhinolaryngology, Louisiana State University Medical Center assistant professor of otorhinolaryngology, New Orleans Polyclinic, from 1900 to 1915 professor of oral surgery, Loyola University, from 1925 to 1930 past president of the Louisiana State Medical Society and the Orleans Parish Medical Society assistant surgeon, Ear, Nose and Throat Hospital from 1899 to 1915 senior visiting surgeon division of otorhinolaryngology, State Charity Hospital since 1915 aged 65, died September 28

John English McWhorter, Tenafly, N J Columbia University College of Physicians and Surgeons New York 1898, assistant professor of clinical surgery at his alma mater and assistant professor of surgery, University and Bellevue Hospital Medical College, New York member of the American Association of Pathologists and Bacteriologists, surgical pathologist to the Bellevue Hospital pathologist to the French Hospital and Hospital for Ruptured and Crippled, consulting pathologist to the Home for Incurables New York, and Englewood (N J) Hospital, aged 61, died, September 19

Albert Belcham Keyes, Chicago, Chicago Medical College 1890, formerly assistant professor of obstetrics and gynecology Rush Medical College, and professor of gynecology at the Chicago Polyclinic fellow of the American College of Surgeons, served during the World War gynecologist to the

Henrotin Hospital and the Chicago Maternity Hospital, aged 74, died, October 11, at his home in Evanston, Ill, of cerebral thrombosis

Howard Earl Marchbanks ♂ Pittsburg, Kan, University of Kansas School of Medicine, Kansas City 1916 member of the Central Society of Clinical Research, fellow of the American College of Physicians chairman of the medical advisory board of the Crawford County Red Cross, served during the World War, on the staff of the Mount Carmel Hospital, aged 48, died, August 7, of coronary occlusion

Bernhard Ernst Knolle, Industry, Texas, Tulane University of Louisiana Medical Department, New Orleans 1886, past president of the Austin County Medical Society, formerly county health officer, president of the board of trustees of the school board president of the staff of the Sarah B Milroy Memorial Hospital, Brenham, aged 69, died, August 20, of peritonitis following appendicitis

Arthur J Puls, Milwaukee, Universität Heidelberg Medizinische Fakultät, Heidelberg, Baden, Germany, 1883, fellow of the American College of Surgeons gynecologist to the Columbia Hospital and the Milwaukee County Dispensary member of the board of regents of the University of Wisconsin Madison, from 1902 to 1908, aged 79, died, August 10, of carcinoma of the prostate.

William R Quick, Delphi Ind Kentucky School of Medicine, Louisville, 1891, member of the Indiana State Medical Association, formerly secretary of the Carroll County Medical Society, member of the school board city health officer, and at one time county health officer, aged 74, died, August 20, in a hospital at Lafayette, of carcinoma of the bladder with metastasis

James Albert Knox ♂ Waynesburg, Pa Western Pennsylvania Medical College, Pittsburgh, 1903, past president of the Greene County Medical Society, member of the staff of the board of directors of the Greene County Memorial Hospital bank president member of the board of directors of the Waynesburg College, aged 58, died suddenly, August 10, of acute coronary thrombosis

John Ralph Neely, Spokane, Wash Howard University College of Medicine Washington, D C, 1887 Georgetown University School of Medicine, Washington, D C, 1891 member of the Washington State Medical Association, for many years a member of the city health department, aged 77 died recently in London, England, of heart disease and diabetes mellitus

William Henry Jamieson ♂ Ottawa, Ill, Rush Medical College, Chicago 1910 president of the medical staff of the Ryburn Memorial Hospital formerly on the staff of the Ottawa Tuberculosis Sanatorium member of the school board aged 59, died August 9, in the State of Wisconsin General Hospital, Madison, of coronary thrombosis

Eugene Clower, Cairo Ga, Atlanta College of Physicians and Surgeons 1902, member of the Medical Association of Georgia, past president of the Grady County Medical Society, on the associate staff of the John D Archbold Memorial Hospital Thomasville, aged 60, died, August 19, of cerebral hemorrhage

Seymour Rowland Lee, St Paul University of Illinois College of Medicine, Chicago 1927, member of the Minnesota State Medical Association superintendent of the Ancker Hospital and formerly superintendent of the Willmar (Minn) State Asylum, aged 36, died, August 10, following an operation for appendicitis

Uriah Agrippa James Pittston, Pa University of Pennsylvania Department of Medicine, Philadelphia, 1899, member of the Medical Society of the State of Pennsylvania, on the staff of the Pittston Hospital aged 58, died suddenly, August 3, at his summer home at Lake Winola of coronary thrombosis

Emerson William Goldman, Madison, S D Lincoln (Neb) Medical College of Cotner University 1903 member of the South Dakota State Medical Association state senator, on the staff of the Madison Community Hospital, aged 56, died August 8 of chronic myocarditis

Jacob Livingston ♂ Newark, N J Johns Hopkins University School of Medicine, Baltimore, 1920, on the staffs of the Beth Israel and Presbyterian hospitals aged 42 was drowned August 23, at Lake Hopatcong when he fell accidentally from his motor boat

Thomas Mortimer Lloyd, New York University of Pennsylvania Department of Medicine Philadelphia 1876 at one time on the staff of St. Peter's Hospital Brooklyn aged 81 died August 21, in Bellport L I, of carcinoma of the prostate and diabetes mellitus

James Arthur Sullivan Howell, Elgin Ill. College of Physicians and Surgeons of Chicago School of Medicine of the University of Illinois, 1891, served during the World War, aged 65, died, August 18, in St. Joseph's Hospital, of carcinoma of the prostate

William Wooldredge Dodge, Hamilton, Mass. Harvard University Medical School, Boston, 1886, member of the Massachusetts Medical Society, aged 79, died, August 11, in the Beverly (Mass.) Hospital, of arteriosclerosis and bronchopneumonia

Theophilus Lacy Mastin, Huntsville, Ala. University of Pennsylvania Department of Medicine, Philadelphia, 1902 member of the Medical Association of the State of Alabama aged 62 died, August 3, in the Huntsville Hospital of uremia

William A. Martens, Milwaukee Milwaukee Medical College, 1903, member of the State Medical Society of Wisconsin, aged 58, died, August 3 in Rochester, Minn., of subdural hemorrhage due to an automobile accident, and bronchopneumonia

John T. Freeman, Finley, Tenn., Mississippi Medical College, Meridian, 1910, member of the Tennessee State Medical Association, county health officer, chairman of the county school board, aged 50, died, August 7, of cerebral hemorrhage

William Elias Hedges, Portland, Ore. Chicago Homeopathic Medical College, 1904, College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1908, aged 61 died, August 8, of coronary occlusion

William Humphrey Drewry, Charlotte N. C., Medical College of Virginia, Richmond, 1926, member of the Medical Society of the State of North Carolina aged 35, died, October 1 in a local hospital, following an operation for appendicitis

Carl Ludvick Sandberg, Salt Lake City Northwestern University Medical School, Chicago, 1908, veteran of the Spanish-American and World wars, on the staff of St. Mark's Hospital aged 58 died, August 14 of coronary occlusion

John Robert Hicks, Tulare, Calif., Central College of Physicians and Surgeons, Indianapolis 1897 member of the California Medical Association at one time a member of the state board of health of Indiana aged 65, died August 1

Thomas Edward Hoxsey, Spokane, Wash., Barnes Medical College St. Louis, 1900 aged 62 on the staffs of the Sacred Heart Hospital and the Deaconess Hospital where he died August 23, of coronary occlusion and hypertension

Marcus Keen Mines, Camden N. J., Jefferson Medical College of Philadelphia, 1892, at one time chairman of the city board of health formerly on the staff of the Municipal Hospital aged 67, died August 25, of myocarditis

Corwin Luctus Maxwell, Myra Texas Vanderbilt University School of Medicine, Nashville, Tenn. 1898 past president of the Cooke County Medical Society aged 65 died August 18, of carcinoma of the gallbladder

George Marcus Crowell, Suncook N. H. Harvard University Medical School Boston, 1899 member of the New Hampshire Medical Society, aged 64, died, August 11, in Pembroke of organic heart disease.

Clarence Edwin Gourley, Mingo Junction Ohio Ohio Medical University Columbus 1903 member of the Ohio State Medical Association for many years a member of the school board, aged 60, died, August 11

Samuel Howard Ezzell, Lancaster S. C. Atlanta College of Physicians and Surgeons, 1900 member of the South Carolina Medical Association aged 64 died, September 23, in a hospital at Rock Hill of uremia.

Arthur Everett McCarthy, Buffalo University of Buffalo School of Medicine, 1899 served during the World War aged 59 died August 6 in the Buffalo General Hospital, of carcinoma of the sigmoid

Lucy MacMillan Elliott Guldbrandsen, Oakland Calif. University of Michigan Medical School Ann Arbor 1915 aged 50 died August 18 in the University of California Hospital San Francisco

Leonard Eric de Chantal, Wallingford Conn. McGill University Faculty of Medicine, Montreal Que. Canada, 1918 aged 46 died August 2, in Albuquerque N. M. of pulmonary tuberculosis

Savala Eustace Gunn, Hopewell Va. Medical College of Virginia Richmond 1926, served during the World War aged 44 died August 26 in a hospital at Petersburg of acute pancreatitis

William Francis Hager, Pana, Ill., Barnes Medical College, St. Louis, 1908 and 1909, on the staff of the Huber Memorial Hospital, aged 55, died, August 10, of coronary thrombosis

Charles T. Dyess, Clewiston, Fla., Georgia College of Eclectic Medicine and Surgery, Atlanta, 1912, aged 53, died August 19, in Fort Myers, of pernicious malaria and hepatic cirrhosis

William Frederick Aloysius Gillan, Quincy, Mass., Tufts College Medical School, Boston, 1898, aged 72, died August 14 in the Quincy City Hospital, of myocarditis and arteriosclerosis

Charles Parker Maddux, Imola, Calif., Cooper Medical College, San Francisco, 1898, on the staff of the Napa State Hospital, aged 64, died, July 3, of myocarditis and arteriosclerosis

Guel George Morehouse, Owatonna, Minn., Bennett College of Eclectic Medicine and Surgery, Chicago, 1902, aged 59 was found dead in bed, August 31 of chronic myocarditis

Louis Augustus Sanders, Hazeltown, Ind., Medical College of Indiana, Indianapolis, 1888 formerly county health officer, aged 82, died, August 10, of carcinoma of the prostate.

Marcus C. Hunter, Huntersville, N. C., College of Physicians and Surgeons, Baltimore, 1882, for many years bank president, aged 78 died, August 3, of myocarditis and uremia.

John S. Ragan, Plainfield, Ind., Medical College of Indiana, Indianapolis, 1879, for many years physician to the Indiana Boys School aged 87, died August 20, of arteriosclerosis

Augustus M. Johnson, Arenzville, Ill. St. Louis College of Physicians and Surgeons, 1898, aged 61, died, August 14 in a hospital at Beardstown, of multiple cerebral infarcts

Ira Timothy Johnson, Rochester, N. Y., Bellevue Hospital Medical College, New York, 1889, aged 73 died, August 4 of carcinoma of the larynx and acute myocarditis

John Kerr Crawford, Somerville, Tenn. Vanderbilt University School of Medicine, Nashville, 1904, aged 58, died, August 7, in a local hospital of cholecystitis

Grape Frank Keller, Oklahoma City, University of Oklahoma School of Medicine, Oklahoma City, 1934, aged 44, died, August 12 in a local hospital, of septicemia

Enos H. Leaman, Philadelphia, Temple University School of Medicine, Philadelphia, 1910, aged 69, died, August 8, of paralysis agitans and cardiovascular disease.

Joseph B. Chapman, Seattle, Washington Biochemic Medical College, North Yakima, 1889 aged 73, died, August 15 of cerebral hemorrhage and arteriosclerosis

Edward Newton Flint, Chicago, College of Physicians and Surgeons of Chicago, 1887 aged 72, died, August 31 at the Ravenswood Hospital, of myocarditis

George Shelley Everhart, Hagerstown Md. Southern Homeopathic Medical College, Baltimore, 1897, aged 65 died August 21, as the result of mastoiditis

Simon W. Royer, Wichita, Kan., Kansas City Homeopathic Medical College, 1894, aged 83, was found dead, August 14 of coronary thrombosis

NECROSPERMIA AND VIABILITY OF SPERMATOZOA IN THE CERVICAL CANAL

To the Editor —It is now over twenty years since my book on sterility (*Sterility in the Male and Female*, New York: Rebman Company, 1913) was published in which I gave the results and statistics of my study of the behavior of spermatozoa in the female genitals in hundreds of cases in normal and pathologic conditions of the female genitals. This was the first attempt ever made to study spermatozoa in the female genitals in a systematic manner and in a large number of cases, although a few observations had been made by previous writers. This book was followed by various articles in medical journals and culminated in using this method in the diagnosis of both male and female sterility. This procedure I designated as the cervix test (*The Practical, Scientific Diagnosis and Treatment of Sterility in the Male and Female*, *M Rec* May 9, 1914) and later as the spermatozoa test (*The Value of the Spermatozoa Test in Sterility*, *Urol & Cutan Rec* November 1914) but Reynolds in 1915 (Reynolds, *Edward Prognosis of Sterility*, *THE JOURNAL*, Oct. 2, 1915, p. 1151) referred to it as the Huhner test, by which name it is now known not only in America but also abroad.

In the May 16 (p. 1728) issue of *THE JOURNAL* appears a preliminary report by Dr. Frances I. Seymour on the "Viability of Spermatozoa in the Cervical Canal." My observations were made at various periods after coitus and have the distinct advantage of testing the husband's semen in the genitals of his own wife. After all, in the vast preponderance of cases, pregnancy is the result of coitus between husband and wife, and such observations therefore are of much greater value than if made after the unusual procedure of artificial insemination. All my observations were made in cases of sterility and I succeeded in finding live spermatozoa in the cervix of a woman five days after coitus and dead ones in the fundus as long as seven days after coitus.

The writer apparently tried to relieve sterility by artificial impregnation, using semen from some one not the husband of the patient. I have had the same request made to me by many an anxious patient with sterility but always refused. Not only must it be determined beyond the question of a doubt that the donor is free from gonorrhea and syphilis, but one must know the entire life history not only of the donor but also of his ancestry to rule out such conditions as insanity and epilepsy. To my mind the bringing into existence of a new life is a solemn and serious problem, and the fact that a certain donor is a good breeder adds nothing to our scientific knowledge as we often see about us numerous instances in which a husband is constantly impregnating his wife.

I wish to commend the doctor in making the injections only into the cervix and not into the fundus. The injection of semen into the fundus is a more or less risky procedure, as there exists no known method of sterilizing semen without killing the spermatozoa. I believe that in the ordinary act of coitus the cervical secretions seem to have the power to keep back most of the ordinary bacteria which may accompany the semen and allow only the spermatozoa to pass upward. What we want to know from a purely practical standpoint is what happens to spermatozoa which enter the female genitals during ordinary coitus, and not what happens to them if brought in by the artificial method of a cannula. Obviously, in the preponderance of cases pregnancy follows ordinary intercourse.

Coming now to the article by Dr. Cary which appeared in the June 27 issue (p. 2221) of *THE JOURNAL*, I wish to call attention to one important point which Dr. Cary cites in dis-

agreement with the conclusions made by me in my observations. Dr. Cary states (p. 2222) that in 1929 he was inclined to agree with me that active sperm cells in the cervical mucus indicated the fertility of the husband, but at present he doubts this conclusion for the reason that motile sperm cells have been found in cases in which a direct male specimen was considered as deficient. This is certainly an interesting statement in view of the fact that my article "Methods of Examining for Spermatozoa in the Diagnosis and Treatment of Sterility" published in the *New York Medical Journal* May 4, 1921, called attention to this very fact, citing it as a distinct value of my test as compared to a condom examination. For over twenty years I have been emphasizing that no complex chemical examination of the female genital secretions, no watching the spermatozoa under the artificial conditions of the microscopic stage, no counting of abnormal spermatozoa can give the practical information regarding the value of the seminal secretion in fertility compared to that of the direct examination of the spermatozoa procured from the female genitals after connection. Many years ago I cited cases in which I removed live spermatozoa from the female cervix many days after coitus, and yet these very spermatozoa died quite rapidly on the microscopic slide. Were we to judge from the behavior of these spermatozoa on the slide under the microscope we would put them down as of very poor quality, yet the fact that they had retained their vitality within the female genitals for days shows that they were of good vitality. True, experiments in animals seem to indicate that motility and fecundating power in spermatozoa are not synonymous, yet this fact cannot vitiate the results and observations mentioned.

I wish to record a most important observation concerning spermatozoa as evinced in one of the most disappointing conditions met by the specialist, namely, that of necrospemia. The cause of necrospemia may at times challenge the most painstaking investigations of the male sex organs. At times one does find a markedly congested prostate and prostatic urethra, the relief of such congestions being followed by the cure of the necrospemia. But such cases are by far in the minority. At times one meets cases that are apparently testicular in origin, for large doses of the anterior lobe of pituitary extract relieves the condition. There are of course cases of artificial necrospemia to which I have frequently called attention, namely, those instances in which the patient, in his enthusiasm to prevent the condom specimen from becoming too cold, either puts the condom containing the specimen in a jar of supposedly warm water while en route or puts the condom enclosed in a towel on a warm radiator or hot water bag. In all these cases the heat is much higher than anticipated and all the spermatozoa are dead when they reach the office. I have for many years called attention to this artificial necrospemia and have emphasized the fact that, while spermatozoa may stand a large amount of cold, the least amount of heat above the normal will kill them at once and permanently. Then once in a while a case appears in which the necrospemia is caused by some powder which the condom manufacturer has placed in it to ensure its easy application. For many years I have advised my patients to wash the interior of the condom to get rid of any possible obnoxious powder. But the fact remains that even if all these causes have been eliminated there still remains the largest number of cases of necrospemia in which the most painstaking examination will neither determine the cause nor will a cure of this condition be achieved by any method of treatment.

The up-to-date gynecologist at present will refuse to treat any woman for sterility (in the absence of any other symptom) before he is certain that the husband is normal. He therefore examines a condom specimen, and when he finds that all the spermatozoa therein are dead he advises the patient to have

her husband examined by a urologist to get rid of this important impediment to conception. But, as previously mentioned, the urologist in the vast majority of cases fails either to find the cause or to cure the condition.

I have found quite a few cases in which others as well as myself have repeatedly examined many condom specimens under the most favorable conditions and with all due precaution but always found only dead spermatozoa (even though the specimen was examined within twenty minutes of coitus) and yet a post-coital examination showed numerous normal spermatozoa. In some of these cases the spermatozoa removed from the female genitals after coitus remained alive for several hours under the microscope and yet the direct condom specimen examined only twenty minutes after coitus showed only dead spermatozoa. It may be that in some cases there is an antagonism between the material the condom is made of and the spermatozoa, although in several cases I have advised the patient to use an entirely different brand of condom without result. It may also be that in these particular cases the mere shaking up of the condom contents while en route may have the deleterious effect, although in thousands of other condom specimens examined by me and subjected to greater agitation no disturbance of the motility of spermatozoa was noticed.

I have had cases in which the woman had sought relief for her sterility for a long time, but, as this was the sole symptom the experienced gynecologist wisely refused to do anything as long as it appeared that the husband was obviously at fault. In some cases the gynecologist easily diagnosed a more or less infantile or undeveloped state of the female sex organs but it would be unwise to try to overcome this condition which might necessitate months of treatment as well as expensive endocrine injections when the husband appeared to be obviously at fault and the condition in the wife caused absolutely no annoyance aside from the sterility. It may therefore be laid down as an axiom that in every case of necrospemia a Huhner test should be made to establish a definite diagnosis.

This observation adds another interesting chapter to the contention I have so often made that no observation of a condom specimen, no matter by what method examined, can give such a definite diagnosis as can be made in many cases by examining the spermatozoa removed from the female genitals after coitus.

MAX HUHNER, M.D., New York.

EFFECTS OF BENZEDRINE ON BLOOD PRESSURE

To the Editor—Of possible interest to medical examiners for life insurance companies is this personal experience. In applying for additional insurance I had the usual examination but the policy applied for was refused on the basis of hypertension. Blood pressure examinations had been made in New York and in Chicago at frequent intervals for several years in the past and ran about 135/88. The age is 55. When the adverse report was made a rereading from the first found, 160/98 gave 140/90 the following day. Subsequent readings ran along 135-138 systolic. Because of nasal congestion, I have used various commercial vasoconstricting preparations, such as ephedrine, epinephrine and more recently a volatile drug introduced by breathing through a small tube, made by a well known Philadelphia pharmaceutical house. As an experiment I used this tube according to directions and had my blood pressure read by the original medical examiner who found it 172/105. Two days later it was 135/87. The record of frank hypertension remains on the books of the insurance clearing house but a policy has been issued as applied for because the physicians are convinced that the nasal drug was the source of the anomaly.

WITHEROW MORSE PH.D. Chicago

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS BUT THESE WILL BE OMITTED ON REQUEST.

EFFECTS OF TIN CONTAINER ON CANNED FRUITS AND VEGETABLES

To the Editor—Can you give me the scientific evidence either confirming or refuting the popular belief that any canned goods (meat, vegetables, fruit juices) if left in the original container will develop toxic properties for that reason? It seems to be the custom to empty any tin can as soon as opened and put its contents into some much less sterile container. Outside of the possible addition of a few iron oxides is there any absorption of heavy metals from the can? Please omit name if published.

M.D. District of Columbia

ANSWER.—Spoilage is caused by bacteria, yeasts or molds, everywhere present in the air and often carried on the hands of those handling the foods. So long as food is in a can that is sealed air tight it cannot be contaminated. Open the can and the food is at once exposed to contamination from the air and from the handling it receives. Putting the food in an open earthenware, glass or enamel vessel, even though that vessel is thoroughly cleansed, does not protect it against the spoilage organisms in the air. Such food in open vessels will spoil just as quickly as if it were left in the open can.

Food cans are made of sheet iron, coated with a thin layer of tin. Some acid foods such as grapefruit, peaches, pine apples and tomatoes, if left in a can when exposed to the air, tend to act on the metal of the can. Dissolved iron may give the contents of the can a slightly astringent or "metallic" taste. Any tin dissolved in the food would have no taste and even if all the tin on the inside of the can were dissolved the amount of tin which the food would contain would be small and there is no evidence that such tin compounds as may be present in canned foods are harmful.

The U. S. Department of Agriculture has recently made a study of the effects of feeding canned foods containing known amounts of tin. The results of this work have been summarized as follows by the Bureau of Chemistry and Soils: "Our own experimental work, involving the ingestion of far larger amounts of tin than any previously reported, and supported by the experimental evidence of other investigators, leads us to the conclusion that tin, in the amounts ordinarily found in canned foods and in the quantity which would be ingested in the ordinary individual diet, is for all practical purposes eliminated and is not productive of harmful effects to the consumer of canned foods."

NOCTURIA

To the Editor—Can you suggest something for symptomatic relief of persistent sleep-shattering nocturia? I realize that the primary aim is to treat the cause (high blood pressure, bronchiectasis, nephritis and so on) but the usual measures for these have not been entirely successful and the patient begs for symptomatic relief. Another patient, not an invalid, has the same difficulty the chief underlying cause being arteriosclerosis. Any suggestions you may have will be appreciated. Please omit name.

M.D. Pennsylvania

ANSWER.—It is questionable whether such severe nocturia can be caused alone by any of the conditions mentioned, namely, high blood pressure, nephritis, arteriosclerosis or bronchiectasis. Nocturia is often present with some types of nephritis and with vascular disease, but it seldom is the only cause of a distressing polyuria or of very frequent micturition.

It would seem probable that there is some cause other than those mentioned to account for the distressing nocturia described. It would be difficult to determine the etiologic factors without a careful examination of the entire genito-urinary tract. Such examination should first include a urinalysis. It is to be remembered that the absence of pus in the urine does not necessarily exclude infection, since bacteriuria may be the cause of frequent micturition. A gram stain of the sedimented urine should be made and carefully examined for bacteria, and cultures of the urine also should be made. The hydrogen ion concentration of the urine should be determined since occasionally a hyperacid condition of the urine will cause irritation which can sometimes be relieved by the administration of sodium bicarbonate. The possibility of pressure on the bladder or

irritation by some extravasical condition should next be considered and excluded. A study of the prostate and its secretion is of importance to exclude the possibility of retention of urine or of prostatic infection. A cysto-urethroscopic examination may be necessary to exclude the possibility of a lesion in either the bladder or the urethra. It is taken for granted that a roentgenogram has been made of the urinary tract, to exclude the possibility of lithiasis, which may be accompanied by no other symptom than nocturia.

If such examinations prove to be negative, all fluids should be withheld from the diet of patients after 4 o'clock in the afternoon. This will necessarily be followed by a reduction in the amount of nocturnal renal excretion.

LOSS OF BASES IN ACIDOSIS

To the Editor—It appears that in spite of the body's mechanism for combating acidosis by the buffers of the plasma and the auxiliary mechanism of renal oxidation and excretion of ketone bodies with increased ammonia formation there is in diabetic ketosis an actual loss of base in the urine. I infer from the sources consulted that sodium and potassium are among the bases lost in addition to ammonia. Can you tell me in what form this sodium appears in the urine? Is it conjugated in some way with the ketone bodies or is it in the form of phosphates? Is there an accompanying loss of chlorine with this loss of sodium as in the dehydration accompanying cortical insufficiency? 2. Can you give me the references to the more significant observations on chloride retention in pneumonia and the changes in sodium and chloride balance that occur before and after the crisis? I know that some work has been done by Sunderman and by Mackay and Butler in infections of the upper respiratory tract but I cannot find the references. Please omit name.

W D Massachusetts

ANSWER—1. A certain amount of the ketone bodies can be disposed of by oxidation in the tissues excretion as free acid, and excretion in combination with ammonia. When in the course of diabetes ketone acids in excess of this amount appear, the various fixed bases of the blood (chiefly sodium) are drawn on to neutralize the acids and are excreted with them. The chloride liberated by the removal of the basic radicals is largely excreted as ammonium chloride. Thus there are losses of both the basic and chloride ions as a direct consequence of the appearance of excessive amounts of the ketone acids. The marked diuresis and also the vomiting, which almost invariably accompanies diabetic acidosis, constitute other routes of salt loss. In these phenomena the ions may leave the body in their usual combinations.

HAY FEVER IN WASHINGTON AND CALIFORNIA

To the Editor—Can you advise me concerning the hay fever situation due to ragweed throughout the states of Washington and California? Also advise me concerning the severeness of their winters. Is the climate such that a patient with neuritis could be advised to take up residence in either state?

W E. DELICATE MD Edwardsville Ill

ANSWER—Atmospheric studies made at Seattle and Portland reveal the total absence of ragweed pollen from the air of these cities. This applies not only to the various ragweeds but to such related pollens as that of sagebrush. The results of the atmospheric studies are confirmed by local observation on the part of a number of investigators and are doubtless an index of conditions in the region west of the Cascade Range. Both ragweed and sagebrush are found in eastern Washington, but atmospheric contamination is much lower than in Illinois.

Average minimum winter temperatures for central eastern Washington are about the same as they are in the correspondent's city whereas in western Washington the average minimum winter temperature is only 2 degrees below freezing. Thus it would seem that western Washington would be the more favorable part of the state unless the cool summers and more moist winters, compared with southern Illinois would be undesirable on account of their possible effect on neuritis.

No part of California is entirely free from ragweed but, as in eastern Washington, atmospheric pollen contamination is low at least in the places which have been studied, namely, Sacramento, San Francisco, Oakland, San Joaquin County, Los Angeles and Needles. Atmospheric pollen contamination throughout the state is much less than in the Central states, yet many Californians suffer with hay fever due to a variety of pollens. The usual experience of the Central states ragweed sufferers on removing to California is that they have complete freedom at least for two or three years.

One may find any sort of climate one wishes in a state with the varied topography of California. Minimum winter tem-

peratures for the coastal area, the Sacramento Valley and the San Joaquin Valley are from 5 to 10 degrees higher than for Seattle and Portland, from 35 to 45 F. In these areas frost is rare. Normal January temperatures in southern California are at least 25 degrees higher than in the correspondent's locality. Thus, assuming that a dry warm climate such as that of southern California is most favorable for neuritis and knowing that western Washington is ideal for ragweed hay fever, the choice between these two sections would seem to depend on the relative severity of the two afflictions in this particular case.

DICHORIONIC OR DOUBLE OVUM TWINS

To the Editor—Enclosed is a snapshot of a delivery I had on September 14. The larger fetus lived about thirty five minutes and there was vigorous crying during most of that time. The snapshot was taken about five minutes after the fetus ceased respiration. The mother is a quintipara all births having been normal. There were no unusual symptoms during this pregnancy which was of six and a half months' duration until the last month when severe cramps began in the calves of the legs. These grew more severe and with them a numbness. Pains began suddenly and delivery of the smaller fetus which was very necrotic and of about three months' duration occurred within two hours the larger one was delivered in another hour. The placentas were expelled together the smaller one being necrotic. Both specimens have been preserved. Would you please let me know how usual or unusual these cases are?

H G HARRIS MD Wilmot S D

ANSWER—An occurrence similar to the one shown in the illustration is uncommon but by no means rare. Nearly always it occurs in the presence of dichorionic or double ovum twins. As in the present instance, one fetus dies early in pregnancy. For some unknown reason it is not expelled as usually occurs in the case in which

death occurs in a single fetus in the uterus. The live twin continues to grow but the dead one undergoes degenerative and maceration changes and if it remains in the uterus long enough it becomes mummified. If the dead fetus is expelled a few weeks or months after its death it appears as a macerated, shriveled up fetus and its placenta shows distinct evidence of degeneration. The dead fetus and the placenta are decidedly smaller than the fetus and placenta that continued to grow. The disparity in size between the two fetuses should not be interpreted as meaning that there were two conceptions with an interval of time between them. Had the larger baby continued to live to full term a still more unusual sight would have presented itself, namely, a full term normal baby and placenta and in addition to this a tiny, dried up, flattened fetus known as a fetus papyraceus or fetus compressus.

Twins one of whom died early in pregnancy

DIABETIC COMA—HYPERINSULINISM

To the Editor—Is it possible for a patient known to have severe diabetes who has been under large doses of insulin to show signs of threatening coma (which responded to insulin treatment) with no acetone bodies in the urine and yet a four plus sugar and a very high blood sugar? Do signs of hyperinsulinism ever appear with blood sugars of 200 mg in patients who are being treated for impending coma they showing previously 350 mg? The treatment was rigid. Please omit name.

MD Rhode Island

ANSWER—The answers depend to some extent on what one considers to be the 'signs of threatening coma' and the 'signs of hyperinsulinism.'

There is no definite level of hyperglycemia or glycosuria at which acetonuria appears in all cases, nor is there any constancy as to the amount of acetonuria present in all cases of diabetic coma. As a matter of fact, these relationships may show a fair degree of constancy in a given individual at different times, but they are known to vary widely in different individuals. Thus the appearance of acetonuria may be particularly tardy in elderly diabetic patients. It is therefore possible for a patient with severe diabetes, such as the one in question, who has been receiving large doses of insulin, to show a four plus glycosuria and a very high blood sugar without acetonuria at the time the earliest signs of coma appear. Pre-

sumably acetonuria would have appeared eventually, had the administration of additional insulin been further delayed. However, in evaluating the supposed 'signs of threatening coma' it would be important to consider the direct effects of the infection or other influences which precipitated the loss in carbohydrate tolerance or 'insulin resistance.'

The 'signs of hyperinsulinism' have been seen at a blood sugar level of 60 mg per hundred cubic centimeters and not in instances in which the blood sugar fell below 20 mg. However, the appearance of typical hyperinsulinism at 200 mg would be unusual to say the least. In elderly patients with diabetes and cardiovascular disease the rapid reduction of the blood sugar level, regardless of the absolute level at which this occurs, may result in stenocardial symptoms. This question is discussed by Soskin, Samuel Katz, L N, Strouse Solomon, and Rubinfeld, S H. Treatment of Elderly Diabetic Patients with Cardiovascular Disease, *Arch Int Med* 51 122 (Jan) 1933

HYPERSENSITIVITY TO TOBACCO

To the Editor—A man aged 28 complains of headache some tearing of the eyes a feeling of tightness or puffiness of the eyelids stiffness of the nose and a catch in the voice whenever he smells any cigaret or cigar smoke or if he tries to smoke a cigaret himself. He also complains of stiffness of the nose when in a hot moist atmosphere. Physical examination is entirely negative. One sister has had asthmatic attacks in the fall which have been controlled by ragweed injections. Is there any known method of desensitization to tobacco smoke? Please suggest treatment or give references to the literature. Please omit name

M D., New Jersey

ANSWER—The description of the case and the family history make it appear that this may be an instance of true (and perhaps atopic) hypersensitivity to tobacco. Sulzberger has shown that tobacco allergens (skin reaction-eliciting substances) are thermostable and coctostable and it is therefore highly probable that at least some of the allergens of the tobacco plant are also present in the smoke. There is no available experience on the results of desensitization to tobacco, but it might nevertheless be indicated to make the attempt in this case. The patient should first be skin tested by the application to a scratch of a saline extract prepared from the tobacco of his own cigarettes. The extract should be prepared and the skin tests made in the manner usually employed in pollen disease. If there is no definite whealing or erythema at the scratch site, a minute amount (0.02 cc) of the extract should be injected intracutaneously. (It is imperative to guard against shock with all the usual precautions, i e., test on the forearm have a tourniquet handy and be ready with a solution of epinephrine as well as with a syringe for subcutaneous injection.) If the patient reacts with a wheal to the skin tests, hyposensitization injections, just as employed in hay fever, may be tried. They would seem to have some promise of success, as with the symptoms described and with positive skin tests it does not appear far fetched to consider the case analogous to hay fever or asthma. Further information on recent work in tobacco hypersensitivity will be found in Harkavy, Joseph Hebal, Selian, and Silbert Samuel *Proc Soc Exper Biol & Med* 30 104 (Oct) 1932, Sulzberger, M B *J Immunol* 24 85 (Jan) 1933, 24 425 (May) 1933 and particularly in the summary and discussion of Sulzberger, M B *Bull New York Acad Med* 9 294 (May) 1933

EFFECTS OF SALT WATER IN MORNING

To the Editor—Please advise me whether the habit of drinking a glass of salt water before breakfast is effective for chronic constipation and whether it could have a deleterious effect if used over a long period. Please omit my name and address.

M D Illinois

ANSWER—The drinking of two or three glasses of salty water before breakfast is sometimes a most satisfactory method of relieving constipation. We cannot see how it could possibly have a deleterious effect even if used throughout a lifetime. The principle appears to be that physiologic solution of sodium chloride at body temperature is not held back at the pylorus but runs right on down through the small bowel. Here again it appears to be neither absorbed nor diluted and hence it runs on into the colon where it serves to bring about an evacuation.

Because the pylorus holds back cold liquids the water should not be iced and it must be taken before the pylorus is somewhat closed by the presence of food in the stomach. In order to make physiologic solution of sodium chloride about a third of a teaspoonful of table salt should be added to each glass of water. Three or four glasses should be drunk before breakfast while the morning toilet is being made.

ANTITULARENSE SERUM

To the Editor—I have a patient who has had tularemia for three months. His temperature rises to as much as 102 F in the afternoon, and he complains of joint and muscle soreness and pains. The joints of his hands are definitely stiff and sore. There seem to be no complications other than this. I should like to know whether this is very unusual and whether there has been anything discovered which would be of use in the way of treatment. The primary lesion which resulted from a tick bite, has just about healed. Any information or suggestions would be appreciated.

WILKINS J OZLIN M D South Hill Va.

ANSWER—While the antitularenses serum developed by Foshay appears to be most useful early in the course of the disease, there is considerable evidence to indicate that the duration of symptoms and the period of disability may be shortened by the administration of the antiserum even after the disease has remained active for three months (Foshay, Lee. An Antiserum for the Treatment of Tularemia, *THE JOURNAL*, Nov 4, 1933, p 1447. Tularemia Treated by a New Specific Antiserum, *Am J M Sc* 187 235 [Feb] 1934. On the Treatment of Tularemia, *Ohio State Med J* 31 21-24 [Jan] 1935). The antiserum, together with the directions for its administration, may be obtained directly from Dr Lee Foshay, Cincinnati General Hospital, Cincinnati.

USE OF DIGITALIS

To the Editor—Please discuss the use of digitalis in heart failure in an orthopedic man aged 71 with heart beat below 60 and moderate edema. The only contraindication for its use is a heart beat (irregular) well below the patient's normal rate and when there is no digitalis in his system. Please read the answer to the question in *THE JOURNAL*, March 18 1933 page 840 'Treatment of Disturbance of Circulation in which digitalis is apparently not contraindicated by a heart rate of 30 to 35. Please omit name

M D Minnesota.

ANSWER—If, in a patient with obvious cardiac decomposition, the slowness of the pulse at the wrist is due to a heart rate-pulse deficit caused by auricular fibrillation, it is not only no contraindication to digitalis but the typical indication for digitalis therapy, and a liberal dosage of digitalis should be given. It is assumed that in such a case the digitalis acts by producing heart block setting the ventricle free from the dominance of the auricular contractions, and thus eliminates the weakest ventricular systoles, which do not reach the wrist, and strengthens the others, so that the pulse beat and ventricular beat tend to approximate each other. It is the absolute slowness of the heart beat due to heart block as in Stokes Adams disease, that is the typical contraindication to digitalis.

VENEREAL DISEASES

To the Editor—I have heard the statement made that there are six venereal diseases. Is this so? I can account for only five: syphilis, gonorrhea, yaws, lymphogranuloma inguinale and soft chancre (Ducrey infection). Are Vincent's infection or any of the leishmaniasis considered to be venereal? Any information you can give will be greatly appreciated.

EDWIN E ZIEGLER M D Sao Francisco

ANSWER—The designation of venereal diseases numerically is not desirable and the subject is one about which there is considerable controversy. The venereal diseases that are usually recognized in this country are five in number: syphilis, gonorrhea, chancroid, granuloma inguinale and lymphogranuloma inguinale. As a rule those who speak of a sixth venereal disease consider a Vincent infection to be a venereal disease and lymphogranuloma inguinale to be the sixth disease. Clinically the Vincent infection and granuloma inguinale appear to be identical, but most workers now feel that this entity is due to the so called Donovan's bodies and not to the Vincent organisms.

FOLLICULAR MANGE

To the Editor—Would you kindly give me the following information: Is so-called follicular mange in dogs caused by a single parasitic mite or are there a number of organisms responsible for the condition? Is this condition contagious to human beings and if it is how great are the chances of contagion? If human beings are susceptible to this parasite infection how serious may this infection become? What is the prognosis? What is the treatment? What is the prognosis in dogs when the condition is only slightly to moderately advanced when no pustules are present and when it is manifested only by some degree of loss of hair? What is the treatment for the dog? If this is published kindly omit my name.

M D Connecticut

ANSWER—Follicular mange in the dog is caused by a mite or acarid of the genus *Demodex folliculorum*. The dog acarid like acarids in other animals, is practically not pathogenic for man or at best only rarely and mildly so. It seems that these parasites as a rule do not thrive on the human skin.

Colorado July Report

Dr Harvey W Snyder, secretary, Colorado State Board of Medical Examiners, reports the written examination held in Denver, July 7, 1936. The examination covered 8 subjects and included 80 questions. An average of 75 per cent was required to pass. Sixty one candidates were examined, 60 of whom passed and 1 failed. Ten physicians were licensed by endorsement. The following schools were represented:

Book Notices

The Oxford Medicine By Various Authors Edited by Henry A. Christian A. M. M. D. LL. D. Hersey Professor of the Theory and Practice of Physic Harvard University Volume VII Psychiatry for Practitioners Cloth Price \$10 Pp 634 New York Oxford University Press 1930

This volume, with eleven contributors, is in loose leaf form. The subjects included are the recognition and the management of the beginning of mental disease, by Edward A. Strecker and Harold D. Palmer, the psychiatry of childhood, by Gerald Pearson, postencephalitic and posttraumatic behavior disorders, by Earl D. Bond, mental deficiency, by E. Arthur Whitney, the psychopathic personalities, by Eugen Kahn, the toxic reaction types, by Franklin G. Ebaugh, paranoia and paranoid conditions, by William A. White, the dementia praecox (schizophrenia) group by Clarence O. Cheney, the affective reaction type (manic-depressive), including involuntional melancholia, by D. K. Henderson and psychoneuroses, by T. A. Ross. Each of these writers does well the task assigned to him. All are known for their contributions in this field, and those familiar with the field will know what to expect. The articles are written to appeal primarily to the general practitioner and the student rather than to the specialist. They are illustrated with interesting case reports presented in a succinct manner and for that reason appeal particularly to the general reader. Some of the essays for example that on postencephalitic and posttraumatic behavior disorders, are hardly greater in scope than the contributions one finds readily in current periodicals. Others, however, such as the work of Ebaugh and that of Strecker are monographic. The weakness of a book of this type is the multiple consideration which it brings of certain conditions, which however are taken up from varying points of view. A consultation of the index which is none too complete, makes this multiple reference apparent. Each of the essays is accompanied by a well chosen bibliography.

Reports on Biological Standards IV The Standardization and Estimation of Vitamin A Edited by E. Margaret Hume and Harriette Chick Medical Research Council Special Report Series No 202 Paper Price 1s Pp 81 London His Majesty's Stationery Office 1935

The two most widely promoted vitamins are vitamin A and vitamin D. No satisfactory methods of physical or chemical assay have been devised for them. Animal assays of course are used and are satisfactory for most clinical practice, but they are costly, require a large expenditure of time, and their accuracy does not nearly approach that for ordinary analysis. Therefore attempts to standardize preparations by other than bio-assays are always welcome. In this direction the Medical Research Council of Great Britain has been fostering a series of reports on products now biologically standardized. The two hundred and second report of this council deals with the standardization and estimation of vitamin A.

After the introduction there is an excellent chapter dealing with carotene as the international standard of vitamin A. This alone is a complex subject in view of the fact that carotene exists in three isomeric forms—alpha beta and gamma—and besides that, there are a number of related substances. Notwithstanding carotene has found a place in determining vitamin A activity. In the United States the Pharmacopeial Commission has deviated from this procedure in that it supplies reference standard cod liver oil for use in both vitamin A and vitamin D assays. At present analytical chemistry is undergoing a slow period of renaissance, during which time the examination of products in very small quantities is becoming greatly improved. This is due to the development of the microchemical balance with its remarkable sensitivity and developments which have grown from the use of this balance also in large part to the spectrograph. It appears hopeful that vitamin A may soon be standardized in materials by the use of the spectrograph without the use of biologic assays even for a basis of primary standardization. The purpose of much of the work at the present time is to standardize a method of preparation of the samples. The physical measurement is already in wide use in determining the comparative vitamin A activity of lots of essentially the same material. It is also reported that the degree of concordance was fairly satisfactory when the results of spectrographic examination were compared with the biologic tests. Fortunately for this country and for many of the European countries standards of an international char-

acter are now being used for the estimation of vitamin products. Therefore reports such as "The Standardization and Estimation of Vitamin A" issued by the Medical Research Council with comprehensive discussions of well conducted studies are much to be desired by those who are interested in the subject of accurate measurement and dosage of the vitamins.

A Handbook of Urology for Students and Practitioners. By Vernon Pennell M.A. M.B. B.Chir. Hon Surgeon and Surgeon with charge of Urological Department Addenbrooke's Hospital Cambridge Cloth Price \$2.75 Pp 224 with 34 illustrations London Cambridge University Press New York Macmillan Company 1936

The author presents this book as a handbook for the student and practitioner, and this end is admirably filled by a book having no pretense to being a complete treatise yet presenting its subject matter in concise and systematic style, giving a clear view of an essentially practical urology. The subject is treated in logical sequence with a convenient tabulation of essential and forceful headings. The few illustrations are well selected to give with the text a clear understanding of the subject. Rare diseases, obsolete treatment and controversial matter are omitted of necessity in a book of this size. The earlier chapters on investigation display the order of well organized practice and constitute a model on which the student might profitably base his examination of the urologic case. Thereafter the subject is presented on an anatomic basis with the exception of genito-urinary tuberculosis, which fittingly is considered as a whole in a single and separate chapter. The peculiar problems arising in the nursing of the urologic patient are considered and a useful appendix tabulating drugs urinary antiseptics and so on, closes the book. The author makes apology for possible dogmatism yet his presentation is in accord with the most widely accepted of modern teaching, so that his text only gains in clarity. This book is as remarkable for the wealth of information presented as for its readability. Mr. Pennell has given to urologic literature what Bailey and Love have given to surgery, concise exposition of essentials in practice. Having regard to the limitations of so small a volume, the urologic student must find this book an excellent supplement to the larger works. Though unsatisfying perhaps to the specialist, the work will be welcomed by the student and the intern.

Tendances de la médecine contemporaine La médecine à la croisée des chemins Par P. Delore médecin des hôpitaux de Lyon Paper Price 27 francs Pp 218 Paris Masson & Cie 1936

This book is devoted to a philosophic and critical discussion in general terms of tendencies in medicine, current and developing. As indicated by the title, medicine is believed to be at the crossroads a phrase first used by Cushing. In spite of its great achievements contemporary medicine now suffers according to Delore, from certain unfavorable tendencies such as lack of genuine clinical spirit, early and excessive specialization undue reliance on laboratory tests, failure to consider the patient in relation to his surroundings, and the useless over production of medical publications. In the further evolution of medicine however the author recognizes certain favorable trends, e.g. increased emphasis on physiology and psychology on constitution and heredity, on the relation of disease to social environment, on a more broad and synthetic conception of disease on efforts to detect disease in its earliest and preclinical stages and on the prevention of disease. The style is clear and lively.

The Eye and Its Diseases By 82 International Authorities Edited by Conrad Berens M.D. Ophthalmic Surgeon Pathologist and Director of Research New York Eye and Ear Infirmary Cloth Price \$12 Pp 1,234 with 436 illustrations Philadelphia & London W. B. Saunders Company 1936

In this volume competent ophthalmologists throughout the world cooperate to present a complete textbook. Eighty-two authorities are included. The book follows the classic procedure in medicine of beginning with history and proceeding to anatomy and physiology examination, refraction disease medical ophthalmology, injuries treatment and prophylaxis. There are also chapters on the legal aspects of ophthalmology immunology and laboratory diagnosis. The historical introduction by Shastid is essentially a series of brief biographies of noted discoverers. The sections on anatomy and physiology are excellently illustrated and the section on routine examination is practical. It becomes apparent through this section how

greatly the knowledge of ophthalmology has benefited from the discovery of new types of apparatus. The book is quite up to date and, while concise, at the same time sufficiently complete to be in miniature an encyclopedia of ophthalmology. Especially to be commended are the numerous excellently reproduced illustrations and the extraordinarily complete index. It is interesting to observe that trachoma is still a disease of doubtful etiology, with the author inclined to the belief that trachoma began as an infection of the genital tract transferred to the eye and modified by many generations of passage. The student has now available several textbooks of ophthalmology under a single authorship and the present symposium type of volume. There are certain factors of advantage and disadvantage associated with each type. Certainly however, the Berens book does much to minimize the disadvantages of the symposium type and to develop by its single editorship many of the advantages of the volume produced by a single author.

Einführung in die Physiologie des Menschen Von Professor Dr. Hermann Rein, Direktor des Physiologischen Instituts der Universität Göttingen. Paper Price 18 marks. Pp 404 with 366 illustrations. Berlin Julius Springer 1936

As a distinguished student of Max von Frey, Professor Rein was asked to reedit the former's textbook in physiology. In his foreword Rein points out that von Frey's book was such a product of his personality that it would be impossible for one to do justice to a revision. He therefore chose to prepare a new book. In so doing he has put together a great deal of the new matter in the physiologic literature alongside of much that is classic, in such a way as to provide a useful source of material for the serious student of physiology. There is a liberal amount of factual material in the book so that the student is provided with a great deal of meat to work with. The physical rather than the chemical aspects of physiology have been stressed. Particularly in relation to muscle physiology this appears to constitute a defect. The traditional treatment of muscle physiology from the mechanical point of view deprives the subject of its importance and significance. In connection with the physiology of the kidney, the chemistry is largely of a qualitative sort, and there is no adequate discussion of such important problems as renal clearance. In general the chemical features of the book are all elementary and remain, for the most part, at the descriptive stage. A conspicuous exception is in the chemistry of the blood which is amply discussed. The discussion of the vitamins is quite inadequate for a modern textbook. However, the excellent treatment of the physical side of physiology warrants high praise and makes the book valuable to a certain group of readers.

The Gift of Columbus By Charles C. Dennie, M.D. Cloth. Price \$2. Pp 193. Kansas City, Missouri: Brown White Company, 1936.

When syphilis appeared in Spain during the latter part of the fifteenth century, many Spanish physicians commented on its ravages. Among the most interesting of the writings were those of Francisco Lopez de Villalobos, whose contributions stimulated Dr. Dennie's volume. The book begins with a discussion of the origin and history of syphilis and a brief sketch of the life of Villalobos and of the evidence for and against the American origin of syphilis. There follows a consideration of the various manifestations of the disease all presented in popular form, with a concluding chapter entitled "Syphilis Can Be Conquered," explaining the modern methods of treatment. The final chapter preaches the value of prophylaxis. While the volume cannot be considered a significant contribution in the debate as to the origin of syphilis, it should be read with interest by all who are anxious to inform themselves concerning the nature of the disease.

Kurze Übersichtstabelle zur Geschichte der Medizin Von L. Aschoff und P. Diergen. Third edition. Paper. Price 4.80 marks. Pp 81. Munich: J. F. Bergmann, 1936.

This is the third revised and enlarged edition of the famous Aschoff tables of the history of medicine. They make available in brief form the dates and the records of medical discovery. It is interesting to observe that the leading contributions of the current decades are considered by the author to be the development of insulin, the Aschoff-Zondek test, the anti-allergic rooms, new anesthetics such as ethylene, acetylene and tribrom-ethanol, the use of activated ergosterol for rickets, and the new operations on the sympathetic nervous system. To

these the author would add some new political effects on medicine including the point of view of the Nazi government in Germany.

Heart Disease and Tuberculosis: Efforts Including Methods of Diaphragmatic and Cerebral Respiration to Lessen Their Prevalence By S. Adolphus Knopf, M.D. Cloth. Price, \$1.25. Pp 108 with 56 illustrations. Livingston, Columbia County, New York: Livingston Press, 1936.

There is nothing in this booklet to recommend it unless it is the illustrated breathing exercises to increase the girth of the chest. It is rambling and unscientific, with recourse to selected quotations from "authorities." It is an example of the type of writing which, fortunately, is getting rare in medicine.

American Martyrs to Science Through the Roentgen Rays: With a Short Glossary of the Scientific Terms Used in the Text By Percy Brown, M.D. F.R.C.P., F.A.C.R., Historian. American Roentgen Ray Society. Cloth. Price \$3.50. Pp 276 with 55 illustrations. Springfield, Illinois & Baltimore: Charles C. Thomas, 1936.

When the roentgen rays were first contributed to medical science, early workers failed to realize their menace to the unprotected worker, hence the passing of the years has seen the mutilation and death of many of those who conducted the earliest experiments. They were all martyrs to the advancement of medical science. Dr. Percy Brown gives brief biographies of twenty-eight of these martyrs, indicating as well their scientific contributions to the field they helped to advance. Today there are still among us many roentgenologists who will also in the coming years die as a result of their efforts in this field. Some day, no doubt, medical literature will make available a long list of these physicians who throughout the world have given their careers and their lives to the advancement of roentgenology. Even this brief collection is an inspiration.

Röntgendiagnostik der Knochen und Gelenkkrankheiten. Heft 4 (Abt. 1) und Gelenkkrankheiten) Degenerative Wirbelsäulenerkrankungen Von Professor Dr. Robert Klenböck. Paper. Price 24 marks. Pp 228 with 215 illustrations. Berlin & Vienna: Urban & Schwarzenberg, 1936.

This paper covered monograph is one of the most creditable pieces of work that has come from any radiologist. The author discusses degenerative diseases of the vertebrae, adolescent kyphosis or Scheuermann's lesion, vertebral epiphysitis, spondylitis, lumbosacral disease and its relation to sciatica and arthritis deformans, and hemangioma of the vertebrae. The reproductions of the roentgenograms are excellent.

Disability Evaluation: Principles of Treatment of Compensable Injuries By Earl D. McBride, B.S., M.D., F.A.C.S., Assistant Professor in Orthopedic Surgery, University of Oklahoma School of Medicine. Cloth. Price \$8. Pp 623 with 374 illustrations. Philadelphia, London & Montreal: J. B. Lippincott Company, 1936.

The author presents a book that should be of great value to every one interested in industrial lesions since it appraises the extent of functional loss from the economic standpoint. The writer has formulated a uniform system of arriving at percentage of disability. He discusses the workman's compensation laws, standardizing disability, examination of the disabled and ankylosis of every joint, disabilities resulting from fractures throughout the body, nerve injuries, head injuries and injuries of the eye and ear, burns and hernia. The line drawings are easily understood and instructive.

Medicine in the Bible: The Pentateuch Torah By Charles J. Brim, M.D., Department of Medicine, Beth Israel Hospital, New York. With an introduction by Victor Robinson, M.D., Professor of History of Medicine, Temple University School of Medicine, Philadelphia. Cloth. Price \$5. Pp 384 with 18 illustrations. New York: Froben Press, 1936.

This volume is more correctly a reflection of the medical references in the Old Testament. The author has carefully culled these references and has added to them definitions, excellent notes and Talmudic references. His work appears to be authentic and contains much of interest not only for the scholar but for the general reader. There are a few attractive illustrations and a useful index.

The Hygiene of the Change in Women (The Climacteric) By Isabel Emelle Hutton, M.D. Cloth. Price 5s. Pp 110. London: William Heinemann Ltd., 1936.

This is a sound book of advice for women at the climacteric. It discusses not only the usual symptoms and hygiene of this period but also the diet in relationship to weight, and particularly the art of living. A useful chapter is one of advice to husbands.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Accident Insurance Excessive Application of Heat by Patient as "Medical Treatment"—The defendant insurance company issued a policy to the plaintiff providing stated benefits for "loss resulting directly and independently of all other causes from bodily injuries effected solely from accidental means." Benefits, however, were not to be paid for loss "caused directly or indirectly, wholly or partly, by bacterial infections (except pyogenic infections which occur simultaneously with and through an accidental cut or wound) or by medical or surgical treatment, except such as may result directly from surgical operations made necessary solely by injuries covered by this policy."

A chiropodist in undertaking to remove a callus from the insured's foot pared and cut it too deeply. The callus became infected, an ulcer formed and the insured went to a physician, who lanced it. In accordance with the physician's directions the patient applied heat to the infected place, using, apparently without the physician's knowledge, a device made by a local electrician. The foot was badly burned and it was necessary subsequently to amputate the leg. He brought suit on the policy and from a judgment in favor of the insurance company, rendered by the district court of the United States for the eastern district of Louisiana he appealed to the circuit court of appeals, fifth circuit.

Medical and surgical treatment" said the circuit court of appeals mean what is done by a physician of any recognized type in diagnosing a bodily ailment and seeking to alleviate or cure it, including the things done by the patient to carry out the specific directions of the physician. We may assume without deciding that a chiropodist's treatment is not medical or surgical treatment within the meaning of the policy and that the chiropodist in paring and cutting the callus too deeply performed some unintended act or slip rather than an expected consequence of an intentional act consented to by the plaintiff. Thus assuming there would be an accidental wound, the pyogenic infection following which is not excluded from the coverage of the policy. But this wound did not result "directly and independently of all other causes" in the amputation which was subsequently necessary. Its direct result was to send the plaintiff to his physician to seek medical treatment. The treatment consisted first in lancing the ulcer hardly to be called a surgical operation. Then the physician prescribed as further treatment the use of heat on the foot. It is not alleged that any accident occurred in the use of the heat. The electrical apparatus used for that end was deliberately chosen by the insured. The burn was occasioned by no sudden or extraordinary occurrence and was not the result of any accidental means, but of the means deliberately used. If an accident at all, it was an accident caused directly or indirectly by medical treatment prescribed by the physician. The burn was not the direct or natural consequence either of the ulcer or of the lancing of it, but of the use of heat as a curative agent. Since the policy did not insure against an accident or an injury which is the direct or indirect result of medical treatment, the court held that the insured had no valid claim under the policy and affirmed the judgment in favor of the insurer.—*Barkerding v Actna Life Ins Co* 82 F (2d) 358

Accident Insurance Peritonitis as an "Infection."—Gregory fell from a locomotive suffering an injury to his stomach. Peritonitis developed and nineteen days later he died. His widow brought suit on an insurance policy which provided stated benefits if the insured should through external violent and accidental means receive bodily injuries which shall, independently of all other causes result within six months in death. Benefits however were not to be paid if death resulted from any poison or infection unless the infection is introduced into or by and through an open wound visible to the naked eye. From a judgment in favor of the beneficiary entered on a finding of the jury that Gregory's death was the result of the injury stated indepen-

dently of all other causes, the insurer appealed to the court of civil appeals of Texas, Eastland.

The insurer contended that it was not liable because the evidence showed conclusively that Gregory's death was caused by infection and that that infection was not introduced into his body through any open wound visible to the naked eye. While much of the evidence, said the court of civil appeals, is in dispute, we deem it sufficient to authorize the conclusion that about nineteen days before Gregory's death he fell from a locomotive engine and suffered an injury to his stomach which caused his death. Apparently his injury did not produce any open wound visible to the eye but, according to medical evidence adduced by the beneficiary, the sole and only cause of his death was the blow received on his abdomen, which was sufficient to bruise the tissues and cause peritonitis. The policy, continued the court, provided for compensation for external accidental injuries which, independently of all other causes, result within six months in death. It is difficult to imagine a death six months after such an injury in which infection or disease had not set up as a result of the injury and finally produced death. The provision of the policy that exempted the insurer from liability from a death resulting from infection unless that infection is introduced through an open wound, in the court's opinion, was not intended to provide only for compensation for death resulting immediately from a violent external injury (before disease or infection had time to develop) nor was it meant to exclude death resulting within the period from disease or infection produced solely by such injury. To support such a conclusion the court relied on the familiar rule of law that the ordinary meaning of words and terms as they are commonly understood by the average layman is to be adopted in preference to a technical meaning as understood by members of a profession or by a lexicographer. The ordinary conception of the word "infection" the court concluded, to a layman implies the invasion of bacteria from the air into an opening or abrasion on the surface of the skin or body, causing "toxic or blood poisoning." That being so, this exemption was not intended to operate or apply to the facts in the present case where infection or disease is caused to operate internally as the result of an external injury, even though it may be conceded that peritonitis in its technical or medical sense may be an infection.

In any event, the court concluded, the insurer was liable for the benefits because Gregory's death was the result of the accident and was not the result of the infection, the infection being merely a link in the chain of causation a result of the injury and the medium through which the injury acted in producing death. Without injury to Gregory's stomach caused by his fall, there would have been no peritonitis and no death.

The judgment in favor of the beneficiary was accordingly affirmed.—*Order of Railway Conductors of America v Gregory (Texas)* 91 S W (2d) 1139

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1926 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 17 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

Changes in Neutrophils in Severe Infectious States—Mendell and the Meranzes studied sixty cases of severe infections (septicemia, bacteremia, pneumonia, peritonitis, osteomyelitis and severe mastoiditis), diseases which they have found to be associated with both nuclear and cytoplasmic changes. Since it is generally appreciated that single hemograms are of but limited interpretative value, they made frequent examinations (total white counts, differentials, Schilling and degenerative indexes) during the course of each illness, with repeated comparisons with the clinical state. From these studies they attempted to determine the value of each procedure independently and any advantage that one procedure might have over the other. From these investigations and their experience, they have looked on nonfilament counts of from 8 to 16 as normal, from 17 to 30 as a moderate shift to the left indicative of advancing infection, from 31 to 40 as a marked shift to the left and seen in severe infections, and 41 or more as an extreme shift to the left seen in grave states. In twenty of the sixty cases studied both the degenerative index and the Schilling index proved to be of equal value. Of the remaining forty cases in thirty six the degenerative index was superior to the Schilling index. In only four of these forty cases was the Schilling index superior to the degenerative index. This series showed that at the height of the illness the degenerative index more accurately reflected the existing clinical state and the subsequent course. Degenerative cytoplasmic changes appeared earlier and persisted longer than did the corresponding nuclear changes during the critical stages of the illnesses studied. It is important to note how valuable both tests proved to be, and that, though the degenerative index proved to be superior in the majority of cases, the Schilling index again showed itself to be a very valuable procedure. It is evident that no hemogram in severe infection is complete without determination of the degenerative index.

Intra-Abdominal Torsion of Appendices Epiploicae—To the forty two cases of intra-abdominal torsion or infarction of the appendices epiploicae reported in the literature, Fiske

adds two. A correct preoperative diagnosis was not made in any of the cases reviewed. The diagnosis of appendicitis in some form was the most frequent error. Among the preoperative diagnoses made were torsion of ovarian cyst, diverticulitis, tumor of the sigmoid, tubo ovarian disease, cholelithiasis, degenerated myomas, intestinal obstruction and paralysis and peritonitis. Intra-abdominal torsion and hemorrhagic infarction of the appendices epiploicae are definite clinical entities. The most characteristic clinical symptom was abdominal pain, usually occurring over the site of the lesion. There may be associated localized tenderness. Nausea and vomiting were uncommon. A palpable tumor was present in seven cases. Intra-abdominal disease of the appendices epiploicae resulted in complications causing death in three cases. Preoperative diagnosis is difficult. In any obscure case of abdominal pain that is not explained by operative observation an exploration of the appendices epiploicae should be considered.

Studies on Urticaria from Cold Sensitivity and Effect of Histamine Treatment—Saylor and Wright discuss two cases of cold sensitivity, in one of which there was an unusually high temperature at which the reaction occurs. The blood pressure, pulse, skin temperature and gastric acidity responses of the patient to the cold urticaria are very similar to those resulting when histamine is administered. Therefore they deduce, in agreement with other authors, that these phenomena are due to an H, histamine-like, substance liberated from the tissue cells when they are exposed to certain degrees of cold. This substance is then taken up by the blood from the edematous wheal thus formed, which results in the production of the physiologic responses that simulate those of histamine. Since the temperature of the skin of their patient at which the reaction occurred was 80.2 F, the threshold was raised 60.2 F, an increase as compared with Bray's patient. There was no evidence of allergy in the skin tests, in eosinophil counts, in the passive transfer of serum test (Prausnitz-Küstner reaction) or in a family and personal history. It is not clear, at present, why histamine relieved the patient. The other patient first developed symptoms and became unconscious when swimming in cold water. This patient would probably have drowned had she not been rescued. It would seem, therefore, that wider dissemination of information regarding this syndrome should be undertaken. There are undoubtedly many unrecognized cases of this condition, and the dangers to these individuals of swimming, tub-bathing or taking showers in cold water cannot be overemphasized. It is entirely possible that the reaction might be of such severity as to produce a depression of blood pressure that would be incompatible with life.

Surgical Therapy in Epilepsy—Penfield declares that surgical therapy in epilepsy demands the most exhaustive preliminary study of the anatomy involved. No surgical procedure should be countenanced unless it is directed by rational analysis of the individual etiologic problem. Cervicothoracic sympathetic ganglionectomy has failed, except perhaps in the occasional case in which the condition is associated with obvious abnormality of the sympathetic nervous system. Removal of the carotid body and denervation of the carotid sinus are as yet without theoretical justification except in the rare case of demonstrably abnormal carotid sinus reflex. Nevertheless the practical results secured by Lauwers demand further consideration. Subtemporal decompression should be carried out only occasionally as an incident to craniotomy undertaken for other purposes or in the rare instances of chronic collection of fluid in the subdural space in which case the procedure may result in cure. Spinal insufflation of air or oxygen has been found effective only for patients less than 16 years of age whose seizures have occurred for four years or less. Epileptiform seizures secondary to lesions of the brain (tumor or cicatrix in the adult) call for surgical therapy. Operative excision of such cicatrices and of areas of focal atrophy gives an even better result from the point of view of cessation of attacks than does radical extirpation of the more benign types of tumor. After radical excision of meningocerebral cicatrix (twenty-two cases) 46 per cent of the patients have remained attack free and 32 per cent are markedly improved. After radical excision of areas of focal atrophy and focal cerebral cicatrix (twenty-two cases) 41 per cent of the patients are attack free and 32 per cent are improved. For epileptiform seizures exclusive of those with which neoplasm, abscess or hemorrhage of the brain were associated there have been in all seventy-five major craniotomies during a period of six years, with two operative deaths. In spite of the fact that these seventy-five operations include the negative explorations 32 per cent of the total number of patients are free from attacks and 23 per cent are definitely improved. For discriminating radical operation a wide osteoplastic exposure should be made so that the exploration may be ample. To open a subarachnoid collection of fluid is to do nothing of therapeutic value. When removal is undertaken the line of excision should be made through normal surrounding brain no matter what type the cicatrix may be. The removal must leave no damaged tissue behind and when easily possible should enter the ventricle. Such an excision leaves a fluid-filled space with little or no scarring. This excision should be preceded by painstaking electrical exploration of the cortex under local anesthesia and should be carried out only when the evidence indicates that the location or the area in question corresponds with the pattern of convulsive seizure from which the patient suffers. Spontaneous arrest of habitual seizures is not an unknown phenomenon in essential epilepsy but never occurs when there is a definite objective lesion of the brain. Epilepsy can never be certified as cured. Former sufferers must always be considered potentially epileptic and an illness with high fever may bring on a seizure in such a person years after the apparent cessation of the malady. Therefore the cures listed cannot be considered final but the result is none the less gratifying to the patient.

New Symptom in Multiple Sclerosis—Brickner discusses an apparently heretofore undescribed symptom that was observed in a recent study of sixty-two cases of multiple sclerosis. The name oscillopsia (oscillating vision) is suggested for it. The patient complains that objects seem to move back and forth to jerk or to wiggle. The oscillation usually occurs only during walking, although occasionally it also manifests itself during fixation of gaze at rest. Most common, it applies to near and distant objects equally. The motion may be in any direction, although the lateral component is usually the most prominent. The oscillation under consideration is an oscillatory sensation associated specifically with certain phenomena of walking and fixation of gaze. Nystagmus is the most common mechanism; intention tremor of the head is rather frequent and occasionally oscillopsia depends on tremors. Sometimes two or more factors are combined. In no instance has the symptom been observed unless at least one of these phenomena was present. The symptom occurred in eight of the sixty-two cases (12.9 per cent) and as diplopia without actual oscillopsia in another. Data relevant to the matter were lacking in some of the earlier cases, in which the symptom was not sought, so the incidence may have been even higher. The symptom has been seen five times in another group of patients (one of whom did not present typical multiple sclerosis). In eight of the thirteen cases in which the symptom has been seen it developed within the first two years. In one (in which it was associated only with tremors) it was a first symptom.

Arrhenoblastoma of Ovary—Behrend and Levine present a case of testicular adenoma tubulare of the ovary. Masculine features were lacking; vaginal atresia; lack of a cervix; rudimentary uterus and amenorrhea were present. The case emphasizes that external feminine characteristics are not incompatible with a gonad containing testicular structures. As is well known the other endocrine glands, such as the adrenal cortex, the pituitary body and the pineal gland play an auxiliary though important part in sex differentiation and may well account for the lack of masculinization in some cases of arrhenoblastoma. Thus, in a case of pseudohermaphroditism in which feminine traits predominate, the only gonads present may be testes. Masculinization in a person with arrhenoblastoma usually disappears with the removal of the affected ovary unless recurrence takes place on the opposite side (Moots).

Fibrosarcoma of Soft Parts—In an effort to answer the question of the choice of treatment for fibrosarcoma of the soft parts that is constantly recurring with proponents of radical or conservative surgical intervention and of irradiation, Warren and Sommer analyzed the records of 163 cases of the New England Deaconess Hospital. Fibrosarcoma was found not to be a disease of the young; the mean age at onset in both sexes was about 50 years. Trauma was not an etiologic factor. Most patients have been treated by operation. Radiation therapy has been disappointing. The interval from the onset of symptoms to the beginning of treatment bears no definite relation to the outcome of the treatment. The neurogenic fibro-

carcoma may be recognized as a definite subtype. The appearance of tumor giant cells indicates higher malignant incidence, as was evidenced by a higher mortality and a shorter duration of the disease in the cases studied. Recurrence is frequent (sixty-four cases) and has grave prognostic significance. However, eight patients are alive and well three years after treatment of their last recurrence. Recurrence usually is early and is rare after the first year. Metastasis is infrequent (thirty-four cases) and usually occurs after local recurrence. Metastasis is most frequent in the lungs and may involve regional lymph nodes. Fibrosarcoma involving the head or neck is serious; only 21 per cent of the patients are alive and well three or more years after the onset. Seventeen cases of adenofibrosarcoma of the breast are reported, all but one of the patients have recovered. Lymph nodes were not involved. In two cases fibrosarcoma was apparently secondary to changes caused by irradiation. Ten instances of multiple tumor were found.

Test of Circulation in Venous System of Lower Extremity—Mahorner and Ochsner determine the direction of flow of blood in the venous system of the lower extremity affected by varicosities and evaluate the competence of the valves of the long saphenous vein and communicating veins between the superficial and the deep systems of the thigh in the following manner. The degree of prominence of the varicose veins on standing is observed. It is essential to have a good light placed behind the observer, whose horizontal plane of vision is not much higher than the hips of the patient, and directed toward the area of the room immediately in front of him. The patient then walks to and fro, and any changes in the size of the veins as compared with their size in the standing position are noted. Usually as the patient walks the veins become less prominent, owing to efficient pumping action by the muscles on the deep veins. After the patient has passed in review several times, a tourniquet of thin rubber tubing is tied around the upper third of the thigh, sufficiently tight to compress the superficial veins. The patient then walks at the same rate of speed over the same course as before, and the relative size of the veins is compared with their size when the patient walks without the tourniquet. Usually there is marked diminution (from 50 to 75 per cent) in the prominence of the varicosities. The patient stops walking and the tourniquet is removed and reapplied in the middle third of the thigh, again sufficiently tight to obstruct the flow of blood in the superficial veins. The patient again walks, and the prominence of the veins in the leg is compared with their appearance when the patient walks without the tourniquet and with the tourniquet applied around the upper third of the thigh. Similarly, the patient walks with the tourniquet around the lower third of the thigh. Frequently, when the improvement in appearance is only moderate with the tourniquet around the upper third of the thigh it is marked when the tourniquet is around the lower third. In general, this test may have three results. 1 A frequent observation (40 per cent of the instances) is that improvement is greatest when the patient walks with the tourniquet around the lower third of the thigh and less when the tourniquet is around the middle or the upper third of the thigh, but that even then it is more marked than when the patient is walking without the tourniquet. 2 The most frequent observation is that there is no difference in the size of the veins when the tourniquet is in any one of the three positions and that yet there is definitely more improvement when the tourniquet is around the thigh than when it is not. 3 Least frequently there is no improvement with the tourniquet or the veins are more prominent when the tourniquet is around the thigh than when it is not. If the test shows that the communicating veins between the superficial and the deep system are markedly incompetent and high ligation is made, the patient is somewhat benefited, but little more than if a sclerosing solution should be injected into the veins of the calf without ligation. In instances in which this condition exists low ligation gives by far the greatest immediate improvement. Because fewer recurrences through collateral veins follow high ligation, in addition to this procedure low ligation may be made for an optimal effect and to prevent recurrence through communicating veins.

- Pollution of Animas River J R Earp Santa Fe N M—p 606
Liver Failure Cause of Unexpected Postoperative and Organic Death
G Z Williams Denver—p 609
Rocky Mountain Spotted Fever R L Cleere Denver—p 617

Liver Failure—Williams discusses the accumulating evidence which points to liver failure as the cause of many unexplained deaths. The syndromes characterizing these deaths are divided into three classes. 1 Those in which there is a sudden onset with high fever, coma and rapid death without signs of uremia, at necropsy, only necrosis of liver cells is found. 2 Those in which there is a similar picture with later onset and longer duration, with more gradual increase in symptoms including signs of uremia before death, necropsy discloses liver damage of varying degree accompanied by degeneration of renal tubule cells. 3 Those cases in which slowly increasing exhaustion, muscular weakness, subnormal temperature and decreasing blood pressure progress to terminal vascular collapse, coma and prostration, necropsy usually shows some change of the liver cells, if not definite necrosis. Liver deaths are not limited to postoperative incidence but occur also in many organic diseases of chronic debilitating nature, acute toxemias, liver trauma and certain drug poisonings. Liver functions cannot be quantitatively determined by any single test, but several reliable tests simultaneously performed are required. The incidence of so called liver death may be markedly lowered by avoiding surgery when patients are found to possess low physiologic hepatic reserves and by rehabilitating the livers of these patients. Postoperative support of liver function is emphasized. Forcing fluids in large quantities by all routes dilutes excessive toxins in their passage through the liver, adrenals and kidneys and promotes excretion of these harmful substances. Intestinal elimination by mild saline catharsis avoids undesirable absorption of putrefaction products. Reducing ingested proteins diminishes the load of toxic protein decomposition compounds on the liver cells. Increasing carbohydrate intake by large amounts may rapidly build up liver glycogen reserve and combat catabolic degeneration of liver cells. Administering large amounts of calcium intravenously as the gluconate, when urgent, stimulates liver functions and speeds its recovery. Giving dilute hydrochloric acid by mouth to replenish blood and tissue chloride depletion helps to maintain normal water balance. The acid, further, greatly aids intestinal absorption of calcium. Injections of adrenal cortex extract intramuscularly, if available in biologically active preparations, will definitely aid in supporting the patient's overtaxed adrenals. Ingestion of adequate quantities of sodium ions is of equal importance for promoting function. These principles of treatment are equally valuable in preoperative rehabilitation of physiologic hepatic reserve and postoperative promotion of liver metabolism.

charide L D Felton and B Prescott Baltimore—p 114

Jaundice—Martin believes that in discussing the subject of jaundice, there is a tendency to overemphasize the chemical approach and to fail to develop the clinical side. With jaundice established it is possible, with the aid of the history, physical examination and various tests to locate the source of the mischief in a large proportion of patients. The more common routine laboratory examinations, including Van den Bergh tests and determinations of urobilinogenuria and bilirubinuria, are most often sufficient for a diagnosis. The diagnosis once made, therapy, be it specific, supporting or surgical may then be instituted. There will be a certain number of cases in which the diagnosis will remain unsolved. In these the most important decision will lie between the choice of medical or surgical treatment. In youth and early adult life the pathologic condition of the liver is generally a hepatitis for which surgery

affords no aid. In later life the importance of the consideration of surgery is paramount. A stone of the common duct, if permitted to obstruct for too long a period, will cause destruction of liver cells. In cases of carcinoma of the head of the pancreas surgery is not only palliative but of value in prolonging and affording a comfortable existence. Beyond middle age, when the diagnosis lies between some obstructive condition and a hepatitis (generally infectious), surgery is indicated after an adequate period of observation. Lives may be saved, and if the condition turns out to be one of a medical type, little damage has been done particularly if there has been proper preoperative care and the choice of anesthetics has been limited to those least toxic to the liver.

Antibody in Relation to Immunity in Poliomyelitis—Kolmer discusses the possible bearing the relation of antiviral antibody has to resistance and immunity in poliomyelitis, realizing that humoral immunity was probably only part of the mechanism and that tissue immunity may be more important. He believes that this antibody plays some part in both natural and acquired resistance. The amounts occurring in the blood of normal and convalescent human beings do not appear sufficient to establish its value clearly in passive immunization of human beings in the amounts that have been commonly administered but there is no reasonable doubt that large doses are sometimes capable of protecting a percentage of monkeys when given within a day or two after inoculation with the virus. While this antibody can be produced by the immunization of horses, goats and sheep with the virus it may be that both monkeys and human beings produce it more readily, probably because both are susceptible to the virus. It is also true that this antibody is apparently without any neutralizing effect on intracellular virus so that it has proved without benefit in the treatment of both monkeys and human beings once pronounced paralysis has occurred. But it would appear that large

amounts are capable of preventing the virus from entering cells, and, if this is true, its production by vaccination with active virus may be of real value in addition to tissue immunity in affording protection against the disease. Its administration in large doses to human beings with paresis or early paralysis may prevent progressive infection of the spinal cord, so that its therapeutic value in human beings, while uncertain, is by no means clearly disproved. Whether or not some human beings are constitutionally unable to produce the antibody in sufficient amounts to prevent the paralytic type of the disease, when infected with the virus or on vaccination, is both likely and expected just as has been found true in antibody production and immunity against smallpox, diphtheria, typhoid and scarlet fever. Investigations indicate, however, that multiple doses of ricinoleated vaccine are capable of producing the antibody in children in amounts comparable to those found in the blood of convalescents and normal adults. Whether or not immunization with ricinoleated vaccine of active virus engenders a protective degree of tissue resistance in the absence of demonstrable amounts of neutralizing antibody cannot be stated, but both the possibility and the probability exist.

Establishment of New Blood Supply to Heart by Operation—Beck reports that up to the present time he has operated on eleven patients with sclerosis of the coronary arteries and angina pectoris. These patients were totally disabled and constituted an extremely bad risk group for any operative procedure. Six patients are living and five are dead. The tissues available to the heart for a blood supply are the pectoral muscle, the triangularis sterni muscle, the intercostal muscle, the intercostal vessels, the internal mammary vessels, subcutaneous fat, mediastinal fat and the parietal pericardium. Two developments are being carried out. One concerns the reduction in irritability of the heart at the operating table by the application of drugs to the surface of the heart; the other consists in making a vascular bed available to the myocardium by a much more simple type of operation. The author says that in his first experiments, which he conducted in collaboration with Tichy, the mesothelial envelop around the heart was destroyed by roughening the lining of the parietal pericardium and also the epicardium by means of a bur. A new vascular bed was constructed by bringing various grafts onto the myocardium. The tissues that were used for the new vascular bed were fibrous pericardium, pericardial fat, pedicle grafts of skeletal muscle from the chest wall, and omentum brought up through an opening in the diaphragm. Anastomoses between the grafts and the heart could be demonstrated in three weeks after the grafts were placed. Anastomoses increased after a physiologic need for blood was established in the myocardium. The physiologic need for blood is perhaps more accurately defined as a pressure differential between the two vascular beds. It was produced by occlusion partial or complete, of major coronary arteries. After citing several other experiments by which the heart was given a collateral vascular bed the author says that two types of experiment are presented for comparison. A. Complete ligation in one stage of four or five peripheral branches of the coronary arteries over the apex of the left ventricle was always fatal; ventricular fibrillation developed. B. The right and both major branches of the left coronary

arteries could be occluded by about one third of their cross-section in one stage with recovery. The total amount of blood going through the coronary system in A can be assumed to be greater than in B yet A was a fatal experiment and B resulted in recovery. These experiments bring out an entirely new point so far as the heart is concerned, namely, the importance of an equal distribution of blood to the myocardium. Total coronary blood flow is one factor that concerns the preservation of the heart beat but distribution of blood flow is another important factor. The collateral vascular bed can function in effecting an equal distribution of blood to various parts of the myocardium. This is done in two ways: first, by bringing blood from extracardiac sources into the myocardium, and, second, by transporting blood from one part of the heart where the circulation is good to another part of the heart where the circulation is deficient. In the latter respect the grafts act as anastomotic bridges connecting the beds of different vessels.

Clinical Application of Venous Pressure Measurement

—Hussey says that he used a method and an apparatus devised by Griffith Chamberlain and Kitchell. The apparatus consists of a 20 gage needle and a 2 cc. syringe having a sidearm to which a calibrated glass measuring tube is connected by means of rubber tubing of about the size of a 14 F catheter. The other end of the glass tube is connected by means of another short piece of rubber tubing to a glass reservoir of any description. The entire apparatus can be sterilized by boiling. Physiologic solution of sodium chloride is placed in the reservoir and allowed to fill the set, which is then ready to use. The patient is placed in the supine position, a vein is selected at the elbow and the needle of the apparatus is introduced into the vein. The plunger of the syringe is drawn back, allowing saline solution to run through the sidearm into the syringe and thence into the vein. Next, the reservoir is detached from the apparatus and the zero point of the calibrated tube is placed on a plane with the midaxillary line of the patient. This plane has been selected arbitrarily as approximately level with the right atrium of the heart and as a simple means of standardizing readings. The saline solution will continue to fall in the glass tube, fluctuating somewhat with respiration and stopping at a point which indicates the height of the venous blood pressure in terms of millimeters of saline solution. With this technique it has been found that normal persons have a peripheral venous blood pressure of from 40 to 120 mm of saline solution. The author shows that the principal factors influencing the blood pressure in the peripheral veins of normal persons are the heart action, gravity, the intrathoracic pressure, the blood volume and muscular exercise. He presents the results of study of the venous pressure in 150 selected patients. Right ventricular failure always causes a rise in venous pressure above normal, and this rise may be the means to the establishment of the diagnosis of heart failure. Repeated measurements of venous pressure in patients with congestive heart failure are useful to follow the clinical course of the disease and have considerable prognostic importance. High venous pressures in lobar pneumonia have an unfavorable prognostic significance. Measurement of the blood pressure in the peripheral veins is valuable in the diagnosis of cardiac compression and is helpful in estimating the efficacy of surgical treatment in this condition. Measurement of the venous pressure is useful in the diagnosis of mediastinal tumors and in observing the response of certain types to roentgen therapy. Pleural effusion and pneumothorax do not affect venous pressure unless they

are sufficient to provoke dyspnea. Measurement of venous pressure is useful in the regulation of artificial pneumothorax therapy.

Ureteral Transplantations G. V. Foster Pittsburgh—p. 874

Histidine Treatment of Peptic Ulcer—Weigand shows that histidine treatment consists of the daily intramuscular injection, for twenty-four days of 5 cc of a 4 per cent solution of histidine monohydrochloride. No specific dietary regimen is used other than the avoidance of foods obviously so rough as to promise possible mechanical injury. The patient is ambulatory during this treatment and is able to follow his usual daily routine. This treatment was carried out on patients most of whom were in an acute attack. After giving brief histories of twelve of these patients, the author concludes that the intramuscular injection of histidine monohydrochloride should be further studied as a therapeutic measure in the treatment of peptic ulcer. In cases in which recurrence has occurred after surgical intervention, its use should be given consideration. Because of the prompt symptomatic relief afforded, emphasis must be placed on thorough x-ray follow up in addition to the customary clinical observations.

Undescribed Lesion of Shoulder Girdle—Replogle states that an analysis of 250 successive cases of shoulder injury observed at the Bethlehem Steel Hospital, Johnstown, Pa., excluding burns and minor injuries, revealed twenty-six varieties of lesions in and about the shoulder. Twenty-five per cent of the lesions are sprains. One of the frequent traumatic lesions of the shoulder is sprain of the rhomboideus minor muscle. After describing and explaining the symptomatology of this sprain, which occurs usually in those performing heavy or strenuous labor such as swinging a sledge, firing a furnace or lifting a heavy weight, the author takes up the treatment, showing that it is simple and based on anatomic lines to cause relaxation of the overstretched muscle. The shoulders are thrown back so as to lessen the interscapular space, and wide crisscross adhesive straps are applied for the maintenance of this position. The arm is placed in a sling and a small pad placed under the adhesive plaster over the point of tenderness to hasten the absorption of the serous effusion at the point of rupture or strain. This treatment gives immediate relief from aching, and pain on abduction is greatly reduced. The author several times removed the cross strapping too early and patients requested its reapplication to obtain relief. He concludes that the frequency of occurrence of sprain of the rhomboideus minor, the unusually constant symptomatology and clinical picture and the efficacy of simple and proper treatment together with the fact that it is of sufficient seriousness to cause industrial disability, justify a description of the lesion and demand caution in its diagnosis.

Inflammatory Disease in Eye Caused by Gout.—Cases of ocular disease which correspond exactly with those described by Jonathan Hutchinson, and attributed to gout, are encountered from time to time. During the last fifteen years Wood has dealt with four such cases. In them no other gross or manifest evidence of gout existed, and therefore other and more modern etiologies had been sought without success. The first sign of trouble was an attack of episcleritis fugax, and this continued to form part of the syndrome through the course of the trouble. The proof that gout is the principal cause is partly negative, in that the pathologic conditions do not resemble any others that the author has seen. On the positive side are to be placed the fact that in three cases tenonitis was present and that episcleritis periodica fugax was the commencement in all the cases. In three cases the patient's diet and use of alcohol were such as would naturally produce a gouty condition, and in one the cessation of beer and diminution of a heavy meat diet put an end to the troubles. Besides these points in the two cases in which an examination was made the uric acid content in the blood was greatly increased during the acute attacks.

Hormone Regulation of Number of Blood Platelets.—Zondek and Kaatz show that the blood platelet count in the peripheral blood is increased by the hormone of the thyroid gland. The action is more constant than in the case of red blood cells. The increase usually appears from twenty-four to forty-eight hours after the administration of the hormone and has disappeared within about seventy-two hours. The thyrotropic hormone acts in the same way, but its action is more protracted. In a case of chronic thrombopenia in a child a gradually increasing number of platelets was counted after repeated administration of thyrotropic hormone (single dosage 500 rabbit units). Adrenal cortex extract showed a diminishing effect on the number of blood platelets in a large number of experiments but in several other experiments this result was not obtained.

Frequency of Micturition in Female.—Close states that it is in the lower part of the urinary tract that the lesions responsible for the ailments of frequent micturition peculiar to women occur that is that part which developmentally belongs to the wolffian duct—the trigon, urethra and their adnexal glands. The following pathologic conditions affecting the female urethra and trigon are discussed separately: (1) urethritis embodying acute generalized infections due to the gonococcus, a gram-negative extracellular diplococcus, *Bacillus coli*, the enterococcus and mixed organisms such as staphylococci, diphtheroids and trichomonads, together with the foregoing organisms, and chronic glandular inflammations of the deep "prostatic" glands, submucous follicles or Skene's glands, which may be infective, owing to organisms mentioned non-infective conditions of the so called "prostatic" glands or passive venous congestion, (2) stricture of the urethra accompanied by chronic infection as cause or effect, (3) carunculae, (4) trigonitis pseudomembranosa, or trigonitis exfoliativa, (5) senile atrophic urethritis, (6) diverticula, (7) defects in the supports of the lower part of the urinary tract and (8) neuroses.

Virus of Inguinal Lymphogranuloma.—Miyagawa and his co-workers found that by the intracerebral inoculation of inguinal lymphogranuloma virus only squirrels among guinea pigs, albino rats and domestic fowls show typical cerebral symptoms with typical pathologic changes and numerous special granulocorpuscles. Under the intratesticular inoculation there appeared typical pathologic changes and granulocorpuscles in the albino rats and squirrels but not in the guinea pigs and rabbits. The affected testicular material is capable of causing typical infection with special granulocorpuscles in mice. By the intradermal inoculation into guinea pigs albino rats rabbits, squirrels and domestic fowls typical papules occurred with special granulocorpuscles in the guinea-pigs albino rats mice and squirrels and the content of the papules caused typical symptoms by means of intracerebral inoculation into mice. By the dermal passage of the virus, the virulence of which was already decreased in the successive passage through mice brains and through guinea pigs and albino rats the virulence of the virus increases so remarkably that it again causes severe symptoms in mice. From this fact it may be said that the virus has a certain dermatotropism. Special granulocorpuscles are always found when the disorder is produced distinctly.

*Treatment of Infantile Diarrheas by Raw Apples S F Bakal and R M Sigal—p 578
Fetitis of Nursing and Young Child S Mehler—p 585

Treatment of Infantile Diarrhea by Raw Apples—Bakal and Sigal report fifty one cases of infantile diarrhea. Twenty-eight children were less than 2 years of age, eighteen were between 2 and 5 and five ranged from 6 to 10. In all instances the authors introduced a forty-eight hour diet of apples without preliminary treatment. In only two cases did the diet last only one day because the children refused the apples. The skins and cores of the apples were removed. In most instances the children ate the apples willingly. During this diet the patients received no other nourishment. Liquids were given as needed. The first day of transition toward a regular diet the patients were given such foods as rice gruel, bouillon and gelatin. By the third day vegetable puree could be given. The results obtained were good. During the first day the stools became thick, from five to seven hours after the first apple meal and developed the odor and appearance of pureed apples. Toward the end of the second and third days the stools became formed, the general condition improved, the toxic phenomena disappeared and the temperature fell. During the apple diet the weight of the children decreased, but it returned rapidly to normal later. The history of the illness was almost the same in all the cases. The authors believe that the rapidity of action, the duration of effect and the absolute innocuousness of the apple diet should lead toward application of this method not only in the clinic but also in ambulatory practice.

Journal de Médecine de Lyon

17: 563-592 (Sept.) 1936

- *Acute Curable Subarachnoiditis in Young Subjects J Chalier M Plauchu and L. Badinand—p 563
Measles Meningo-Encephalitis. J Chalier M Plauchu and L. Badinand—p 579

Subarachnoiditis in Young Subjects—Chalier and his colleagues report twenty personally observed cases of acute benign lymphocytic meningitis in young subjects. They believe that the latter name is inappropriate. Actually the cerebrospinal fluid albumin is ordinarily little increased, certainly less than in acute or subacute meningitis. By contrast the level of sugar instead of decreasing as in meningitis is in general increased initially and returns rapidly to the neighborhood of normal. The leukocytosis, which is marked at the beginning, does not increase as in tuberculous meningitis but usually decreases with rapidity. A cytologic examination reveals the frequent presence of cells the characters of which allow them to be classed with the monocytes. Because of their frequently elevated level, these elements, so far poorly understood, have an important prognostic value. They augur a recovery. The chemical observations oppose the opinion that this is a true meningitis. Furthermore, the frequently elevated number of monocytes testifies against the qualification of the term meningitis by adding "lymphocytic." The term that seems in the authors opinion to describe the condition best is "acute, curable subarachnoiditis in young subjects."

Measles Meningo-Encephalitis—Chalier and his colleagues discuss the meningeal and encephalitic manifestations of measles. They report ten cases personally observed. These complications almost always arise after the disappearance of the measles exanthem. They consist, according to the case, in convulsions, torpor, somnolence, coma, hyperthermia and meningeal signs. Various forms can be described: (1) acute or subacute generalized forms, (2) a localized hemiplegic form, (3) a form of hemorrhagic meningo encephalitis, (4) a pure or predominantly meningeal form and (5) a slight or larval form. The cerebrospinal fluid shows a slight increase in albumin and sugar and a slight or marked cellular reaction usually in the form of lymphocytes and monocytes. The diagnosis must be differentiated especially from the meningo encephalitis due to otitis and mastoiditis. Hyperthermia or association with a bronchopneumonia constitutes the most unfavorable

prognostic sign. The anatomic foundation is represented especially by generalized deterioration of the brain, predominantly in the white substance. Microscopically this is revealed by multiple lesions, inflammatory, degenerative and proliferative. The pathogenesis remains an object of discussion. If there exists a post measles meningo encephalitis, is it or is it not due to the measles virus? Further research is necessary on this point.

Archivio di Ostetricia e Ginecologia, Naples

43: 319 396 (Aug.) 1936

- *Rupture of Uterus G Tesauro—p 319

Rupture of Uterus—According to Tesauro spontaneous or posttraumatic rupture of the uterus complicating labor takes place more frequently in multiparas than in primiparas and generally in women more than 35 years of age. The frequency of the complication is 0.3 per cent. Predisposition of the uterine wall due to lesser resistance of the organ by previous febrile puerperiums, obstetric operations and inflammatory or cicatricial processes exists in most cases. The author reports thirty cases. Spontaneous rupture was produced in the scar of a myomectomy in one, by shoulder presentation in four, by pelvic stenosis in two, by face presentation in one and for other causes in six women with normal pelvis and fetuses in vertex presentation. The rupture was complete in twenty-three cases; it took place at the lower segment of the uterus in twenty-two and at the fundus in one. In one case the bladder and in another the vagina and the bladder were involved in the tear. Subtotal hysterectomy was performed in twenty-nine cases. A drain left in the ruptured area (subperitoneal) was the only treatment in one case. Hysterectomy was closed without drainage in one case, after a Mikulicz drain had been left in three cases and two drains in twenty-three. In the latter group a Mikulicz drain and an abdominal and vaginal gauze drain were left. According to the author, this is the reason for the great number of recoveries obtained (74 per cent). Two patients died during the operation, six from septic or pulmonary complications within five days and one from embolism, within twenty-five days of the operation. The operative mortality rate was 25 per cent.

Diameter of Erythrocytes in Normal and Pathologic Conditions G Cozzutti—p 567
*Neurologic Complications of Pernicious Anemia Clinical Study A Baserga—p 603

Neurologic Complications of Pernicious Anemia—Baserga reviews the literature on neurologic complications of pernicious anemia. There are two types of neurologic complications: those of moderate intensity in pernicious anemia not treated with liver and those of the typical subacute combined degeneration of the spinal cord (Lichtheim syndrome). Neurologic complications of moderate intensity are so frequent that they are considered characteristic symptoms of pernicious anemia. Grave forms are rare. They result in invalidism by paralysis and develop only in patients who have suffered long and been insufficiently treated. Intramuscular injections of liver in daily doses corresponding to 700 Gm if given by mouth and for long periods, would prevent neurologic complications, control those already developed and, in some cases, result in regression of the symptoms. Discontinuation of the treatment results in immediate diminution of hemoglobin in the blood and aggravation of the symptoms, which sometimes do not regress. Once regression of the symptoms or improvement of the blood takes place, injections of liver extract corresponding to 5,000 Gm of liver should be given once a week or every other week. The frequency of the injections is determined by controlling the amount of hemoglobin in the blood by weekly blood examinations in order to maintain hemoglobin at not lower than 100 for men and 90 for women. The treatment in these cases should be given without interruption for a period varying from fourteen months to three years. Large doses of iron and physical reeducation are resorted to as complementary treatments. The author discusses the economic aspect of liver treatment.

Discontinuation of the treatment because of the patient's financial status is the main cause of the neurologic complications. It is advisable to establish centers, supported by the government or the community, for free administration of liver treatment to those unable to pay for it. The expenses of these centers will be small compared to those of supporting invalids from the disease. Two cases of the typical and atypical forms, respectively, are reported by the author.

Policlinico, Rome

- Mens Agitat Molem Psychic Influences on Etiopathogenesis of Gastric Ulcer B. Schiassi—p. 425
- Adamantinoma of Lower Jaw Cases G. Selvaggi—p. 454

Experimental Tetanus—Caminiti says that hyperthermia induced by pyretogenic substances, fails in treating experimental tetanus. Conflicting opinions are reported in the literature on the therapeutic value of several forms of anesthesia. The author made experiments on rabbits and found that ethyl chloride, chloroform and ether anesthesia fail to retard fixation of the toxin on the nervous tissues, to free the toxin from the tissues and to make it liable to be neutralized by the antitoxin in the blood. Rabbits treated with the anesthetics died early in the course of experiments. The sodium salt of *n*-methyl-cyclohexenyl-methyl barbituric acid associated with tetanus antiserum in large doses (1,500 Rosenau units for each injection given intramuscularly) gave satisfactory results. The greater number of rabbits that received the combined treatment thirty-six and forty hours after inoculation of the toxin and eighteen and twenty-four hours after onset of contractures survived the disease. The action of the treatment seems to be due to sedative and antispastic properties of the sodium salt of *n*-methyl-cyclohexenyl-methyl barbituric acid by which the excitability of the nervous tissues diminishes and the tissues become permeable to the entrance of antitoxins. The development of the disease is favorably modified, especially by great attenuation of the nervous symptoms of the clonic-tonic type. The results of the experiments according to the author, indicate the advisability of the use of the combined treatment in tetanus in human beings for evaluation of clinical results.

- *Primary Giant Cell Tumors of Patella Case. E. Sorge—p. 399

Primary Giant Cell Tumors of Patella—According to Sorge, the number of cases of primary giant cell tumors of the patella reported in the literature is sixteen, including his own. He reviews the operation performed in each case and the results reported. In his case he resorted to rotulectomy followed by reconstruction of the extensor femoris muscles and plastic correction of the tendon of the quadriceps by means of a flap, previously prepared. The operation was satisfactory as to cosmetic and functional results (complete extension of the leg and active flexion of the knee joint of about 130 degrees). Functional improvement is expected from time and physical exercise.

Treatment of Vomiting in Pulmonary Tuberculosis—Ramondi and his collaborators find magnesium sulfate efficacious in the treatment of alimentary vomiting not originated in any pathologic gastric condition and complicating pulmonary tuberculosis. It is advisable to resort to the treatment as soon

as vomiting begins, not only to prevent denutrition and psychic reactions of the patient but also to improve his general condition. The treatment consists in subcutaneous or intramuscular injections of from 3 to 5 cc of a 12 per cent solution of magnesium sulfate to which a 1 per cent solution of procaine hydrochloride or 0.02 Gm of paraphenolsulfonate of ethylamino benzoate for each 5 cc of the solution is added. Two daily injections are given, each of which is administered half an hour before meals. Vomiting is controlled in all cases after the first few injections. It is advisable, however, to give the treatment for ten days to consolidate the satisfactory results and to repeat it at any time if vomiting reappears. The treatment may be used in pregnant tuberculous women, it does not interfere with the digestive functions and is better than other medical treatments that are now used for the condition.

Influence of Bile Salts on Vaginal and Intestinal Trichomonas—Fischer experimented in vitro and found that bile, in normal condition, develops a proteolytic action on vaginal and intestinal Trichomonas. The toxic action of bile depends on its concentration, which in turn depends on the normal function of the liver. Greatly diluted bile favors the development of Trichomonas. Sodium cholate, glycocholate and taurocholate are parasitocides for Trichomonas.

Treatment of Erysipelas by Ultraviolet Irradiations—Desmaison resorted to ultraviolet irradiations in treating erysipelas of the medical or surgical type. Care should be taken that the eyes of both the patient and the roentgenologist are protected by glasses. He prefers Hanan's mercury vapor lamp because of the regularity of the radiations emitted. The lamp should be focused at a distance of 50 cm. so that the beam touches the skin obliquely or horizontally in relation to the position of the patient without bringing him directly under the lamp but beside it. The irradiation covers not only the involved area but the surrounding zone of apparently normal skin as well. Treatments are given daily or every other day with a duration of five minutes for the first and ten minutes for the following irradiations. The complete treatment consists of from three to six irradiations. It gives immediate sedation of the local and general phenomena and complete control of the disease, generally after the third irradiation and rarely after the fifth or sixth. The efficacy of the treatment is the same in patients suffering from erysipelas, but otherwise normal, as in those with diminished organic resistances and physiologic insufficiency. Pulmonary tuberculosis, myocarditis, heart diseases in decompensation and certain dermatitis of the vesicular type are contraindications of the treatment.

Transfusion of Preserved Blood—Tachella Costa states that blood from living persons preserved at a temperature of 4°C keeps its therapeutic properties for eight days when preserved in an isotonic citrated solution and for several weeks when preserved in a dextrose solution. When compared with direct transfusion from donor to patient preserved blood transfusion has the following advantages: same efficacy, more exact serologic control of the blood in relation to possible contamination and blood grouping, easier technique, lower cost and opportune availability. These advantages prove the advisability of

using preserved blood. Surgical clinics and emergency departments, even those located in small communities, should have a department for blood transfusion with a supply of preserved blood available at all times. The author does not consider transfusion of preserved blood from cadavers, since it is difficult to obtain cadavers of normal persons who have died suddenly and to be sure of the preservation of the cadaver before taking the blood. Another great objection is the repugnance of patients to be treated with blood of cadavers.

*Intravenous Galactose Tolerance Test K Hitzemberger and E Fantl—p 1017

Histidine Treatment in Ulcerating Disorders—Kahler and Duregger were able to corroborate the favorable action of histidine on gastric and duodenal ulcers in forty cases. They employed a sterile 4 per cent isotonic solution of histidine monohydrochloride, using ampules of 5 cc each for intramuscular injections. In the majority of the cases they observed disappearance of the pains after the third or fourth injection and at the end of the histidine treatment (from eighteen to twenty five injections) they nearly always observed that the objective ulcer signs subsided (muscular stiffness, pressure points and occult hemorrhages). The roentgenogram likewise revealed improvement. It is especially noteworthy that, in contradistinction to other internal methods of ulcer treatment, histidine therapy is effective also if no particularly strict diet is adhered to. In four cases relapses appeared after four and eight months respectively but renewed treatment with histidine was again successful. The authors decided to try this treatment also in other disorders that are accompanied by ulcer formation. They found that in ulcerative colitis histidine injections result in rapid improvement, which can be proved rectoscopically. In large pulmonary abscesses histidine treatment was ineffective, but in small pulmonary abscesses improvements were observed. Many cases of bronchiectasis responded favorably to histidine treatment in that the quantity of the sputum and its bad odor were nearly always reduced. The authors think that the fact that histidine is effective in ulcerative processes of various organs indicates that it exerts a direct influence on the chemistry of the diseased tissues.

Intravenous Galactose Tolerance Test—Hitzemberger and Fantl point out that, in oral tolerance tests with 40 Gm of galactose, cases are frequently detected in which no galactosuria results. This so-called agalactosuria was considered by some authors as a differential diagnostic sign of pernicious anemia. It was soon found, however, that this sign appeared also in other forms of anemia and even in disorders without anemia. Further, the authors mention investigators who assumed that disturbances in the intestinal absorption or in the renal function might be a cause of the agalactosuria. They point out that in the latter cases there should be a high galactosmia. They observed a patient with parenchymatous icterus of such severity that acute atrophy of the liver had to be suspected. Repeated oral galactose tolerance tests (40 Gm of galactose in 400 cc. of tea) disclosed complete agalactosuria. Although the patient was free from noteworthy intestinal disturbances a defective resorption was suspected as the cause of the agalactosuria, for renal disorders were likewise absent. In order to detect the possible disturbance in the intestinal resorption, the authors made an intravenous injection of galactose and at once observed a severe galactosuria. Following preliminary tests they found that 40 Gm of galactose must be administered intravenously in order to obtain practical results. They now make the intravenous galactose tolerance test with 40 Gm. of galactose in the form of a 40 per cent solution.

They stress that with this test the always doubtful component of intestinal absorption can be eliminated. They found that normal subjects eliminate in the urine up to 5 Gm of the intravenously administered 40 Gm of galactose. Patients with parenchymatous icterus or with pernicious anemia who show agalactosuria after an oral tolerance test show a typical galactosuria following intravenous administration. The authors conclude from this that the agalactosuria after the oral test is caused by deficient intestinal resorption. In case of renal lesions, the galactosuria is low even after intravenous galactose tolerance tests.

Interstitial Tubal Rupture Case R Leupold—p 1652

Substitute for Blood in Abdominal Hemorrhages—Hajek points out that the reinfusion of the blood which accumulates in the abdomen in ruptured tubal pregnancy was first recommended by Thiess. The advantages of this reinfusion over transfusion were so pronounced that the method soon found wide acceptance. To be sure, there also were some failures but these were usually traced to some defect in the technic and efforts were made to improve it. The author reviews several methods that have been suggested for the preparation of the blood and then shows that the reinfusion itself has been done with different apparatus. After discussing some of the complications that have developed in connection with the reinfusion, he directs attention to the technic suggested by Knaus who aimed at reintroducing the blood as nearly as possible in its physiologic condition. Knaus employs neither defibrination nor dilution with sodium chloride, Ringer's solution or sodium citrate. By dispensing with these procedures he not only prevented impairment of the blood but also simplified the method considerably. Following opening of the abdomen, Knaus takes up the blood into a sterilized apparatus consisting of three parts, the upper being a sieve, the middle the blood container and the lower containing water at 40 C to keep the blood at the proper temperature. The sieve separates the fluid blood from the coagulated blood. The fluid blood thus obtained is introduced into the vein of the arm as in case of blood transfusion from man to man. The author says that no further complications have occurred since this method of reinfusion was introduced at his clinic.

Thoracoscopy with Severance of Adhesions (Jacobus' Operation)—Altschuler analyzes the results of 165 thoracoscopies with or without cutting of the adhesions performed in the last three years in the surgical division of the Central Tuberculosis Institute. The majority (ninety-nine) of the patients presented a bilateral disseminated or fibrous cavernous process. Only one third (fifty-two) presented a unilateral involvement. The operation was performed in 117 cases because of cicatrices which prevented the collapse of a cavity and because of the presence of tubercle bacilli in the sputum. It was performed in sixteen cases because of adhesions that were deforming the collapsed lung and because of the presence of tubercle bacilli in the sputum despite the fact that the existence of a pleural cavity could not be demonstrated either clinically or roentgenologically. Adhesions were the sole indication for operation in fifteen cases. The adhesions were responsible in

those cases for the continuance of toxic symptoms such as temperature and moderate blood spitting after reinflation. In two cases the operation was performed for a persisting exudative pleuritis. The operation of thoracoscopy with cutting of adhesions gave positive mechanical and clinical results in 64 per cent. It brought about obliteration of the pleural cavity, disappearance of tubercle bacilli from the sputum and toxic symptoms. Reinflation had to be done, but the patients felt well and were able to work. Collapse of the lung was improved in thirteen. In 3 per cent of the patients a supplementary phrenico-pleuresis had to be done to obtain a satisfactory collapse. The author considers the following absolute indications for thoracoscopy: 1. The presence of cicatrices that deform a cavity and tubercle bacilli in the sputum. 2. When in the absence of a demonstrable pleural cavity, there exist adhesions that deform the collapsed lung and when tubercle bacilli are present in the sputum. 3. When, in the absence of tubercle bacilli in the sputum and a demonstrable pleural cavity, toxic symptoms persist that can be explained on the basis of trauma of tuberculous foci resulting from cicatrizing adhesions. 4. Persistent or recurring pneumopleuritis in the quiescent period. In such cases adhesions frequently traumatize the pleura and interfere with the subsidence of the inflammatory process. 5. Failure on the part of the pleural cavity to become obliterated even if roentgenograms do not demonstrate the presence of adhesions. Among the relative indications he mentions: (1) the presence of cicatrices in an otherwise satisfactory artificial pneumothorax, (2) protracted pneumopleuritis in the quiescent period without roentgenologically demonstrable adhesions, (3) certain cases of spontaneous pneumothorax caused by the rupture of an adhesion close to the visceral pleura (thoracoscopy here has a diagnostic as well as a therapeutic value), (4) the cutting of the adhesion, which permits the lung to collapse and the perforation to close, and (5) before an induction of an oleothorax in order to demonstrate the condition of the pleura. Hyperemic pleura points to activity of the inflammatory process and therefore to continuation of exudation in spite of introduction of fat (oleothorax).

Blood Plasma Transfusion for Arrest of Pulmonary Hemorrhage.—Kazarnovskaya and Mordvinkina report ninety-six transfusions with blood plasma in fifty-three patients. Thirty-three of the patients had a persistent profuse bleeding, which had resisted the various hemostatic measures such as administration of calcium chloride, autohemotherapy and horse serum. The amount of blood plasma infused at one time amounted to from 20 to 40 cc. Hemorrhage was arrested after one transfusion in thirty-one cases, after two in nine cases and after three in eleven. The method failed in two instances. It was thus effective in 96 per cent. The plasma was secured from the Leningrad Institute for Blood Transfusion. It is prepared from donors of groups A and B. It does not contain agglutinins and can be given without regard for the blood group of the recipient. It does not produce anaphylactic reactions on repeated injections. It differs from serum in that it does not contain fibrinogen. The advantages of the method claimed by the authors are the small dose required, the rapidity of action, the few general reactions and total absence of focal reaction. Infusion of blood plasma has the effect of increasing blood coagulability, the lowering of which constitutes one of the most important factors in the complicated mechanism of pulmonary hemorrhage.

- *Nervous Disorder with Fatal Outcome After Spinal Anesthesia with Symptom Free Interval of Four Weeks. Case. D. Elstad.—p. 959

Reticulo-Endotheliomas in Lymph Nodes.—Harbitz says that there are conditions in the lymph nodes originating from the reticulum which are not related to tuberculosis or to lymphogranulomatosis and its atypical forms or to other known

inflammations or tumors. Diagnosis can be made only by the microscopic structure and by exclusion. These disorders of the lymph nodes are partly hyperplastic processes at the start but show transitions to malignant tumors in their later development. Temporarily they may be called reticulosarcomas or reticulo-endotheliomas if histologically agreeing with tumors. The prognosis is doubtful, they often recur after extirpation and appear rather resistant to irradiation in that recurrence is frequent after this treatment. These conditions, the author says, seem to be of considerable importance and should be distinguished as a separate group. He gives a classification and reports six cases. The first three represent hyperplasia of the reticulo-endothelium, one in a boy aged 14, with general trichophytosis and progressive enlargement of the lymph nodes, the second in a woman aged 27, with probably benign enlargement of the lymph nodes in the neck, and the third in a woman aged 31, with chronic enlargement of the lymph nodes in the neck. The last three cases represent reticulo-endotheliomas and reticulosarcomas, the first in a woman, aged 62, with progressive disease of the lymph nodes of the breast and infiltration in its papilla, with death after three years, the second in a man, aged 46, with tumor in the cervical glands, fatal after two years, and the third, in a man aged 29 with tumor in the lymph nodes of the neck and later general spreading, fatal after fifteen months.

Stenosis of Aortic Isthmus.—In Blegen's two patients a man aged 36 and a woman aged 34, there were typical signs of the lesion. The first patient, who died from hemorrhagic diathesis, showed definite signs of another congenital lesion in Gee-Herter's disease. Examinations revealed blood calcium as low as 3.4 mg per hundred cubic centimeters, whereas six months earlier it had been 7.8 mg. He says that, although hypothermia is not excluded the grave hemorrhages are ascribed to the low blood calcium. The diagnosis of aortic coarctation was verified on necropsy. No anatomic substrate for Gee-Herter's disease was found. The atrophic spleen (weight, 20 Gm) without signs of normal structure may be considered related to the intestinal disorder or an independent anomaly and the presence of abundant Jolly's bodies in the red blood corpuscles may be connected with the spleen.

Ischiopubic Osteochondritis.—Torgersen reports two cases in children aged 8 and 9 years. Roentgen examinations show a nut-sized swelling of the synchondrosis sclerotic at the border and vacuolic in the center. Ischiopubic osteochondritis is a disorder of children in the synchondrosis between the lower branch of the pubis and that of the ischium. It was singled out as an entity by Van Neck and studied more closely by Heeren and has been described only once before in the Scandinavian literature. While the disorder is relatively rare it is common enough to be considered in differential diagnosis of disturbances in the pelvis and when clinicians and roentgenologists become more familiar with it, it will be diagnosed more often. The symptoms are pain in the inguinal region on walking. The roentgenograms of ischiopubic osteochondritis and of osteomyelitis are similar but in osteomyelitis there is no sclerotic border zone. All roentgenograms in ischiopubic osteochondritis show that the two bones have begun to touch, in some cases ossification is strikingly unsymmetrical. The author thinks that the disorder may be caused by a mechanical factor. It probably predisposes to secondary infection when ossification occurs the pain ceases and the danger of secondary infection is past. The prognosis is good. Treatment may be limited to guarding the patient against overexertion and to correction of possible static defects.

Fatal Nervous Disorder After Spinal Anesthesia.—Elstad states that four weeks after appendectomy done under spinal anesthesia in a man aged 42 marked neuralgia-like pains suddenly began in the right leg partly also in the right arm, accompanied by violent headache and double vision and colic like pains with vomiting. The pain soon abated but paralysis of the right upper and lower extremity and the right facialis and abducens nerves developed increasing in two days to complete paralysis of the right side together with slight paralysis of the left lower extremity. Death was due to respiratory paralysis. The author says that while the spinal anesthesia might seem the probable cause of the paralysis, the long latent period before appearance of the symptoms is unexplained.

THE PRESENT STATUS OF RESEARCH AND TEACHING IN PHARMACOLOGY

NORMAN A. DAVID, M.D.

CINCINNATI
AND

GEORGE A. EMERSON, PH.D.

MORGANTOWN, W. VA.

The conspicuous role played by pharmacology in the development of modern medicine has established this comparative newcomer among the medical sciences as an outstanding and independent field for scientific endeavor. Through the numerous discoveries and valuable therapeutic contributions pharmacology has given medicine, this study has demonstrated its ability to work shoulder to shoulder with its older, fellow sciences and today it fulfils in a highly creditable manner its many important duties to research and medical education. Compared to past research achievements in this field, even greater gains for the future are promised by the vigorous activity and interest displayed in the pursuit of present pharmacologic investigations. In medical education also pharmacology is advancing to a recognized position as one of the major subjects of the curriculum. Scarcely a generation ago it was included as a very minor part of the course in materia medica, today it dominates the field of drug studies.

Few medical sciences provide as many excellent opportunities for significant and important future contributions to scientific medicine as does pharmacology. It is therefore desirable that certain problems inherent in the subject be examined critically and met frankly, to assure further advance of medical pharmacology and to forestall a reaction leading to subordination of the science to its former minor place in the medical curriculum. At present, pharmacology is advancing rapidly, but even now there are again evidences of drug nihilism¹ which must ultimately react against it. Thus, it is necessary to take cognizance of the present state of research and teaching of therapeutics in any discussion of pharmacology. Our purpose is to record what we believe to be the views of a number of younger men in pharmacology, bringing to attention certain serious problems that threaten the maintenance of the present high status of pharmacology.

RESEARCH IN PHARMACOLOGY

Current interest in pharmacologic investigation is keen both in research institutions and in commercial

laboratories. A general movement is under way, particularly among pharmaceutical concerns, to devote as much money and time as practicable to the scientific development of new and better medicinal agents. Recently several large and well equipped laboratories, dedicated almost entirely to pharmacologic research, have been completed. In medical schools greater opportunity for study is continually being made possible through the growth and strengthening of present departments by personnel and budget increases. The recent establishment of independent departments of pharmacology in two of the score or more schools that have continued to place this subject under the control of another department has been a definite step forward. Numerous financial gifts and substantial research grants, while small compared to the monetary benefits some of the other medical sciences receive, have materially increased the number of workers who are devoting their time and energy to pharmacology. Due credit must also be given to those pharmaceutical concerns which have furthered the cause of pharmacology through the many fellowships and liberal grants they have bestowed on our medical schools.

In line with these increased opportunities for pharmacologic research, the development of cooperative efforts in which the pharmacologist plays a dominant rôle has been a healthy symptom of the growth of modern pharmacology. Since the practical demonstrations of the worth of such cooperative efforts by Ehrlich and later by Loevenhart, there has been little question of the value of such work in facilitating advances in pharmacologic knowledge and, more importantly, in therapeutics. An outstanding example of cooperation is that now in progress in various laboratories and government institutions which have taken on themselves responsibility for dealing with the problems of morphine addiction.² Both authors received their introductory research training in less pretentious but satisfactory cooperative studies of the chemotherapy of amebiasis³ and leprosy, in which a number of commercial pharmaceutical laboratories, university departments, hospitals, leprosariums, a tropical medicine research institute and a state prison were included. Since we are convinced that the success attained even in such minor examples was far above that which could have been made by any single laboratory working independently, our plea is for expansion of combined endeavor with more laboratories deliberately entering on such a course. A particularly important advantage is the possibility of the pharmacologist so seeing the problem through to its therapeutic application, which is often difficult in independent work.

From the Departments of Pharmacology, University of West Virginia School of Medicine and the University of Cincinnati College of Medicine. Read before the Section on Pharmacology and Therapeutics at the Eighty-Seventh Annual Session of the American Medical Association, Kansas City, Mo., May 15, 1936.

3 Leake, C. D. Chemotherapy of Amebiasis. J. A. M. A. 98: 195 (Jan. 16) 1932.

A closely allied problem is that of the varying quality of pharmacologic research. Since pharmacologists are primarily individuals, it is to be expected that the individual approach to a problem will differ in each case. Too often this results in an imbalance—either intense, difficult work is expended on a very minor action of a drug, or else therapeutic application is made of a drug that has not been adequately investigated as to its major side-actions. The need for some standard pharmacologic analysis of new agents is becoming recognized generally, but opinions as to exact methods vary widely. Certainly pharmacology is in a position to formulate at least the main points of investigation of new compounds before these agents are tested on human beings.

The aims of pharmacology are sometimes misunderstood by the profession, because the more dramatic advances are concerned with the introduction of new therapeutic agents. There are no ideal drugs today, or none that could not conceivably be improved on. Past accomplishments in the improvement of therapeutics have been made chiefly through the use of new agents, but equally important is the phase of pharmacology which deals with the actions of known, older drugs and which leads to the discarding of ineffective agents while pointing the way to the rational development of new drugs.⁴ Thus, while the aim of medical pharmacology must be the determination of the action of pure chemicals with regard to their possible therapeutic application, pure pharmacology, though not dealing directly with therapeutics, is of such importance to the advance of medical pharmacology that it should not be unsupported by the medical profession and the medical schools.

TEACHING OF PHARMACOLOGY

Part of the current confusion with regard to the present status of teaching in pharmacology, evidenced by the symposium of the Association of American Medical Colleges,⁵ is due to an inability or reluctance to differentiate properly between pharmacology and therapeutics. Advance in the preclinical sciences has been general but in biochemistry and physiology has been adequately met by relatively minor teaching adjustments, while in pharmacology the medical course has necessarily been entirely revised. Whereas, in the past, a large part of a course in pharmacology was devoted to materia medica and therapeutics because of lack of knowledge of basic pharmacology, this knowledge is now more than sufficient to fill the short period in which the student is exposed to pharmacology. In many instances this has resulted in almost complete ignoring of all but the major therapeutic facts, in most cases, much less therapeutics is now taught than formerly. The important development, which has not been universally appreciated, is that pharmacology is no longer synonymous with therapeutics.

The purpose of modern pharmacology in the medical curriculum is to widen the student's knowledge of biochemistry and physiology and so prepare him for a rational approach to therapeutics. If this ideal is fully served, students will learn more sound therapeutics than if they are subjected for an equivalent period to superficial therapeutic aspects of drugs, the applications of which can never be understood completely with-

out explanation of the basic pharmacology involved. Unfortunately, the course in pharmacology comes at a time when the student "begins to feel like a doctor" and is resistant to any serious mental work which does not have immediate practical application. At the same time, the student needs "sufficient information of a pharmacologic character to enable him to employ safely, sanely and thoroughly, not many, but a few agents in the treatment of abnormal functional and structural states" (MacNider⁶) and should not be impatient with studying such material. At West Virginia, students are told, "you will be learning practical applications of drugs for the rest of your career. Now is your only formal opportunity to learn why and how drugs act." However, through lack of interest or inspiration, Dr. Hayman's⁷ statement that "the pharmacological knowledge of too many students seems confined to linking a certain disease with a particular drug, whose proper dose has been jotted down in a notebook carefully carried in his pocket" still remains generally true everywhere. His next words, "That is not pharmacology," seem to have no appeal to our future physicians.

One rational remedy for both horns of the dilemma—the lack of interest of students in pharmacology per se and the need for this information to be imparted to them as an introduction to modern therapeutics—is to provide adequate instruction in therapeutics as a separate course during the third or fourth year, rather than forcing the student to pick it up piecemeal from a dozen courses, as at present. Nor should the student be expected to have a perfect knowledge of modern therapeutics after completing what is, after all, only a transitional course from his preclinical work. As Dr. Lamson⁸ so well expresses it, "Medicine, besides being a science, is an art and the giving of medicines in the best form and amount, and at the proper intervals, can only be taught by those who are in daily contact with disease. It is therefore wrong to expect the student to appear for the first time in the wards with a perfect understanding of how to treat patients, the art of which he will learn only after years of experience. The teaching of the action of drugs in disease as well as health [is] not necessarily therapeutics."

Viewed in this light, there is ideally no more reason why therapeutics should be taught in pharmacology than in biochemistry, anatomy or physiology. Yet because of the practical limitation that few schools offer adequate courses in therapeutics at the time it could best be taught,⁷ some compromise must be made with the present conditions, which, we have seen, are definitely a holdover from past practice. That this practice was good at the time is no excuse for resisting improvement now. Each teacher must make his own compromise, but one in which one of us took part has proved valuable. This experiment, now closed, was conducted in the Pharmacological Laboratory of West Virginia University for ten years⁸ and involved the study of human reactions to drugs by the students, in addition to the classic animal experiments. The details of this method and its results cannot be suitably given here but will appear as a separate report by one of us (N. A. D.).

If pharmacology is to develop fully in its rightful place as a major preclinical subject, it is necessary that

specially trained men be put in charge of didactic work in the subject. We sincerely hope that the day when any man with simply a medical training was considered eligible to teach pharmacology is past. Certainly no man without sufficient ability or interest in the subject to become a member of the Pharmacological Society should teach pharmacology. It is only fair that the same standards be set for pharmacology as are in force for physiology and biochemistry in our medical schools, and it is necessary for further advance in the subject that such standards be strictly adhered to. Equally rigorous standards must be set to assure the competence of men teaching therapeutics, and it is apparent that it would take an unusually gifted person to be able to teach both adequately.

The chief reason for the present necessity of a thorough course in basic pharmacology before the student is properly qualified for therapeutics is, of course, the great change in the nature of therapeutic practice brought about by the constant introduction of valuable, dangerous or sometimes worthless new therapeutic agents. In order that the student may be fit to judge their actions and worth, it is now necessary to emphasize the chemical aspects of pharmacology a bit more than has been customary with the older pharmacologists. In this regard, the splendid work of the Council on Pharmacy and Chemistry has served admirably to prevent a deplorable condition. But just as proper pharmacologic training should fit the student to make his own therapeutic prejudices independently of the therapeutic prejudices of his authorities, so it should fit him to make, at least grossly, conclusions similar to those of the Council in regard to the background of newly introduced therapeutic agents.

Overemphasis of chemical aspects of pharmacology is as reprehensible as Dr MacNider⁵ has shown it to be. A method that nicely avoids this, almost by definition, is to limit chemical discussion to the relation between the physiologic action and the chemical constitution of the drug, touching only on well substantiated examples of the application of the various laws involved. Such "biochemorphology" has shown itself to be a powerful weapon both in research and in teaching, although its full value cannot be appreciated until more data are available on many important points of biochemorphic relationships.⁶ Its function at present, in didactic work, is to show the student by dramatic examples that pharmacology is the study neither of chemical properties of drugs nor of purely physiologic actions, but the interrelation of the two. It permits an assimilation by the student of an orderly series of facts and aids in placing pharmacology as a discipline on a scientific par with physiology and biochemistry.

Finally, the laboratory course in pharmacology has been criticized constructively by authors of papers in the symposium mentioned.⁶ It is necessary that cognizance be taken of the criticisms of students as well. It is our belief that the laboratory course should serve only to supplement lecture material. In it the student learns methods of pharmacologic research without attempting to verify all pharmacologic knowledge or establish new facts. A major part of the experimental work, particularly of the more tedious and difficult setups, may well be shown by demonstrations. All experiments should be as simple and illustrative as possible, and the occurrence of unusual reactions thor-

oughly explained, as Dr MacNider⁵ points out. Emphasis must be placed on drugs useful in therapy or on closely allied drugs which illustrate certain phases of their action, rather than on beautiful, tenuous explanations of complex physiologic reactions which have no interest for medicine and may never have. Physiology is best taught in the physiologic laboratory, and the pharmacologist does not begrudge the physiologic use of drugs as molecular dissecting knives to illustrate physiologic principles—in physiology. Unless such drugs have important therapeutic applications, they have little place in the pharmacologic teaching laboratory. Just as chemical aspects of pharmacology should never be overemphasized, so only the pertinent physiologic information should be given in the student laboratory.

CONCLUSION

The encouraging results following the detailed analysis of the ailments of pharmacology at the last annual meeting of the Association of American Medical Colleges give hope that pharmacologists at least are awake to the present status of their specialty. For complete success, the medical profession as a whole can aid by being aware of the potential dangers in the rapid advance of modern pharmacology, particularly in its reaction on methods of teaching. It is our hope that the new generation of pharmacologists will live up to the present responsibilities of advancing the science as well as those before us have done and are doing.

ABSTRACT OF DISCUSSION

DR. H. B. HAAG, Richmond, Va. Pharmacology should be in a key position in the medical curriculum, apparently, however, some medical executives are not cognizant of this enviable position of pharmacology and have relegated the teaching of pharmacology to physiologists, biochemists and even sometimes pharmacists. This negative attitude does much to discourage young men from entering pharmacology. It does much to make good men leave pharmacology. In view of the position of pharmacology in the medical curriculum, it is unfortunate that pharmacologists have apparently so little interest in clinical medicine. This is certainly exemplified here this morning and in the meetings in general, there being scarcely more than a half dozen pharmacologists attending this annual meeting of the American Medical Association. Whereas a primary function of pharmacology is to deal with fundamentals, I do think there is a lack of clinical application which might well be considered. A student studies the action of drugs on normal tissue, on normal animals, on normal individuals, as the authors have pointed out. It seems to me that these studies might well be extended to the third and fourth years, either as applied pharmacology or as therapeutics, either under the department of pharmacology or under the department of medicine. Here it could be extended to a study of the effect of drugs on the sick. This is an excellent place for the practical teaching of prescription writing, for in my experience it is quite hopeless to teach it purely didactically. I think that endocrines should be considered more extensively. We should consider the vitamin preparations, how they are given, how they are available, and their method of assay. The significance of bio-assays in general and their clinical application should be considered. The course on anesthesia should be extended by a cooperative arrangement with the department of surgery or the department of anesthesia. By a cooperative effort with clinical men the use of the old apothecary system could at once be done away with and the more scientific metric system substituted for it immediately. We have drifted too far away from *materia medica* and incompatibilities. Ignorance of these two makes the students when they graduate easy prey for the detail man.

DR. CHARLES W. GREENE, Columbia, Mo. There were no pharmacologic teaching laboratories as late as 1900 offering required courses as a part of the medical curriculum. We

⁵ Knoefel, P. K., Lonergan, Lester and Leake, C. D. *Biochem. Aspects of Paraldehyde and Certain Acetals*. Proc. Soc. Exper. Biol. & Med. 28: 730 (March) 1932.

were then in the active throes of expanding medical instruction into a four year curriculum, with ever increasing premedical training requirements. Physiologic, biochemical and ultimately pharmacologic laboratories were then in the process of organization and development as required experience in the preparation for medicine. In 1900 I established at the University of Missouri the first teaching pharmacologic laboratory. It is true, as the authors state, that in this first decade of the present century courses in therapeutics and in materia medica along the old-time lines of didactic development were in the field. The establishment of pharmacologic laboratories in a way had to compete with and, in a degree, displace time allotted to these courses. In the University of Missouri laboratory of pharmacology the basic concept was that pharmacology to be of value to clinical medicine must be founded on the modifications of physiologic action induced by drugs. The emphasis in a teaching laboratory must be placed on this principle. It presupposes a thorough knowledge of physiologic actions as such and normals of such minute and effective detail that the modifications induced by drugs can be quickly identified, classified and stored for use in clinical application. During this first decade of the development and organization of teaching courses in pharmacology, progress was handicapped by an inadequate supply of trained pharmacologists. That deficit has been long since met and we have now the benefit of such leaders as Hunt, Sollmann, Loevenhart, McNider and Leake. As for research in pharmacology, it is only the natural unfolding of the science that has carried forward in the second and third decades from its elementary and organized teaching basis into the field of advanced problems and constructive research. This has been the second cycle of growth and development. In the first decade, the organization and foundation for normal teaching, in the second decade, development of constructive research and the advancement of research problems, and now, at the present, wide distribution of well organized laboratory courses required in every medical school, with staffs specially trained and doing constructive investigational work of the type and quality that have so rapidly expanded the pharmacologic field. I am old enough to have seen the successive steps and therefore to emphasize the fact that in the past thirty-six years there have been sweeping epochs of development of teaching, of research, of application of the principal of research to practical therapeutics.

DR CARL A. DRAGSTEDT, Chicago. This timely paper calls attention to problems confronting the men attempting to teach what I think is one of the most difficult subjects in the curriculum to teach interestingly, adequately and well. With regard to the scope of the course, I do not like to feel that we should be constrained in teaching pharmacology to the practical matter of only the drugs that are used in practice and thus make our course a part of a trade school. I conceive of the department of pharmacology as a department in a university, that it should have university status and should aim to teach the subject with the same degree of perfection with which all the other sciences in a university are taught.

DR GEORGE E. WAKERLIN, Louisville, Ky. The question of bringing in a certain amount of applied pharmacology is important. The course in pharmacology in my estimation ought to bridge the gap between pure pharmacodynamics and therapeutics. Some of the courses in the various schools at present might be improved in this respect. One's attitude on the question of bridging the gap between pure pharmacodynamics and therapeutics depends to a certain extent on the training one has had. I think there will in the future be more agreement as to just exactly how this ought to be done in view of the fact that the training of pharmacologists is becoming more uniform. The same question arises in the teaching of physiology. For example, I have had students ask frequently if the department of physiology at the University of Louisville would not give a course in applied physiology, clinical physiology or pathologic physiology. In other words, the students will say 'We learned about the physiology of respiration, we know the normal mechanisms of respiration but we don't know what the mechanisms involved in paroxysmal dyspnea are when we reach the clinical years'. I am of the opinion that in physiology also an attempt should be made to bridge the gap between academic physiology and clinical physiology more effectively

than is being done. I grant that some of this gap is still unknown territory, but there exists a good deal of information, some of which ought to be given to students in physiology and pharmacology.

DR. DAVID R. CLIMENKO, Cold Spring Harbor, N. Y. I should like to make a direct suggestion for counteracting one of the faults the authors found that is, the lack of interest that is usually shown by students in pharmacology. I think this can be overcome in a simple manner: there is no necessity for multiplying the number of drugs the student must consider. The careful study of a few well selected drugs, with the demonstration of the pharmacologic and therapeutic principles they illustrate, would more than make up for the lackadaisical instruction in the effects of a much larger number of drugs. This elimination of a large mass of purely factual knowledge would in itself tend to make a course in pharmacology far more interesting to the student. This increase in interest may be augmented by the introduction of clinical material. I do not mean the presentation of a patient with auricular fibrillation to students in pharmacology but rather the demonstration of clinical charts and records illustrating therapeutic effects. I have always noticed that one of the subjects that students pay most attention to and seem to be most interested in is the cardiac glucosides, and I think this is largely due to the fact that the teaching of this subject is largely dependent on the demonstration of clinical material.

DR. CHAUNCEY D. LEAKE, San Francisco. If the chairman might be permitted a remark, it is to emphasize again the distinction between the scientific aspects and the artistic aspects of medicine. In pharmacology, the actions of drugs may be demonstrated in a factual manner. That is the science of it. The application of this factual information to the problems of diagnosis or of the prevention of disease or the cure or the treatment of disease by means of chemical agents is a matter calling for artistic judgment, which depends on the individual problem presented by the patients, the knowledge that the clinician has and the judgment or skill he uses in making the application. That judgment can be trained only by long experience. But the scientist in teaching the action of drugs can point the way by which applications may be made.

DR. GEORGE A. EMERSON, Morgantown, W. Va. I am grateful for the discussion and constructive criticism that has been offered here. I was particularly struck by the recommendation of Dr. Haag that pharmacologists be aware of the newer developments in therapy and in other sciences and show this by the introduction of more material on endocrines, for example. At West Virginia we have attempted to do this in a smaller way with the subject of anesthesia and have introduced a comprehensive course in elementary anesthesia into the pharmacology course. I appreciated Dr. Greene's remarks as to the history of pharmacology. I hope that the younger men in pharmacology will continue to build up the science as thoroughly as the older men have done. Dr. Dragstedt's recommendation that pharmacology should have the same status as any other university department should have the full support of all university administrators. One point that I did wish to bring out was that the change in the pharmacology course is necessary because of the change in the nature of therapeutics in recent years. The tremendous advance in the chemistry of drugs, the large volume of new, valuable, inactive or dangerous drugs that are constantly coming out, makes it necessary that the student be fit to judge drugs for himself. The pharmacology course should fit the student to make his own therapeutic prejudices independently of the therapeutic prejudices of his instructors or of the detail men later on. In the matter of therapeutics and pharmacology, perhaps I have been contaminated in my early training. Both Dr. David and I have been told at California that pharmacology is concerned with the action of drugs. Drugs have four applications in medicine: prevention, diagnosis, alleviation of symptoms and cure of disease. Half of the use of drugs in medicine is not strictly therapeutic use. We are concerned with diagnosis of disease or the prevention of disease as well as the cure or the alleviation of symptoms. Dr. Climenko's recommendation that fewer drugs be taught is well taken. If the course is restricted to drugs that really work, we have few enough drugs to work with.

FRACTURE OF THE NECK OF THE
FEMUR IN CHILDREN

JOSEPH I. MITCHELL, M.D.

MEMPHIS, TENN.

The problems encountered in treating a small group of young patients with fracture of the neck of the femur have demonstrated specific hazards in the management of this fracture which affect the prognosis and the ultimate functional result. Bony union takes place promptly, as is true of most fractures in childhood, there being slight danger of nonunion and disaster so greatly feared when this fracture occurs in the aged. The unfavorable prognosis that is associated with fracture of the neck of the femur in childhood arises from the frequent occurrence of malunion in the *coxa vara* position. This deformity tends to increase with weight bearing and may lead to extreme disability.

The reasons for the occurrence of union of the fracture in malposition may be structure of the bone at the site of fracture, muscular contraction or early weight bearing. The difference in osseous structure in youth and old age influences the character and site of the fracture, in children the fracture line generally crosses the base of the femoral neck, and separation of the fragments may be incomplete. Muscle pull in children is weaker than in adults, consequently reduction should be accomplished with ease and with most fractures displacement of the fragments after reduction should be less imminent. That these observations are not always constant is proved by the too frequent occurrence of poor functional end results following fracture of the neck of the femur in children. Furthermore, after most fractures in childhood, moderate deformity and displacement of the fragments may be overcome by the natural tendency for growth and repair of young tissues. This physiologic maxim does not hold true in fractures of the neck of the femur in childhood which have united with *coxa vara* deformity, under influence of weight bearing the shortening and impairment of function may increase, owing to a further descent of the depressed neck of the femur, until the head of the bone rests on the lesser trochanter.

HISTORICAL REVIEW

As is well known, fractures in and about the hip joint are common in the aged and relatively infrequent in childhood. Among the early records of the lesion is a report by Sir John Bland Sutton¹ of a pathologic specimen of an intracapsular fracture of the neck of the femur from an individual of about 15 years. This specimen was found in the museum of the Middlesex Hospital in 1883. In 1885 Cromwell² reported the fracture in a young subject. Whitman³ in 1890 reported a case and in subsequent articles, the last of

which appeared in 1909 added additional reports, making a total of thirty-one cases reported by him. Even in the early cases he differentiated between fracture of the neck of the femur in children and slipped femoral epiphysis, although the diagnosis was not confirmed by roentgenogram until 1897. Russell,⁴ Telford,⁵ Taylor,⁶ Colonna⁷ and others have emphasized the probability of latent symptoms following fracture of the neck of the femur in adolescents. In modern textbooks on orthopedic and traumatic surgery, however, this injury is generally dismissed with the brief statement that, although no age is exempt, fractures of the upper extremity of the femur occur more frequently in those past middle age. The method of treatment usually employed in the past for all age groups has been immobilization of the hip in abduction. Few surgeons have recognized that a technic which affords a high percentage of excellent end results in elderly patients may not be the method best adapted for the treatment of younger patients. The single modification of technic found in the literature is the recommendation by Bohler⁸ that "the condition is best treated by continuous traction for three months."

CLASSIFICATION

From careful inspection of a number of roentgenograms illustrating injuries of the femoral neck in childhood it can be demonstrated that the lesion may be divided anatomically into three types: (1) epiphyseal separation, (2) transcervical fracture and (3) cervicotrochanteric fracture. Traumatic separation of the upper femoral

Fig. 1 (case 1)—Traumatic separation of the upper femoral epiphysis

epiphysis is extremely rare, while the variety in which the fracture line is situated at the junction of the femoral neck with the trochanters the fracture classified by Delbet as the cervicotrochanteric type, is the most common. The fracture may be incomplete or the fragments may be impacted by the violence of the force.

In seven cases of this series the fracture occurred in the cervicotrochanteric area, two cases were transcervical and one was an epiphyseal separation. Of twelve cases reported by Colonna, eleven were cervicotrochanteric and one was transcervical. In adults, on the contrary, fracture of the neck of the femur is most commonly of the transcervical or subcapital variety.

FRACTURE OF FEMUR—MITCHELL

TYPE 1 EPIPHYSEAL SEPARATION

CASE 1—B O, a white boy, aged 10 years, who had been well previously, fell down a flight of stairs and struck his hip against a door. In spite of immediate pain in the hip and thigh he was able to walk three blocks to his home. He was put to bed and remained there for one week. A roentgenogram of the hip was said to be negative and his attending physician allowed the boy to walk with crutches. The pain gradually subsided, but shortening of the limb developed and movement of the joint was limited. On examination the leg was found to be one-half inch shorter than the right and fixed in external rotation and adduction.

Fig. 2 (case 1)—Five months after reduction by closed manipulation

TYPE 2 TRANS-CERVICAL FRACTURES

CASE 2—R A, a white girl, aged 13 years, brought to the clinic July 31, 1930, had fallen from a swing one week previously a distance of 15 feet injuring the left hip. On examination there was tenderness about the hip most marked over the greater trochanter.

Under gas anesthesia the limb was manipulated, full abduction and internal rotation being secured, a roentgenogram at that time showed excellent reduction of the fragments. The limb was immobilized in a double spica plaster-of-paris cast, which was removed September 25 and an abduction hip brace applied. The fracture appeared to be firmly united at that time, with a slight coxa vara deformity. Weight bearing was not permitted for three months. In spite of treatment, the coxa vara deformity progressed and the apparent shortening of the limb increased until the left leg was apparently $1\frac{1}{2}$ inches shorter than the right. In May 1931 a wedge shaped osteotomy of the coxa was performed, this did not however fully correct the deformity. In December 1934 the patient again returned to the hospital because of adduction deformity of the hip that seriously interfered with walking. There was actual shortening of one half inch and apparent shortening of 2 inches. Operative correction was once more advised and carried out Dec. 11, 1934. On this occasion an oblique osteotomy of the femur was done beginning at the greater trochanter and extending downward and inward for a distance of about 3 inches on the shaft of the femur. The lesser trochanter of the femur was detached in order to release the pull of the iliopsoas muscle. A wire was inserted above the union of the osteotomy was firm. Three months later union of the osteotomy was firm. The deformity has been relieved and the patient walks without a perceptible limp.

CASE 3—E S, a white boy aged 14 years examined July 5, 1930 had sustained a fracture of the neck of the right femur

fifteen months previously, when the automobile in which he was riding was struck by a railroad train. The fracture had been reduced and immobilized in plaster casts, but union had not occurred. The roentgenogram showed a fracture of the neck of the femur with nonunion. Operation was advised and the patient was returned for treatment in June 1931. A bone graft to the neck of the femur resulted in solid union. Motion in the hip is, however, greatly limited, and it is necessary for the boy to wear an elevation of 2 inches on the sole of the shoe.

TYPE 3 CERVICOTROCHANTERIC FRACTURES

CASE 4—S A, a white girl, aged 6 years, admitted to the hospital Oct. 26, 1931, had fallen from a porch, a distance of about 4 feet, two weeks before admission, and had been unable to bear weight on the right leg. The roentgenogram demonstrated the fracture at the cervicotrochanteric region of the femur, with considerable angulation of the fragments. The fracture was reduced by the Whitman method, and following immobilization in a plaster cast for three months union was solid. The result is classified perfect function, since the mother reports by letter that the child does not limp.

CASE 5—J T, a white boy aged 16 years, brought to the clinic July 12, 1934, complained of an old fracture of the right hip which he received nine months before when he fell from a tree. The fracture had been recognized, immediately reduced and immobilized in a plaster cast for ten weeks. Union had occurred with adduction deformity and with $1\frac{1}{2}$ inches shortening of the extremity. The roentgenogram showed a fracture of the neck of the femur with absorption of the neck and coxa vara. Operative correction consisted of an oblique osteotomy of the femur along the intertrochanteric line, detachment of the lesser trochanter so that it could be reattached higher up after traction, and insertion of a wire through the lower end of the femur for skeletal traction. Fixed internal rotation of the thigh necessitated a second operation of supracondylar osteotomy for derotation of the lower leg. One year later the patient was walking with a slight limp, there was 1 inch shortening but greatly improved function of the limb.

CASE 6—J E. M.

a white boy, aged 8 years, brought to the hospital Aug. 21, 1935, had fallen 10 feet from a stack of barrel heads eleven months before while at play, sustaining a fracture of the neck of the left femur. After reduction of the fracture, a cast was worn for six weeks. The child was then allowed to walk. A deformity at the hip developed with 1 inch shortening of the leg causing the boy to limp. The roentgenogram demonstrated the typical cervicotrochanteric fracture of the neck of the femur which had united in malposition. Operative correction consisting of oblique osteotomy and skeletal traction similar to that employed in cases 2 and 5 was carried out. The shortening of the limb was reduced to one fourth inch and although the child is still wearing a brace function has been greatly improved.

Fig. 3 (case 2)—Trans-cervical fracture of the neck of the femur

CASE 7—M D B, a white boy aged 6 years, was admitted to the hospital Nov. 9, 1935 for a fracture of the right femur. The injury had been sustained four days before when the patient fell under and was struck on the hip by a seesaw on which several other children were sitting. The roentgenogram revealed a cervicotrochanteric fracture of the right femur. There was displacement and angulation of the fragments.

Under ether anesthesia the fracture was manipulated and reduced. Roentgenograms in both planes showed excellent position. A double spica cast was applied with the Hoke-Martin apparatus incorporated for continuous traction on the leg. The cast was worn for ten weeks and walking in an abduction brace was permitted at the end of three months. Firm union of the fracture occurred in the anatomic position.

Fig. 4 (case 2)—Immediately following reduction by closed manipulation

injury the right hip, and had been unable to walk after the accident. The roentgenogram showed a cervicotrochanteric fracture of the right femur, with absorption of bone along the fracture line. A plaster cast was applied without manipulation of the fracture. The boy has moved from the city and has not been reexamined but the parents report by letter that he has an excellent functional limb without a limp.

CASE 10—R L M., a Negro girl aged 11 years, seen Jan 27, 1936, had fallen down a flight of stairs five months previously, receiving a fracture of the left femur at the hip, a fracture of the pelvis and a fracture of the left radius and ulna. The original roentgenograms were obtained, which showed a cervicotrochanteric fracture of the femur and excellent postoperative position immediately following reduction. The limb had been immobilized in a cast for five months. Union of the fracture had occurred in a position of coxa vara with 1 inch shortening. Surgical correction of the deformity has been advised but was refused by the parents.

Fig. 5 (case 2)—Eight months after reduction showing bony union with coxa vara

Of ten patients with traumatic lesions of the neck of the femur, four were girls and six were boys. Their ages when the accident occurred, varied from 4 to 15 years. Three of the patients were seen within a few

days following the accident and seven were seen late. In three patients examined late, bony union had occurred with coxa vara deformity, and in one there was nonunion of the fracture. Two Negro patients cannot be traced, and in these cases the end results are not known other than that bony union was occurring when the patients were discharged from the hospital. In seven of the cases the site of the fracture was at the cervicotrochanteric junction, in two the fracture was transcervical, and one was an epiphyseal separation.

The cause of the fracture in each case was trauma of much greater violence than is associated with fracture of the neck of the femur in adults. This fact is forcibly demonstrated in the case histories. One patient fell from a swing a distance of 15 feet, one was injured when the automobile in which he was riding was struck by a railroad train, one fell from a high porch, two patients were injured by falling from trees, one fell from a stack of barrel headings, one fell under and was struck by a seesaw on which several other children were sitting, two fell down steps and one fell from a second story window. The violence of the injury is further demonstrated by the association of other traumatic lesions with the fractured femur. Two patients received in addition a fracture of the pelvis, one of these also had a fracture of the radius and ulna, and one had a fracture of the tibia and fibula. Bony union occurred promptly in nine instances. However, solid union in the anatomic position, which is necessary for a good functional result is known to have occurred in only three of the cases. Four fractures united in malposition there was one nonunion, one patient cannot be traced, and one is wearing a brace.

Fig. 6 (case 2)—Five years after fracture occurred. Coxa vara has been corrected by osteotomy

The diagnosis of fracture must always be excluded following injury to the hip. The positive physical signs are shortening of the limb of from one-fourth to three-fourths inch, prominence of the greater trochanter, which is elevated above Nelaton's line, and adduction and external rotation of the leg. A roentgenogram should be made in every case of suspected fracture. In children the fracture line is usually, as previously stated, at the cervicotrochanteric junction. Errors in diagnosis are due largely to failure to examine the small patient carefully. In untreated cases differentiation must be made between fracture and disturbance of growth in the upper femoral epiphysis.

TREATMENT OF RECENT FRACTURES

Two of the three recent fractures in this series, cases 2 and 4, were reduced and immobilized in the Whitman position. In case 4, a girl aged 6 years, a good result was secured. In case 2, a girl aged 13,

FRACTURE OF FEMUR—MITCHELL

1606

years, the Whitman method failed to give a satisfactory result and two subsequent operations were necessary to correct coxa vara deformity. In case 7, a boy, aged 6 years, a perfect anatomic and functional result was obtained by continuous well leg traction, the Hoke-Martin apparatus being incorporated in a plaster cast. Therefore, since angulation of fragments causing coxa vara is so imminent and results in such serious disability, it is recommended that all recent fractures of the neck of the femur in children be treated by continuous traction for eight weeks and that the limb be protected from full weight bearing for three months even after the patient is allowed to be ambulatory.

but of fractures of the neck of the femur per se. These have been the incomplete and the complete fractures, the incomplete or the hinge type that Dr. Henry Ling Taylor described years ago being the more frequent. Fortunately, one can hear a discussion of fractures of the neck of the femur without feeling that one is going to be worried about nonunion. Union is the usual result in children, but union, unfortunately, in poor position many times. Many of these patients walk into the clinic or into the office presenting very little local symptoms of pain. In some instances the pain has been directly referred to the knee joint and no attention has been paid to the hip. I think that the mildness of the symptoms in the incomplete type is very striking. I have been accustomed to immobilizing these patients for at least three months and I think that a longer period in plaster is sometimes advisable as well as protection with a brace following the removal of the plaster.

DR. S. L. HAAS, San Francisco. There are two points I wish to bring out. One is the occurrence of nonunion in children; the other is the necessity of differentiating congenital coxa vara from fracture of the neck of the femur. A girl at the age of 10 years fell from a height and fractured her femur. Successful reduction was obtained by a physician in a small town in California. Subsequent to the reduction the fragments displaced. Three years later the patient was seen at Shriners Hospital. There was no complaint of pain but there was a limp, a short leg and limitation of motion at the hip joint. The roentgenogram at this time showed nonunion of the fracture at the neck of the femur. Walking was possible as the stump of the neck impinged on the border of the acetabulum. At the first operation the fibrous tissue was excised at the site of union and a small graft from the intertrochanteric region placed across the line of fracture. Osseous union occurred promptly.

TREATMENT OF MALUNITED FRACTURES

In four of the patients the fracture united in malposition causing coxa vara deformity, shortening of the extremity and a

Fig. 7 (case 7) — Cervicotrochanteric fracture of the neck of the femur

limp with serious disability. The coxa vara deformity has been corrected and the femur lengthened in three of these patients (2, 5 and 6) by an oblique osteotomy of the femur followed by skeletal traction. The operation has been advised also in case 10, but the child's parents have not given their consent. In a boy aged 14 (case 3) there was nonunion of the fracture requiring a bone graft to the neck of the femur.

CONCLUSIONS

Fracture of the neck of the femur may occur in childhood and is probably not an uncommon accident, although it may be unrecognized until a later period. The lesion may be one of three types: (1) epiphyseal separation, (2) transcervical fracture and (3) cervicotrochanteric fracture. The site of the fracture is usually at the cervicotrochanteric junction.

Bony union occurs promptly as a rule, but often with coxa vara deformity, which causes subsequent disability of a serious nature.

Treatment by continuous traction combined with immobilization of the hip in abduction is advised to prevent coxa vara and shortening of the extremity.

After union in malposition great improvement in position and function may be secured by an oblique osteotomy of the femur, followed by skeletal traction.

869 Madison Avenue

ABSTRACT OF DISCUSSION

DR. PAUL C. COLONNA, New York. Fractures of the neck of the femur in children occur far more frequently than is ordinarily thought. In the last ten years I have had eighteen. They followed the same general rule with regard to the history and to violence as a causative agent that Dr. Mitchell has pointed out. My patients ranged in age from 3½ to 15 years. The fractures have been in the main of two types, I am speaking not of the epiphyseal slippings or epiphyseal fractures

of the hip joint had a definite defect across the neck of the femur which was a congenital or developmental change. In this patient the films showed a similar condition on the opposite side. Careful study showed a small triangular area on the lower side of the neck which placed it in the type of coxa vara juvenilis. In unilateral cases this condition may be mistaken for a fracture. In this patient the area of maldevelopment of bone was exposed. The cartilaginous and osteoid tissue were excised and a graft was inserted across the defect. The coxa vara was corrected by a diagonal intertrochanteric osteotomy.

DR. RALPH G. CAROTHERS, Cincinnati. There is one point which has not been brought out but which I have had called to my attention a number of times and that is a history of two accidents. A boy fell out of a swing and bruised his hip and a few days later he fell downstairs and broke his hip. That story has come too often to be disregarded. I believe these patients get a greenstick fracture and then get another one on top of it. One never sees a picture of the first accident but in the majority of cases I have seen there have been two

LATE INFECTION FOLLOWING THE USE OF PINS AND WIRES IN BONES

S L HAAS, MD

SAN FRANCISCO

Pins and wire are being used today with increasing frequency in bone surgery, and the practice has been held by many to be free from dangerous sequelae. Various ingenious types of apparatus have been

Fig 1 (case) —Thickening and eburnation of cortex two years after lengthening operation. Rarified area found filled with granulation tissue. Small area containing polymorphonuclear and dead bone found on microscopic examination

designed that require the utilization of pins or wire to obtain fixation and correction of alignment of fractures and for bone lengthening. Although I accept the use of pin or wire extension as an excellent means of obtaining reduction of certain types of fractures, I maintain that it is often used in the treatment of many fractures which could be easily handled by other efficient methods not demanding skeletal traction.

In spite of every aseptic precaution there is always the possibility of an infection when a metal pin or wire is inserted into a bone. There are no definite statistics but there has been a considerable number of disastrous results following the use of wire or pins for traction. Extensive infections of the soft parts, persisting sinuses and osteomyelitis with sequestrums occur, at times necessitating extensive surgery and even amputations.

The indiscriminate and careless use of this method will increase the number of untoward results. Well can one remember the bad results following the promiscuous insertion of the Lane plate so that today metal plates are being used in relatively few clinics, and then with special indications. It behooves the surgeon to be careful in his selection of cases for wire and pin traction so that this method also will not come into disrepute.

Even though the pins or wires are inserted under strict aseptic technic, the tract is potentially an infected one. Wires and pins have an external opening which in itself acts as a drain and gives some protection. On the other hand the external opening serves as a portal of entry for bacteria. Fortunately, after the insertion of the wire or pin a defense barrier of granu-

lated tissue is formed along the course of the wire and serves to inhibit infection. The prevention of motion is important in order not to injure this barrier and open up new avenues for the invasion of bacteria. For the same reason the pins or wires should be removed with aseptic technic and with the minimum amount of trauma.

After removal of the pin one finds a narrow, deep sinus part in bone and part in soft tissue. The soft parts heal faster than the bone, so that there is formed a sealed off firm, noncollapsing tube in the bone. With the hemorrhage produced on removal of the foreign body and the sealing off due to the more rapid healing from outside, one has the ideal set up for the incubation of latent bacteria. Fortunately this does not take place very often, and healing proceeds in an orderly manner. In a certain number of cases there is a slow healing of the wound, and a sinus may persist for a considerable length of time. Occasionally small sequestrums may discharge or one may be called on to curette the wound and remove these sequestrums.

Having escaped any trouble immediately after the removal of the pin, one is not sure that there may not remain within the bone some dormant infection that may light up at a subsequent date, even after many months. This is not merely a theoretical possibility but does actually occur, as is shown in the following experiences in lengthening operations of the leg (tibia and fibula). There were three cases of latent osteomyelitis in a series of seventy operations. Following the healing of the wounds and when it was thought that everything was normal there were mild symptoms

Fig 2 (case 1) —Section of tissue removed at operation. The marrow has been replaced by fibrous tissue containing mononuclears. At one place there is a piece of dead bone surrounded by polymorphonuclear cells.

of pain followed by local signs of swelling and tenderness demanding operative intervention.

REPORT OF CASES

CASE 1—G O, a boy aged 11 years, had had infantile paralysis at the age of 2 years. July 16, 1930, the tibia and fibula were lengthened in a routine manner. A single metal pin was used in each fragment. September 17, sixty-three days after insertion the pins were removed from the leg. The healing was complete about two weeks later.

April 9, 1931, seven months later, there was swelling at the upper pinhole. The roentgenogram showed what appeared to be a small sequestrum. The swelling subsided and there was no further pain.

July 21, 1932, about twenty-two months after healing of the pinholes, he began to have severe pain in the leg at night. Examination showed a little increase in the size of the tibia but no pain on pressure.

September 22 he again began to have pain at night in the upper part of the tibia. Examination showed slight swelling and tenderness. Roentgenograms showed a heavy increase in density and thickness of the cortex of the upper end of the tibia. There were two areas of bone destruction within this region. The patient was then practically free from pain for about six months, when the leg once more became painful. There was some swelling but no redness, and slight tenderness on pressure.

March 26, 1933, two and one-half years after the lengthening operation, the patient was admitted to the hospital because of persistence of pain in spite of rest and protection. Examination showed an enlargement of the upper end of the tibia. There was no tenderness at this time and no fever. Roentgenograms showed what appeared to be two small sequestrums in an oval cavity 10 cm. from the knee joint (fig. 1).

April 3 an incision was made over the upper end of the tibia. The periosteum was found thickened with a considerable osseous reaction beneath it. The cortex was eburnated and thickened. After the cortex had been cut through, a cavity was found about 2.5 cm. in length. It was filled with granulation tissue, which was completely removed down to healthy bone. The overhanging edges were smoothed off, after which the cavity was washed out with ether. The skin was folded into the wound and a petrolatum pack was inserted. Plaster was applied. The patient made a good recovery with little reaction about or discharge from the wound.

Pathologic examination showed at one place dead bone surrounded by polymorphonuclear cells. The normal marrow

Fig. 3 (case 1)—High power magnification of area marked 2 in figure 2 showing dead bone surrounded by polymorphonuclear cells.

elements were replaced by fibrous tissue with a collection of lymphocytes, some of the plasma cell type. In places there was evidence of bone being regenerated (figs. 2 and 3).

Twenty-two months after removal of the pins patient 1 began to have pain in the leg which subsided gradually and remained quiescent for six months. Recurrence of pain demanded operation two and one-half years after removal of the pins.

CASE 2.—T. W., a boy aged 13 years, had a short left leg following infantile paralysis. Stabilization of the foot and

transplantation of the biceps into the patella had been performed on the left side.

Operation, March 11, 1931, consisted of routine lengthening of the tibia and fibula and the achilles tendon. Two pins were placed in the upper fragment and one in the lower fragment. By April 11, full degree of lengthening was obtained. May 11 two months after insertion, the pins were removed.

Feb. 11, 1933, about two years after the lengthening operation, the patient stated that he bumped his leg three days previously, after which it became sore and swollen. There was

Fig. 4 (case 2)—Enlargement and increased density of the bone with rarefied area toward the medulla, two years after lengthening operation. At operation a cavity was found in the bone filled with granulation tissue.

a slight discharge near the upper pinhole. Swelling had subsided some and there was no pain when he was examined in the clinic.

March 23 the patient was admitted to the hospital because of returned swelling and discharge from the upper end of the tibia. Examination showed a fluctuating area $1\frac{1}{4}$ inches in diameter over the upper inner side of the left tibia and a small granulating sinus tract on the outer side. There was tenderness on pressure over the bone in this region. The temperature was within normal range. The roentgenogram showed marked thickening and increased density of the upper end of the tibia. There was a small rarefied area present toward the center (fig. 4).

March 24 the fluctuating mass was opened from which place a sinus led down to the cancellous bone. There was a considerable amount of granulation tissue present, which was cleaned out. No sequestrums were found. The cavity was washed out with ether and packed with petrolatum gauze. Plaster was applied from the toes to the thigh. He had an uneventful postoperative course. Healing was not complete until September.

On pathologic examination there was some bone the nuclei of which were poorly stained. Some of the apparently dead or degenerated bone was surrounded by new bone. The marrow was replaced by fibrous tissue containing in places collections of mononuclear cells (plasma cells).

In case 2, two years after the lengthening operation it was necessary to drain an infected area in the upper end of the tibia.

CASE 3.—P. G., a boy, aged $10\frac{1}{2}$ years at the age of 9 months had had anterior poliomyelitis resulting in paralysis of the right arm and leg. At the time of admission he had 2 inches (5 cm.) of shortening.

Aug. 4, 1933 the right tibia and fibula were lengthened. Four bicycle spokes were used—two in the upper and two in the lower fragment. September 12 lengthening was completed. There was considerable reaction about the lower of the two upper pins. The highest temperature after operation was 38°C (100.4°F) and was normal after three weeks. The pins were removed sixty-five days after their insertion.

November 30 all areas were completely healed and the patient was sent home.

Sept 5, 1935, two years after the lengthening operation, the patient returned, stating that he had recently bumped his right leg. Following this the bone became enlarged and was slightly painful. Examination showed enlargement of the upper end of the right tibia just below the site of the former pinholes. It was slightly tender to deep pressure. The roentgenogram showed an area of rarefaction in the upper end of the tibia. The bone was enlarged in this region and was very dense (fig 5).

September 11 an incision was made in the upper portion of the leg, on the medial side. Dissection was carried down to the tibia, where a sinus tract presented through the periosteum. The tract was traced down and through the cortex to a cavity in the region of the medulla which was filled with granulation tissue and a puslike material. The cavity was cleaned out, after which the edges of the cortex were tapered off. The skin and subcutaneous fat were folded in and sutured in place without drainage. A plaster was applied from the toes to the groin. Culture on plain agar gave no growth. The wound was completely healed, October 12.

The patient was last seen April 9, 1936, seven months after operation, at which time he stated that he had had no subsequent trouble. The leg looked normal and x-ray examination showed no evidence of disease of the bone.

Two years after apparent healing following a lengthening operation, patient 3 hit his leg. There was a swelling of the leg and some pain. At operation

Fig 5 (case 3)—Thickening of bone and increased density of cortex two years after lengthening operation. Moth-eaten appearance of bone. At operation a cavity was found filled with granulation tissue.

granulation tissue was found in a rarefied area in the upper end of the tibia. No growth was obtained on plain agar.

COMMENT

The reported operations were all in children, in whom osteomyelitis is more prone to develop.

Trauma appears to have been an exciting factor in stirring up the latent infection.

The infection is usually in the cancellous bone near the metaphysis.

In lengthening operations there is greater force required than in most corrective procedures. The greater pressure may tend to produce necrosis of the bone, which in turn may favor infection.

There is less local disturbance if stainless steel wire is used in bone.

Pathologic examinations revealed evidence of a low grade infection. Small areas containing dead bone and pus cells were found in one case. The marrow was replaced by a fibrous tissue such as one sees in osteitis fibrosa. No definite sequestrums were found, but on

microscopic examination there was evidence of necrotic trabeculae, some showing signs of regeneration about the periphery.

Operations on an extremity subsequent to the insertion of a pin or wire may be followed by an infection.

CONCLUSION

Pins and wires inserted into bone may cause immediate or late infection of the bone.

These latent infections may be stirred up by trauma several years after the insertion of the pins.

Skeletal traction with pins and wires should be limited to cases in which other methods are not as efficient.

450 Sutter Street

ABSTRACT OF DISCUSSION

DR. ROGER ANDERSON, Seattle. This paper is very timely, as skeletal traction is widely used. The dangers that may occur must be kept in mind. Many infections occur at the time the transfixions are inserted and these can all be avoided if the proper technic is used. The Steinmann pin may be contaminated when it is removed from the sterilizer with the lifting forceps which is frequently unsterile. When the sharp end of the pin is placed on the table it not infrequently penetrates the sterile sheet and thus becomes infected. This can be avoided by placing a cork over the point and attaching a handle to the opposite end of the pin before it is placed in the sterilizer. Thus, the transfixion is inserted without being touched by the gloved hand. Careful preparation of the sterile field is also essential. One of the frequent causes of late infections is the repeated observation and dressing of transfixion wounds. Sidewise motion of the limb on the transfixion will also result in an infection. These dangers can be eliminated by firmly incorporating the transfixions in a snug-fitting plaster cast. Another means of preventing infection from sidewise motion—paradoxically as it may seem—is to insert two transfixions at an angle to each other. An aseptic necrosis with discharge not infrequently results when too much traction is applied to the bone, such as occurs in bone-lengthening operations. This can be avoided by equalizing the traction with the insertion of two or more transfixions and incorporating them in the plaster cast. A wire improperly tightened is another source of danger. It has been my experience that the placement of the transfixions is an important factor. If the transfixions are placed closer to the joints, the structure of the bone in that area is such that it stands the traction better than when they are placed through marrow or dense cortical bone. Pulling of the skin against the transfixions will in time result in an irritation discharge and some pain. This can be avoided by extending the cast for some distance both above and below the transfixion. However when it is advisable to obtain joint movement, this discharge and pain may be disregarded as it is not a cause for concern. It is only an aseptic reaction and if the limb is kept quiet for a few days, it usually subsides.

DR. W. K. WEST, Oklahoma City. At the University of Oklahoma Children's Hospital we have been using Kirschner wire traction in many types of orthopedic cases. We do not use Steinmann pins because our experience in the past has shown that the danger from infections, when pins are used, is much greater. We have had no late infections develop as described by Dr. Haas. We did have one case of primary hematogenous osteomyelitis develop around a wire which was being used to correct knee flexion in a case of poliomyelitis. This child developed a furuncle on the wrist and ten days later the infection invaded the upper part of the tibia—that portion of the bone which surrounded the Kirschner wire. The destruction was so extensive that we were positive that it was not an infection resulting from a local contamination. This is the only case of the kind we have seen. When wire traction is used in compound fractures, it frequently happens that local infection develops about the wires, but in all cases the bone sinus clears up within two or three weeks following removal of the wire. It is my opinion that wire traction has the most

important place in the prevention and correction of deformities. In the great majority of cases no reaction will take place because of its use and in cases in which infection does develop the percentage of bad results is very small.

DR SYLVAN L. HAAS, San Francisco. I have been doing lengthening operations for more than ten years. These three cases occurred during one year. Fortunately, I had none before and have had none since. I keep this in mind as a warning and hesitate to say that there will be no further trouble later on. With the pins and wires that are being inserted now one might go along for a number of years and not have any trouble, but there is the possibility of a late infection in the bone.

RESULTS OBTAINED BY SUBCUTANEOUS PINNING OF FRACTURES THROUGH NECK OF FEMUR

AVERY ROWLETTE M.D., J. R. HASLEM M.D.,
R. B. SIEGERT, M.D., H. D. MORRIS M.D.
AND
J. ALBERT KEY M.D.
ST. LOUIS

During the past five years, 380 patients who had fractures of the hip were admitted to the fracture service of the St. Louis City Hospital No. 1, 214 of these were trochanteric fractures and 166 were fractures through the neck of the femur.

The routine treatment for the trochanteric fractures has been suspension and traction in a Hodgen splint, and this method can be depended on to give a satisfactory result with bony union in good functional position in from eight to twelve weeks in those patients who survive. As will be mentioned later, our mortality in trochanteric fractures has been 37.7 per cent.

In the fractures through the neck of the femur neither the large abduction plaster-of-paris spica nor the treatment by traction has given satisfactory results in our hands. Consequently we have sought a method which we could use that would increase the percentage of union in these fractures and not greatly increase the mortality. We early recognized the value of the flanged nail of Smith-Petersen but found that the hospital administration objected to the expense of the nail and that very few of the patients could afford to pay for the nail. A further objection was that the introduction of the nail required an open operation, and we wished to avoid this if possible.

Having been impressed by the reports of Knowles¹ and Gaenslen² concerning their experiences with the methods of fixing the fragments by subcutaneous pinning and by the cheapness, simplicity and relative safety of the methods we decided to use the methods as a routine on all fractures through the neck of the femur. The method of Knowles has been modified to the extent that the stainless steel pins are threaded and are screwed into the bone. This was because one of us (J. A. K.) had the unhappy experience of having a smooth pin back out in a patient who had several furuncles. Infection of the pin wound and eventually of the upper end of the femur occurred and death resulted.

The method used at present is as follows. After a preliminary hypodermic of morphine about 20 cc of 1 per cent procaine hydrochloride is injected into the hip joint, the method described by Moore³ being used of inserting the needle vertically to the surface of the thigh at a point 1 inch below Poupert's ligament and three-fourths inch lateral to the femoral artery. The patient is then placed on a fracture table and the hip is reduced by the Leadbetter⁴ method. The thigh is flexed to 90 degrees and slightly adducted and externally rotated to unlock the fragments, and then traction is made directly upward in the long axis of the femur while an assistant pulls the upper thigh outward and downward to get the fragments in line and tighten the capsule around them. While the traction is maintained the thigh is circumducted outward and downward and internally rotated to bring the extremity down to the level of the table and in a position of moderate abduction and full internal rotation. Then the Leadbetter heel-palm test is applied. The heel of the abducted and internally rotated extremity is supported on the surgeon's palm. If the limb remains in internal rotation the reduction is considered satisfactory and the extremity is fixed on the fracture table, and anteroposterior and lateral roentgenograms are made. If the limb rolls outward the reduction is repeated until the internally rotated and abducted extremity can be supported on the palm of the hand.

While the films are being developed the skin below the trochanter is painted with iodine and it and the deeper tissues over the lateral surface of the thigh below the trochanter are anesthetized with procaine hydrochloride. The local anesthesia is carried down to the femur. When the films are developed and the reduction is found to be satisfactory, a stab wound is made in the skin at a level of about 3 inches (7.5 cm.) below the tip of the greater trochanter and a stainless steel pin or drill is inserted down to the femur. It is directed in a horizontal plane and upward at an inclination approximating that of the neck of the femur. In some instances the reduced hip was examined under the fluoroscope and the outline of the head and neck and trochanters of the femur were drawn on the skin with ink. This outline served as a guide in introducing the first pin. This drill or pin is one-eighth inch in diameter and 8 inches long and the end next to the point is threaded for a distance of about 1 inch. The pin is drilled into the bone for a distance of about 3 inches. Then anteroposterior and lateral roentgenograms are again made.

From the position of the first pin as determined by the roentgenograms, the second pin is inserted. If the first pin is satisfactory, the second pin is inserted parallel to it and about one-half inch above or below it depending on whether the first pin is nearer the lower or the upper border of the neck of the femur. Likewise the depth to which the pin is inserted is determined and if the first pin penetrates the head to about the desired degree an effort is made to insert the second pin to this depth. If the first pin is not deep enough or is too far into the bone due allowance is made for this in inserting the second pin and after the second pin is inserted to the desired depth the first pin is either driven in farther or withdrawn to the desired point.

If the angle or position of the first pin is unsatisfactory it is still useful as a guide and from it the

From the Department of Surgery, Washington University School of Medicine and the St. Louis City Hospital, No. 1.

correction for the second pin can be made. Then, after the second pin is in position the first pin is withdrawn entirely and replaced parallel to the second pin.

When both pins are in position, final anteroposterior and lateral roentgenograms are made and if necessary the pins are either drilled in a little deeper or withdrawn to the desired point. Then the skin is pushed down around the pins as far as possible and the projecting end of each pin is clipped off with a pair of heavy bolt cutters which have been sterilized. The pressure is then released and the skin and subcutaneous tissues slip back into place leaving the projecting ends of the pins deep in the thigh. A dry dressing is placed over the two stab wounds and the patient put on a fracture bed with the limb suspended in a Hodgen splint. As a rule we have kept the patients in bed for three months and have left the pins in for from four to six months.

The principal danger associated with the insertion of the pins is that of getting them into the pelvis. It is said that one can tell by the feel when the pin enters the more dense head of the femur but this has not been our experience and on three occasions a pin was drilled in too far and had to be partly withdrawn and in the one postoperative death in our series the autopsy showed that the pin had penetrated the external iliac vein. Apparently the pin can be drilled through both articular surfaces and on into the pelvis without causing pain to the patient.

During the past eighteen months we have treated forty-six patients with fractures through the neck of the femur by the two pin method. In all but a few instances the reduction and pinning has been done by the resident in the fracture service at the time the patient came into the hospital, and the results here reported represent the work of six different surgeons. It is thus evident that our results with this method are about what an average surgeon who is qualified to

there is apparently firm bony union, that is, 45 per cent of the first twenty-nine cases have what appears to be firm bony union. If we subtract the six deaths, the incidence of bony union is 58 per cent. It is to be noted that only one of these fractures appeared to be impaled and that fractures at the base of the neck, where the neck is split off from the shaft, were treated as trochanteric fractures and are not included in this

Fig. 2—Above, fracture through the neck of the femur with moderate displacement. Below, same fracture after reduction and insertion of the pins. One pin has entered the pelvis and was withdrawn.

Fig. 1—Material used in the two pin method. There should be added a heavy mallet for impacting the fragments before the pins are inserted.

treat major fractures might be expected to obtain and are perhaps not as good as would be those of an expert who is especially skilful in using this method.

Of the total number of patients who have been treated by this method there are thirty in whom more than eight months has elapsed since the pins were inserted and of these it has been possible to trace twenty-nine. Of these, six have died, seven have non-union, and in three the pins are still in and the fragments in good position, thus leaving thirteen in whom

group, that is, all these were typical central or intra-capsular fractures of the femur and in twenty-nine of them there was definite displacement of the fragments.

Of the remaining sixteen cases treated by the double pinning but in which insufficient time has elapsed to judge the final result, there are three deaths and two cases in which, from x-ray appearance, we expect nonunion.

In analyzing our failures we have considered the following points as being responsible: (1) poor general condition of the patient, (2) poor reduction, (3) faulty insertion of the pins, (4) failure of the pins to remain in position and (5) bending of the pins. Apparently the question of whether the head was adequately supplied with blood or not has had little to do with the success or failure of the method.

The failures due to poor general condition of the patients represent four of the six deaths in our series. In only one of these could the death of the patient be attributed to the method. The other death was due to heat stroke. Nine of the forty-six patients in whom the pins were used died. This is a mortality of 19.5 per cent while the mortality of sixty-six patients in 1933 and 1934 who had similar fractures through the neck of the femur and were treated by traction or by the large abduction plaster cast was 28.7 per cent. This mortality is largely explained by the fact that these

patients averaged 64.8 years in age and were drawn from an underprivileged portion of the population, many of whom were poorly nourished and had little to live for. However, it is to be noted that our mortality by the two pin method is considerably less than it was in those patients who were treated by traction or by immobilization in the large abduction plaster cast. During the last five year period 126, or 33 per

Fig 3—Above same fracture two months after reduction and pinning. Below, five and one-half months after reduction and pinning. Firm bony union with head in slight valgus position.

cent of the 380 patients with fracture of the hip, died in the hospital. The cause of death was given as bronchopneumonia seventy-six, heart disease thirty, and miscellaneous twenty. The trochanteric fractures averaged 71.7 hospital days and the fractures through the neck of the femur averaged eighty-three hospital days.

The importance of the age factor is evident when one considers the trochanteric fractures treated in the same wards during the same years. Most of these patients were treated with the Hodgen suspension and traction method and it has been our observation that patients treated by this method are relatively free from pain, can sit up or be propped up at will and can move around in bed. Consequently we would expect the Hodgen method to result in a minimum mortality in trochanteric fractures. Yet in forty patients with trochanteric fractures in 1935 the mortality was 45 per cent and of eighty-one patients of the same type who were treated during 1933 and 1934 the mortality was 39.5 per cent. The average age of 214 patients with trochanteric fractures was 66.6 years, with an average mortality of 38.7 per cent; the average age of 166 patients with fractures through the neck of the femur was 63.8 years and the mortality 25.9 per cent; a difference of 2.4 years and of 12.8 per cent in mortality.

Contrary to popular opinion, age does not appear to have any influence on union, but it does have a very definite influence on the prognosis as regards life. The average age of the patients with trochanteric fractures who died was 73.8 years, while the average age of those who survived was 60 years. In the neck fractures the average age of those who died was 71.2 years, while the average age of those who survived was 60.9 years. In addition to the age factor it is probable that increased mortality in the trochanteric fractures is partly due to the fact that, as a rule, the trauma and pain and hemorrhage into the tissues are more severe in trochanteric fractures than in fractures through the neck of the femur.

Unsatisfactory reduction has not been a very important cause of failure of union. The question naturally arises: What is a satisfactory reduction? Theoretically, an exact anatomic reposition of the fragments is the most satisfactory reduction, and perhaps this is true, yet we believe that a better chance of union is produced when the head is placed slightly on top of the neck in a valgus position. In this position the shearing force is lessened and if the fragments are first impacted (as we are doing now) a more thorough impaction is possible than if one attempts to drive cortex into cortex, as would be necessary were an exact anatomic reduc-

Fig 4—Above comminuted fracture through the neck of the femur after reduction and pinning. The result was bony union. Below, first pin was inserted too high. Lower pins were in satisfactory position. The result was nonunion due to bending of the pins. Pins are now threaded for only 1 inch and are stronger. Also, impaction should have been done.

tion obtained. For this reason we apply strong traction throughout the Leadbetter maneuver and attempt to overreduce the displacement by pulling the distal fragment down slightly beyond its original level. On the other hand, union has been obtained in one of our cases in which the distal fragment was slightly higher than normal, thus in the slight varus position.

In no instance in which the heel-palm test was satisfactory has it been necessary to repeat the reduction. However, it is to be noted that apparently the heel-palm test is a criterion of a satisfactory lateral reduction, but not of the position of the head in the vertical plane, as with a positive heel-palm test the head may be in the valgus, normal or varus position. In our forty-six reductions the heel-palm test was positive in forty-five. In one instance it was necessary to hold the extremity forcibly in position while the pins were inserted, yet in this patient bony union occurred.

We have taken lateral roentgenograms in all our cases but have not paid much attention to them and in not a single instance have we repeated a reduction because of the lateral roentgenogram. The chief value of the lateral view is in determining the position of the first pin.

Of the seven nonunions, one is believed to be due to unsatisfactory reduction. In three instances the first pin was inserted too far (into the acetabulum or pelvis) and had to be partly withdrawn, and in one of these the pin injured the external iliac vein and caused the death of the patient. In two instances one pin did not get a satisfactory hold on both fragments. Of the seven nonunions, two are believed to be due to a final faulty position of the pins.

In the great majority of our cases, not only have the pins remained in place but their removal at the end of six months has required the exertion of considerable force. In three instances one of the pins has become loose, and two backed out and one wandered into the acetabulum. In one instance this is believed to have been a factor in the nonunion. We have encountered no instance such as that reported by van Ravenswaay⁵ in which a pin wandered into the bladder.

In two cases the pins bent sufficiently after their insertion to permit displacement of the fragments and resulted in nonunion. The other nonunion is explained by us as being due to a dead head, but we know that under proper conditions union may occur in the presence of a dead head.

CONCLUSIONS

The two pin method can be used by the average surgeon who is trained to treat major fractures.

In such hands it tends to reduce the mortality in fractures through the neck of the femur.

In our hands thirteen, or 45 per cent, of twenty-nine patients with fractures through the neck of the femur who were treated by the two pin method obtained bony union. Of the remainder, six died, seven had nonunion and in three cases the result is still doubtful.

ABSTRACT OF DISCUSSION

DR. EDWIN W. RYERSON, Chicago. It is evident that this pinning of the fractured necks of the femurs will have to be treated with respect. When I first saw this method advocated and saw some of the immediate results, it didn't seem to me that it was mechanically sound or that it was likely to be free from danger, and as seen from this presentation there are dangers connected with these operations. To speak of the mechanical proposition. It does not seem that two pins inserted through the upper end of an elderly person's femur and into a head which probably is not any too hard will give the mechanical stability and fixation that is required in such cases unless external fixation by apparatus is used. I don't think that I should feel so safe in allowing a patient to lie in bed

with only two small pins securing the head of the femur in place. But the results reported speak for themselves. In a very fair proportion of the authors' cases a bony union has been achieved in spite of what has been done. It is a matter for consideration that these femoral necks do not unite in two or three months. It takes four months for a good bony fusion of any fracture of the neck of the femur that I myself have had anything to do with and I advise all orthopedic surgeons who operate by this method or by any method to keep patients from weight bearing for at least four months afterward. Up to this time it has seemed to me that the best fixation was the Smith-Petersen nail put in by the Johansson method, with a wire first and then the pin threaded on the wire and driven home. I am not enthusiastic about impacting these hips. The hip has been insulted sufficiently after it has been broken and after somebody has stuck a lot of wires up into it. Why insult

Fig 5—Above nonunion due to poor position of the pins; upper pin did not get a firm grip on the head of the femur. Below union with coxa vara. In spite of the bending of the pins bony union was obtained with moderate absorption of the head. The hip is painful.

the hip any further by beating it with a mallet? It will unite if one doesn't impact it. It will unite if one gets it in good position and keeps it there long enough, no matter what method is used. The pin fixation is simpler than the other methods but I don't think that it is as safe as a Smith-Petersen nail. I don't think that either of these types of fixation is as likely to be successful in a large majority of cases as an autogenous bone graft put up through the neck of the femur, preferably a piece of fibula. It will be necessary to wait a good many years and see more and more of the late results. I heartily congratulate the authors on their success in so many cases and on their admirable carpentry. In all the literature on the subject there is a surprising number of cases in which the pin didn't go in the right place. Why it didn't was bad carpentry, and in most cases it is due to the fact that it isn't put in low enough down below the trochanter. Years ago everybody spoke of putting pins through the trochanter. One should forget the trochanter and put the pins up through the shaft of the femur well below the trochanter and at as acute an angle as possible and every time the muscles pull on that fractured hip they will jam the fragments together without any artificial impaction and

⁵ van Ravenswaay, Alexander. Steel Pin Inserted into the Neck of the Femur Found in Bladder. *Am J Surg* 31:566 (March) 1936.

will make the bones stick together better and more firmly, by far, than if the pin is put in at a more obtuse angle

DR FRED KNOWLES, Fort Dodge, Iowa The presentation of fifty cases of internal fixation of fractures of the neck of the femur gives an excellent view of the results possible in the use of internal fixation. The results from external fixation have been so uniformly bad in such a high percentage of cases that internal fixation has received serious work from several surgeons in the United States. The teaching of Kellogg Speed that intracapsular fractures of the neck of the femur require from nine months to three years for complete bony reconstruction focused the attention of surgeons on the fact that external fixation could not possibly be maintained over this long period. Internal fixation has been advocated by Dr Albee of New York with the autogenous bone peg by Dr Smith-Petersen of Boston with the Smith-Petersen nail, by Dr Moore of Columbia, S C with the three pins, by Dr Gaenslen of Milwaukee with multiple pins, and by the method I have used for three and a half years, double parallel pinning, using one-eighth inch chrome nickel steel pins with a shoulder. The authors have changed this technic by threading the pins. Out of this comparatively early work on internal fixation undoubtedly will come more uniform technic and I believe that parts of several of these methods will be eventually adopted which can be carried out by the general surgeon. There should be several more years of work and perhaps thousands of cases studied with a better classification of the types of fractures relative to results obtained and compatible with the various ages of patients before final decision can be made as to what has proved to be the best operative technic. To the present I have operated on thirty-eight patients ranging from 50 to 89 years of age with the average age of 71 years. This has included both intracapsular and intertrochanteric fractures taking all cases as they come. The average mortality age has been 77 years and only one death at the age of 89 has been definitely due to fracture of the hip. Counting the living patients, I have had union in 92 per cent of the cases. The two points that definitely establish internal fixation in my opinion, as being far better than external fixation are a much higher percentage of union and a far greater comfort to the patient during the entire period of convalescence.

DR. FRED J. GAENSLER, Milwaukee I have observed seven or eight cases of impacted fracture of the neck with very transient and very mild support all going on to bony union and normal function. The reason why these patients get well with little or no external support is that first reduction is practically perfect second immobilization is absolute by reason of the impaction and third these patients move the extremity very early, thus insuring a good blood supply. In the spiking operation or internal fixation by any adequate method, the same principles obtain. Accurate reduction is a prime essential. If the fracture cannot be reduced properly, fixation with a Smith-Petersen or any other kind of nail is useless. If a satisfactory reduction is obtained and one succeeds in placing the spike securely and in proper position immobilization is complete and the patient is able to move the leg early, thus facilitating circulatory repair. A slight valgus deformity is not objectionable. In fact, it is rather desirable because of the mechanical advantage of more perpendicular weight bearing. The technic is not difficult if one follows definite rules. I am coming to believe that more difficulty is encountered in properly reducing the hips than in the introduction of the spikes. Staking out of the trochanter with long Keith needles is most helpful. With a little experience and careful study of the angle of the shaft and neck, the degree of anterior torsion and the length of the neck the spikes are introduced without difficulty and are checked up with the x-rays. As far as impaction is concerned if one will try on the cadaver to impact a fracture of the neck one will be greatly surprised that it is practically impossible because the cortex of the neck is thick and hard. I have stopped trying to impact. There are dangers of course in this and in other forms of treatment of fracture of the neck. Mortality statistics run from 20 to 30 per cent. I feel that if a satisfactory reduction is obtained and if the spikes hold efficiently for three or four months the case will go on to union. The paper of Dr Key and his associates is an excellent

one which should encourage orthopedic surgeons in the use of internal fixation a method which I believe is efficient and here to stay

DR KELLOGG SPEED, Chicago It seems to me that there is some confusion existing in our minds between ways and means and results. One man talks of one pin or two pins, and another of a screw and a third of 3 or 4 cm of necessary penetration and so on. We are apparently losing our way as to what we are really after. What we want to get is an ordinary harmless way that the profession as a whole may use to care for or possibly cure fractures of the neck of the femur. Last year I had the temerity to describe these fractures as the "unsolved fracture," to the amusement of surgeons, colleagues and friends. But I still believe that the problem is unsolved and the fact is illustrated by the outburst of these papers and this very well worth while discussion of the ways and means of attempted cure. The primary requisites in treatment still remain, as most of the speakers have confessed, apposition and immobilization. In Chicago we find that quite a long immobilization is necessary. Is this method or is any method, then that we discuss here still the final method? I suggest that judgment be withheld until the last word has been said. In the meantime each one of us should study the problem along the line of a hobby or belief and eventually, perhaps years from now a proper method will be found to be employed by all caring for these fractures. I have heard discussions like this as far back as thirty-five years ago, when J B Murphy of Chicago first introduced the nailing of the hip, frequently successful often not successful.

DR J ALBERT KEY, St Louis We tried out this method because we are not able by the Whitman plaster or by traction or by any other method to get results which are to us, satisfactory. These are not satisfactory either, but they are a lot better than we have been able to get any other way. All are familiar with the literature about 50 per cent union in intracapsular fractures treated by the Whitman method some men think it higher. I myself have never been able to get it in noninfected fractures. I know that in the City Hospital at St. Louis I couldn't find any of them that united. We are looking for a method that can be used by the ordinary man. Only two of these hips were pinned by me the first two. All the others were done by the resident, whoever happened to be on. We think at least I think that the average man who can do major fracture work can have better luck in putting in these two pins than he can in putting on a Whitman plaster. A Whitman plaster sounds simple but to put it on and keep it on a patient for four months and have the patient survive is a very difficult thing. As to the insult of impaction we don't insult after we put the pins in. We think that impaction should be done first and then after the patients have survived the impaction we put the pins in. Our mortality has been cut down about 35 per cent by this method in the same hospital. As to the question of reduction I don't think reduction is so important if one gets the fragments together. It isn't necessary to have anatomic reduction. In fact as I stated here, I would much rather not have an anatomic reduction. I don't believe in the ring that Dr Knowles has mentioned because I don't know how long a pin is going to be necessary. I have to drill it in until I can see in the roentgenogram how far it is. With regard to the pin backing out through the skin I had that happen once. The only difference between his patient and mine was that mine died. His apparently got well. When they come through the skin now we take them out.

Nature of Thirst—If we survey the foregoing evidence as a whole we are led to the rather banal conclusion that thirst is what it seems to be—a disagreeable sensation due to drying of the mucous membranes of the fauces and pharynx. The real interest in localizing the origin of thirst at the back of the mouth is found in the relation of the salivary glands to that area. The area set where the moving air tends to dry it is normally kept moist by secreted saliva—a liquid which is almost pure water. If the salivary glands do not have water supplied to them they cannot function the area dries and we experience thirst.—Cannon W B. *Digestion and Health*. New York W W Norton & Co., Inc 1936

CHOLANGIOGRAPHIC DEMONSTRATION
OF BILIARY DYSSYNERGIAAND OTHER OBSTRUCTIVE LESIONS OF THE
GALLBLADDER AND BILE DUCTS

R RUSSELL BEST MD

AND

N FREDERICK HICKEN MD

OMAHA

Although during the last fifteen years definite advances have been made in the diagnosis of lesions of the biliary tract, we not infrequently are unable to appreciate the relation of the common bile duct to the patient's complaint. It is true that biliary surgery gives very gratifying results in most instances, but it is that group of patients whose response has not been entirely satisfactory which concerns us. Cholecystograms, as sponsored by Graham and Cole,¹ furnish valuable evidence regarding the gallbladder, but they are of little value in disturbances of the common bile duct. Elsewhere in the body, tubular organs can be injected with radiopaque solutions that graphically outline such organic changes as tumors, stones, strictures and inflammation and depict any variation in activity or motility resulting from functional disturbances. It is our purpose in this paper to present clinical and x-ray evidence of spasm of the lower end of the common duct, which we have termed biliary dyssynergia, and to describe the method of diagnosing other obstructive lesions of the extrahepatic bile ducts by injecting opaque substances into the biliary tract. We also offer some experiences in the management of these conditions.

For the past two years, we have been visualizing the biliary tract by injecting radiopaque fluids into the common duct during operation. This method has been called immediate cholangiography. The injection of radiopaque substances postoperatively, through catheters, tubes or fistulas, has been designated delayed cholangiography.

TECHNIC

A satisfactory contrast medium produces a clear outline and is nonirritating to the tissues. After experimenting with many contrast solutions we have found lipiodine, thorium dioxide sol and hippuran to be the most suitable, however, each of these has its advantages and disadvantages. These solutions must be absolutely sterile and must be warmed to 120 F at the time of injection.

Lipiodine-Ciba is a nonirritating iodized oil which apparently exerts a soothing, therapeutic influence in the common duct. We have not hesitated to use it in the face of biliary infection complicated by high temperature. Being an oily solution, lipiodine is very viscous and some difficulty may be encountered in injecting it into the biliary tract through a small bore needle, as is necessary in making an immediate cholangiogram. If a large caliber needle is used, the oil seeps out the puncture wound and infiltrates the extraductal tissues, thus giving a hazy, indefinite cholangiogram. After considerable experience we have concluded that this solution is so dense that the smaller stones in the common duct may be obscured.

Thorium dioxide sol is a labile solution and gives an excellent pattern of the bile ducts. Some authors have asserted that it has carcinogenic properties but to date no authentic report of this occurrence has been made, even though it has been used intravenously as a diagnostic aid in hepatic, splenic and vascular lesions in a rather large series of cases. We believe that this fear is unwarranted and have used thorium dioxide sol freely.

Hippuran is a 48 per cent aqueous solution of organic iodide and has proved to be a very satisfactory cholangiographic medium.

IMMEDIATE CHOLANGIOGRAPHY

In 1932 Mirizzi² suggested that the common bile duct could be visualized at the operating table by injecting it with radiopaque substances. During the past

Fig 1—A normal immediate cholangiogram taken at the operating table

two years we have developed several methods of obtaining satisfactory cholangiograms, and our experience indicates that the site for injection may vary with the case.

Site of Injection During Operation Without Sacrificing the Gallbladder—1 The most direct method consists of injecting about 20 cc of the radiopaque solution directly into the common duct, which has been isolated and steadied with Allis clamps or two small sutures. A 22-gauge needle on a "Lok" syringe is used. The clamps are then removed and gauze is placed lightly against the puncture wound. If the duct is dilated it may be necessary to aspirate its contents before the injection is made.

2 Another method is the injecting of 40 cc or more of the contrast medium directly into the gallbladder.

after the bile has been aspirated. A clamp or suture seals the puncture wound. This method is unsatisfactory if the cystic duct is occluded.

Site of Injection at Operating Table with Sacrifice of the Gallbladder—1 A very satisfactory technic is to clamp and divide the cystic duct, remove the clamp, and inject about 20 cc of contrast medium into the stump of the cystic duct with a small cannula or blunt needle. This method is most useful if the common duct is thickened and the cystic duct is dilated.

2 Not infrequently the cystic duct is very small and cannot be probed successfully. In this event the cystic duct is ligated, and injection is made into the common duct, which has been steadied with Allis clamps or fine sutures.

3 In some instances the cystic duct is isolated and the neck of the gallbladder is exposed and clamped in such a manner that a needle can be inserted below this point. The clamp prevents the contrast medium from

infiltrating the gallbladder. In all cases in which tubes or catheters have been left in the gallbladder or common duct, between 20 and 50 cc of contrast medium is injected on about the third post-operative day, and these injections are repeated as necessary.

STUDIES IN IMMEDIATE CHOLANGIOGRAPHY

1 *As an Aid in Diagnosing Elusive Common Duct Stones*—Lahey³ and Clute⁴ have definitely demonstrated that the incidence of common duct stones in cholelithiasis has almost tripled since they have increased their explorations of the common duct rather than depending on palpation. Experience has proved that unnecessary choledochostomies may be avoided by making roentgenographic visualizations of the common duct at the operating table (fig 1). This method has revealed the presence of stones when palpatory evidence was negative (fig 2).

CASE 1—Mrs. S., aged 45, had repeated attacks of pain in the right upper quadrant referred to the right shoulder and associated with nausea, gas and an aversion to fatty foods. She had never been jaundiced nor had the pain necessitated morphine. Physical examination revealed obesity with tenderness over the gallbladder region. The gallbladder did not concentrate the dye and the icteric index was normal. At operation the gallbladder wall was thickened and several stones were palpable. The common duct appeared about normal size, no stones were palpable and the head of the pancreas felt normal. A cholangiogram was made at the operating table by injecting 20 cc. of thorium dioxide sol into the stump of the cystic duct. The film revealed a small negative shadow near the lower end of the common duct. Choledochostomy disclosed a single small stone.

2 *As an Aid in Diagnosis of Pancreatitis or Tumors of the Head of the Pancreas*—We believe that these give rather definite pictures when they compress the common duct although the differentiation from spastic closure of the lower end of the common duct would prove difficult at times.

CASE 2—Mrs. S., aged 68, had complained of indigestion and intolerance for greasy foods for many years. About two months before admission she began having pain in the right upper quadrant, which radiated to the shoulder. During the last two weeks she had suffered from nausea, vomiting and jaundice associated with clay colored stools. On physical examination the patient was found to be obese, jaundiced, dehydrated, acutely ill and very tender over the right upper quadrant, with liver margin down about three fingerbreadths. After ten days of preoperative observation and preparation a cholangiogram at the operating table revealed a dilated common duct with an obstruction at its lower end. No evidence of stone was found and the picture was not typical of stricture or spasm. The cystic duct was patent. A cholecystogastrostomy was carried out.

3 *To Determine Patency of the Cystic Duct*—We have assumed that certain types of bile in the gallbladder were significant of a patent cystic duct and, if a cholecystogastrostomy was indicated, one had little fear of an inadequate short-circuiting operation. However, on two occasions we have proved that the contrast medium did not reach the hepatic or common bile duct, although we felt that we were dealing with a patent cystic duct. This may be one explanation for the high mortality in such operations in that the procedure does not decompress the biliary system and the

Fig. 2—An immediate cholangiogram depicting a small stone at the lower end of the common duct which had not been palpable.

invading the gallbladder. After the needle has been withdrawn, the puncture wound is momentarily clamped to prevent leakage.

X-Ray Technic—Before the operation is begun a wooden tunnel containing a 14 by 17 inch film is placed beneath the patient. At times a cystoscopic table has been used. After the contrast medium has been injected all clamps are removed from the wound, including the towel clips at the upper angle of the incision. A large sterile sheet is then thrown over the operative field the operator and assistants step aside the portable x-ray machine is wheeled into place and the picture is taken. The film is immediately developed and interpreted and the operation is then continued.

DELAYED CHOLANGIOGRAPHY

We have found repeated check-up cholangiograms definitely valuable in ascertaining why biliary fistulas have failed to close and in demonstrating stones stric-

patient has to carry the insult of operation as well as the original pathologic condition (fig 3)

CASE 3—Mr B, aged 65, presented a history of vague subcostal pain following meals for one year. He became nauseated and vomited every evening, was slightly jaundiced, and lost 40 pounds (18 kg) during this time. Physical examination revealed general abdominal tenderness and a mass in the epigastrium. After ten days of preoperative observation and preparation, a mass the size of an egg was found at the lower end of a greatly dilated common duct. Heavy dark bile was aspirated from the distended gallbladder, about 30 cc of lipiodine was injected, and an immediate cholangiogram revealed the cystic duct to be occluded. However, a cholecystogastrostomy was done in the hope that our cholangiogram was in error or that some valvular obstruction or edema in the region of the cystic duct would be released after decompression of the gallbladder. At autopsy ten days later, the cystic duct was still occluded.

4 *The Effect of Spinal Anesthesia on the Choledochal Sphincter*—In our early investigations we believed that the sphincter was relaxed under spinal anesthesia, but fortunately we were wrong. If the sphincter relaxed it would be impossible to obtain a satisfactory immediate cholangiogram, because the contrast medium would immediately enter the duodenum. Its contraction under spinal anesthesia is well demonstrated in practically all immediate cholangiograms.

STUDIES IN DELAYED CHOLANGIOGRAPHY

1 *Demonstration of biliary dyssynergia*. Our histologic studies reveal practically no muscle tissue in the cystic, hepatic or common ducts. At the lower end of the common duct, however, there exists a concentration of muscle tissue termed the sphincter of Oddi. This sphincter, like those of the stomach and colon, has an innervation derived from the sympathetic and parasympathetic systems, and it is probably subject to similar disorders of function, in particular, spasm or hypertonicity. For some years authors have described gallbladder colic existing without stone or infection and have frequently reported cases of jaundice with no apparent obstruction to account for the dilated common duct.

In 1887 Oddi,⁵ in his original description of this choledochal sphincter, was of the opinion that spasm of this sphincter of the ampulla might be the cause of biliary colic or icterus in some patients. The work of Meltzer⁶ and Lyon⁷ with magnesium sulfate on the duodenal mucosa also suggests the occurrence of this spastic phenomenon. In 1922 John Berg,⁸ a Swedish surgeon interested in biliary colic without stone or infection, proposed that functional disorders of the biliary passage might be the cause of biliary stasis and supported his contention by observations of hypertrophy of the muscle at the lower end of the common duct. Nuboer⁹ and Newman¹⁰ have also observed this hypertrophy. Westphal,¹¹ in 1923, went so far as to

classify disorders of motility of the biliary tract into the hyperkinetic and atonic types. In 1933 Ivy, Voegtlin and Greengard¹² further substantiated the existence of this phenomenon by a series of experiments on human beings. They found that an injection of secretin-cholecystokinin was generally followed by a copious flow of pancreatic juice and bile which could be recovered through a duodenal tube. In three out of nineteen normal subjects studied, bile was not recovered after the injection and the patients suffered right hypochondrial distress, which became so severe that relief was sought. The introduction of magnesium sulfate into the duodenum resulted in immediate alleviation of the distress and in a few minutes bile was recovered from the duodenum, thus indicating that the choledochal sphincter had relaxed.

These experiments suggested that the existence of this sphincterismus of spastic dyssynergia could be con-

Fig 3—Carcinoma of pancreas. Immediate cholangiogram also reveals a cystic duct obstruction. Cholecystogastrostomy proved to be of no value.

firmed by roentgenographic visualization of the common duct. Therefore, in a series of gallbladder cases, postoperative injections of radiopaque solutions were made through a small catheter left in the cystic duct. Similar studies were instituted in all cases with common duct catheters, T tubes or fistulas. We have found spastic biliary dyssynergia to exist in 15 per cent of the patients in our series of seventy-five. This can best be exemplified by presenting actual cases (fig 4).

CASE 4—Mrs M, aged 52, experienced typical gallbladder distress for ten years with several attacks of severe colic but no jaundice. Examination was negative except for slight tenderness in the right subcostal area. In cholecystographic studies the gallbladder appeared distended and contained several small stones, and the wall was moderately thickened. The wall of the common duct was also slightly thickened but there was

no evidence of gross dilatation, stone or neoplasm. The head of the pancreas was normal. Exploration of the common duct released a thick, dark brown, tenacious bile laden with flakes of biliary pigment. Examination with scoop and probes demonstrated a pseudo obstruction in the region of the sphincter. On stronger pressure the probe suddenly slipped into the duodenum, indicating that some impediment had been overcome. Twenty-four hours following operation, 40 cc of lipiodine was injected into the common duct and the roentgenogram revealed a pronounced dilatation of the entire biliary tree with a cone-shaped narrowing at the lower end of the common duct. There was no evidence of stone or stricture. Twenty-five minutes later the apparent spasm was still present for the lipiodine had not escaped from the biliary tract. In three hours there was a slight trickle of oil into the duodenum. At forty-eight hours the biliary tract was practically free from the contrast medium. During the latter part of the injection, and as the tube was clamped, the patient complained of distress similar to her gallbladder attacks.

CASE 5—Mrs. W., aged 41, had had typical gallbladder disease for five years, associated with severe colicky pains and deep jaundice. She was operated on and a gallbladder filled with pea sized stones was removed, twenty-two pea-sized stones were also removed from the hepatic and common ducts. Within

Fig. 4—A delayed cholangiogram depicting spasm of the lower end of common duct (left). A 1/100 glyceryl trinitrate tablet was given and five minutes later spasm had disappeared (right).

four months the attacks of colic jaundice and high temperature recurred. Eighteen months later she submitted to a second operation. When the common duct was opened thick pus was encountered and a large soft calculus was removed. The lower orifice of the duct was patent and a T tube was inserted. Postoperative hemorrhage into the wound was a troublesome factor. On the tenth postoperative day the biliary discharge had a bloody tinge and on the twelfth day the T tube had become blocked; the stools were acholic and the jaundice was increasing. A few days later at a third operation, a blood clot was removed from the common duct. The lower end of the duct was definitely patent at this time. Following this procedure the stools remained acholic and there was a free flow of bile through the common duct catheter and later through the fistula. Clamping the catheter and packing the fistula did not force bile into the duodenum and always caused severe distress within a few hours. Antispasmodic drugs did not alter the situation and after forty-five days of a complete biliary fistula and acholic stools a cholangiographic study with lipiodine evinced a definite obstruction at the lower end of the common duct not suggestive of stone but rather typical of choledochal sphincter spasm. A roentgenogram taken three minutes later showed a few drops of oil in the duodenum and a third roentgenogram taken in twenty minutes disclosed that the lipiodine had escaped from the common duct and was within the jejunum.

Within twenty-four hours the fistula was closed, the stools were of normal color, and now, more than a year later, the patient has had no recurrence of biliary obstruction.

It has been very noticeable in our cases that the spasm of the sphincter of Oddi was in no way correlated with the degree or type of pathologic condition of the gallbladder or common duct. One may venture that in some instances spasm is the prelude of biliary or pancreatic disease and is followed by stasis and infection. Again, in those cases in which the lower end of the common duct is atonic and the contrast medium immediately passes into the duodenum, regurgitation of infectious duodenal contents into the common duct might well be the source of biliary or pancreatic disease. Experiments by Brendolan¹³ show that section of the sphincter of Oddi in dogs frequently results in ascending biliary infection.

The hypertonic type of dyssynergia occasions pain because of increasing pressure. This was frequently demonstrated during injection of the opaque medium against the spastic sphincter. Patients with atonic dyssynergia did not complain of distress.

2 Demonstration of the cause of persistent biliary fistulas

CASE 6—Mr. B., aged 56, had a cholecystostomy performed four months previously at which several small stones had been removed from the gallbladder. There had been intermittent drainage from the site of operation, and, when it was not draining, colic and epigastric pain ensued. This sinus was injected with 60 cc of lipiodine and a roentgenogram revealed an irregular spiral-shaped shadow obstructing the cystic duct. No oil reached the common duct. Here was rather conclusive evidence that an obstruction at the cystic duct prevented the gallbladder from emptying. Operation revealed a well organized bile-stained mucous plug occluding the cystic duct.

Injections of other persistent biliary fistulas have revealed stones remaining in the cystic duct or draining sinus, strictures and spasm of the sphincter of Oddi.

3 Aid in diagnosis of remaining stones, mucous plugs and the like

CASE 7—Mrs. K., aged 35, suffered attacks of pain in the right upper quadrant radiating to the scapula, severe enough to require morphine, and associated with gas, nausea and vomiting. One month previous to admission she had her first attack of jaundice. Physical examination revealed marked jaundice with tenderness and rigidity in the right upper quadrant. After a week's preoperative preparation and study the gallbladder was found to be a sclerotic mass adherent to the common duct with a fistulous communication existing between them. A stone the size of a marble was removed from the common duct and catheters were fixed into both the hepatic and the common duct. A cholangiogram taken on the fifth postoperative day was negative. On the eighteenth postoperative day there was a negative shadow in the region of the ampulla which on a second cholangiogram a few hours later was shown to be movable within the common duct. This was interpreted as a mucous plug or stone and the patient was forewarned. She returned home feeling well but one month later had an attack of terrific pain in the upper part of the abdomen. A year has now passed and she has had no further trouble and it is possible that she passed this foreign body during the attack.

4 To ascertain patency or deformity of the common duct following operative procedures or injuries

CASE 8—Mrs. G., aged 29, accidentally had the common duct severed by a surgeon during a cholecystectomy. This was repaired over a T tube and we were permitted to make follow-up cholangiograms which demonstrated that the radiopaque substances passed freely into the duodenum and after removal of the tube common duct continuity was present.

13. Brendolan, G. The Immediate and Late Effects of the Section of the Sphincter of Oddi. *Arch. ital. di chir.* 40: 529, 1935.

5 As an aid in determining the degree of cholangiectasia and time for removal of common duct catheter. We believe that this is most important in all cases in which common duct drainage has been established, for until the biliary radicles and ducts have somewhat approached normal size the tubes should not be removed. We have found irrigation with warm physiologic solution of sodium chloride or warm olive oil most beneficial. Warm lipiodine seems to have some therapeutic value also.

THERAPEUTIC CONSIDERATIONS

During the injection of the radiopaque substances in those cases in which spasm of the sphincter of Oddi existed, the pain experienced by the patient was typical of the biliary distress or colic existing before operation. On some occasions, after the injection of the warm oily contrast medium through T tubes or catheters, the sphincter relaxed almost immediately and at other times the spastic condition was not relieved. In case 5, in which spasm was apparently the cause of acholic stools and a persistent draining biliary fistula for a period of forty five days, the spasm was relieved by instillation of warm lipiodine on the choledochal side of the sphincter and now, eighteen months later, it has not recurred. Of late, in all cases presenting biliary catheters or fistulas, irrigation with warm olive oil or saline solution is done and when the status of the sphincter is checked up, lipiodine is used. For ruling out the presence of a foreign body in the common duct, thorium dioxide sol or hippuran is substituted for reasons stated previously. Attempts are also made to relax the spastic sphincter with atropine, belladonna or magnesium sulfate instilled through the duodenal tube, but not infrequently these drugs fail. We also use olive oil or pure cream night and morning, as suggested by Ivy. A combination of these treatments may also relieve the common duct of any foreign body such as mucous plugs and small stones.

In our first experiments we were at a loss to understand why morphine and atropine did not achieve the desired relaxation of the sphincter except in isolated instances.

At this time we began more enthusiastic treatment of some of our gallbladder cases in which operation had been done some years before with not entirely satisfactory results. We found that the foregoing therapeutic measures produced startling improvements in some instances, while in others the desired benefits were not obtained. Of course in these cases we were not sure whether we were dealing with spasm, stone, mucous plugs or stricture of the common duct. One man was also subject to angina pectoris and during some of these attacks felt that he was having pain over the gallbladder region which was quite similar to the distress he had before operation. He had used glyceryl trinitrate tablets for these attacks and volunteered the information that the soreness over the gallbladder region was also greatly relieved by the glyceryl trinitrate. These tablets were then prescribed to several other patients, who seemed to get partial or complete relief. This appeared only empirical, but in the next two cases of spastic biliary dyssynergia that we could demonstrate with cholangiograms we were able to prove that $\frac{1}{100}$ grain (0.0006 Gm.) glyceryl trinitrate tablets by mouth relaxed the spastic sphincter of Oddi (fig 4). If we clamped off the drainage catheter or packed the fistula so that distress was present, immediate relief was usually obtained.

SURGICAL CONSIDERATIONS

If drugs or diet can be used to control the spastic state of the choledochal sphincter without too much inconvenience to the patient, such surgical procedures as choledochoduodenostomy or sphincterostomy are not indicated. It is perfectly plausible, however, that surgery for spastic biliary dyssynergia may some day be part of the management of certain of these cases. Some type of neurectomy may also prove advantageous.

SUMMARY

1 Spastic biliary dyssynergia has been demonstrated by means of cholangiograms and may be considered a definite clinical entity.

2 Glyceryl trinitrate tablets, magnesium sulfate, atropine, belladonna, cream, olive oil and various oily radiopaque substances have very evident therapeutic value at times in spastic dyssynergia.

3 When possible, postoperative irrigation of the common duct with oils and saline solution is of value.

4 Immediate cholangiograms are a definite aid in diagnosis and may prevent complicating circumstances which arise from incision and exploration of the common duct. The status of the cystic duct can also be ascertained.

5 Delayed cholangiograms are an aid in determining the status of the choledochal sphincter, the presence of overlooked stones, stricture and tumor, and the presence of pancreatitis or tumor of the pancreas, and also help determine when sufficient time has elapsed for biliary drainage.

6 The choledochal sphincter is as a rule in a contracted state under spinal anesthesia.

ABSTRACT OF DISCUSSION

DR. FRANK H. LAHEY, Boston. Up to 1926 I was unhappy because of the number of stones in the common duct which were being overlooked in our clinic. I therefore advocated further investigation of common ducts. Up to 1926 we had operated on 619 gallbladders, opened the common duct in 15 per cent and found stones in 8 per cent. Up to last year we had operated on 2,000 gallbladders, opened the common duct in 44 per cent, and in the last third of the cases found stones in 18 per cent of the cases. It thus becomes obvious that previous to 1926 we were leaving a stone in the common duct in probably one in every ten patients on whom we operated. It is therefore of great interest to hear this paper. Any improvement in the method of distinguishing the possible presence of common duct stones is of great value. When one realizes that in 39 per cent of the cases in which we found stones in the common duct no jaundice was present at the time, or had been present in the history, one must admit that no dependence can be placed on some of the past criteria for the presence of stones in the common duct. When one leaves behind a stone in the common duct it is probable that one has left the stone that is causing the symptoms, and certainly the stone that is most likely to bring about a fatality. For this reason, I feel sure that stones in the common duct should be investigated more than has been done in the past. I have not felt the need for this method of investigation. Dr. Charles G. Mixer at the Beth Israel Hospital in Boston has employed it, and thinks well of it. What is needed is a definite set of criteria as to when common ducts should be investigated, and ours are these: jaundice, or history of jaundice with cholelithiasis, a contracted gallbladder, a thickened common duct or a dilated common duct, a lump that is in any way a possible stone, a thickened head of the pancreas. It does not add to the mortality to open the common duct. It is necessary to provide conditions that will permit those stones to pass on. For that reason I have welcomed the appearance of the Bakes sphincter dilators. They run up to 14 mm. in diameter and can be passed through the sphincter of Oddi. It is not

safe to dilate them to 14 mm. I have reported the occurrence of two ascending gas bacillus infections in such cases, but it is safe to dilate the sphincter up to 9 mm and then to wash any small stone down into the duodenum. The important fact to remember concerning cholelithiasis is that if one finds 18 per cent proved common duct stones in cholelithiasis, one must admit that patients have not been operated on early enough because common duct obstruction is the result of long standing cholelithiasis. What is necessary is to educate medical men not to carry their cases of cholelithiasis through repeated attacks but to submit them to operation earlier while the stones are still in the gallbladder. Then there will be a lower mortality and better end results.

DR. WALTIAN WALTERS, Rochester, Minn. Mirizzi, Bartlett, Thiessen and I and Best and his associates have demonstrated the value of a study of the physiology of the common bile duct using the visual methods of fluoroscopy and roentgenography. Our interest in the method was stimulated by Mirizzi's interesting monograph "La cholécystectomie sans drainage (cholecystectomie ideale)," published in 1933. After using the method at the operating table on a few occasions we discarded it as being too time consuming. It did not yield sufficient additional information beyond that which could be obtained from the anatomic and pathologic changes to warrant its continuation. However, its use subsequent to operation has been of inestimable value in cases in which the common bile duct has been opened and explored and closed around a small T-tube. Two and a half weeks after operation the T-tube is injected with 10 cc of brominol, which is opaque to roentgen rays, and a roentgenogram is taken immediately. Ten minutes later two additional roentgenograms are made. Although, fortunately, to date we have not found any cases in which it would appear that a stone persisted in the common bile duct, we have found that in some cases of pancreatitis there was persistent narrowing of the lower end of the common bile duct interfering with proper drainage of bile into the duodenum, and that in an occasional case reflux into the duct of Wirsung could be demonstrated. In some cases, also, a partial stenosis or spasm in the region of the sphincter of Oddi was causing stasis within the common bile duct. Space permits only the briefest reference to this problem of pancreatitis and malfunction of the sphincter of Oddi. In regard to the pancreatitis, if persistent narrowing of the common bile duct continues after a period of from six to eight weeks of T-tube drainage (at which time the T-tube would have ordinarily been removed), and the cholechochograms show continued retardation in the emptying time of the common duct, the T-tube should be left in for an additional period until complete subsidence of the stasis demonstrable roentgenographically, occurs. In this particular type of case it seems to me that the practical value of cholechochograms is apparent.

Mary Baker Eddy and Dr. Francis Lieber's Manuscript.—The newly discovered Source Document, a deeply thoughtful philosophic discussion of Hegelianism by a German-American, at last brings to the light of day what a discerning scholarship should have detected long ago—namely that Mrs. Eddy was the mouthpiece, however distorted for the ghost of the distinguished German philosopher Georg Wilhelm Friedrich Hegel. The contention is not that she plagiarized in all her writings, for a considerable part of what she produced bears her own indubitable mark. But the fact is irrefutable that the chief doctrinal points, the main ideas in Science and Health including the major portion of the 'Scientific Statement of Being' are appropriated verbatim from this antecedent statement the newly discovered Source Document. This remarkable essay from which Mrs. Eddy so extensively appropriated proves to be a manuscript of 8,200 words, comprising a philosophical treatise on Hegelian Metaphysics by the justly celebrated man of letters Dr. Francis Lieber. The Lieber Manuscript gains distinction as one of the most notable documents in the history of American letters for Lieber's summation of Hegel's philosophy became none other than the basis of Science and Health—Haushalter W. M. Mrs. Eddy Purlouns From Hegel Boston A. A. Beauchamp 1936.

SEGMENTAL NEURALGIA IN CHILDHOOD SIMULATING VISCERAL DISEASE

JOHN HART DAVIS, MD
CLEVELAND

In the past five years I have observed in a group of 250 children the various manifestations of a pain syndrome that seems to be commonly misinterpreted, most commonly as an evidence of visceral disease. I have seen it called acute appendicitis, chronic appendicitis, renal colic, ureteral stones, gallstones, pleurisy, colitis, and the like, without any subsequent developments to warrant these diagnoses. I have seen it confused, in certain of its aspects, with arthritis, bursitis, tenosynovitis and other types of pain affecting the extremities.

The fact that the distribution of this pain was always segmental would seem to divorce these cases from a serious consideration of visceral disorder. That very fact, on the contrary, is commonly interpreted as irrefutable evidence of its visceral origin, especially by those who have been trained in the infallibility of the viscerosensory reflex.

Since my own observations in these children failed to establish any evidence of visceral disease, and since all of them recovered without surgical intervention, I began to cast about for an explanation of segmental pain that would apply more consistently than the classic theory of Mackenzie¹ and Head.²

I think I have arrived at such an explanation, an explanation based on a perfectly simple mechanism and quite in harmony with the most modern concepts of disease. It will be well, in attempting to build up this theory, to bring out the details of history, symptoms, examination, treatment and results in this group of children as I have observed them.

GENERAL DESCRIPTION

The material for this study was derived from the roster of the Cleveland public schools and from the clinics of the University Hospital. It includes those children, more than 250 in number, who voluntarily sought out the doctor because of pain, the prime feature of the disorder. The age range of the group was from 6 to 16 years. The great majority of the children so affected were between the ages of 12 and 16 years. Most of them were boys, but largely because there were more boys than girls available for observation. In mixed groups there seemed to be no greater incidence in the one sex than in the other.

They were recruited largely from the underprivileged and lower middle classes, yet to casual inspection they seldom were undernourished. None of the children gave a significant history or evidence of vitamin deficiency or allergic disturbance. In fact, there was nothing unusual about any of them that could not be duplicated in their fellows who were unaffected.

The history, with respect to the onset of symptoms, is especially significant, since it brings to light a second important feature of the disorder, i. e., infection. Fully

From the Department of Pediatrics, Western Reserve University School of Medicine.

Read before the Section on Pediatrics at the Eighty-Seventh Annual Session of the American Medical Association, Kansas City, Mo., May 14, 1936.

90 per cent of the group had had recently an infection of the upper respiratory tract, varying in severity from a simple cold to influenza with prostration. In the majority, the infection seems actually to have been mild. Not infrequently it accompanied the onset of pain but more often preceded it by one to two weeks. The seasonal incidence of the disorder has corresponded consistently with the "cold season," and the peak incidence with that of cold epidemics. The remainder of the group (10 per cent) was divided about equally between those children who had had some trauma previously and those whose history was not significant in any way. Curiously, however, these patients came to my attention only during the time when the disorder was prevalent generally.

The characteristic symptomatology always featured pain which was variously described as "tingling," "sticking," "sharp" or "burning." It often was mild in fact so mild that it might not have come to a doctor's attention except in a free dispensary. Just as often it was severe, paroxysmal or lancinating, a source of genuine discomfort to the patient and a problem in differential diagnosis to the attending physician.

The pain commonly was localized in the anterior abdominal wall (75 per cent) in the area supplied by the ninth, tenth, eleventh and twelfth dorsal segments. In a much smaller group (10 per cent) it was limited to the thoracic wall in the distribution of the fourth to the eighth dorsal segments. In the remainder of the group (15 per cent) it was distributed in the more bizarre areas supplied by the cervical, upper dorsal, lumbar and sacral segments. In 60 per cent of all the cases the pain was unilateral, in the remaining 40 per cent it was bilateral.

In a few of these cases, vomiting occurred as an initial feature of the disorder accompanying the onset of the pain. None of the patients complained of headache or dizziness. There was no fever except in the preliminary "cold" phase, and no motor disturbances or weakness other than the natural limitations of movement resulting from pain.

The clinical signs consisted of cutaneous hyperesthesia and hyperalgesia in the affected areas, as well as irregular pain reactions to pressure. In a few instances hypesthesia was noted, usually after a fairly long period of hyperesthesia. In these cases, however, the children complained of the same tingling and lancinating pains as did the children generally.

The presence or absence of hyperesthesia and hyperalgesia was determined by the simple device of stroking with an applicator, a cotton pledget or a piece of paper across the pathway of the spinal nerves or by pinching with the thumb and forefinger along the distribution of the nerve trunks. Ordinarily, by this method, the borders of hyperesthesia were so sharply delineated, and conformed so remarkably to the sensory zones, that no one could seriously doubt their accuracy or their segmental distribution. An exception was noted, however, in those cases in which the involved segments were supplied through the cervical, brachial and lumbosacral plexuses, where there was ordinarily some confusion as to the exact limitation of the pain area, a confusion that seems natural enough in consideration of the complex distribution of the root fibers.

Pressure, as I have remarked, was often productive of pain, especially deep pressure in the paravertebral area. In fact, pressure anywhere along the course of the sensory trunk was likely to elicit pain. However,

on the anterior abdominal wall it did not ordinarily elicit muscle guard and rigidity as in appendicitis.

There were several miscellaneous observations, aside from these characteristic ones, that would seem to be worthy of mention. For instance, there was no evidence in any of the group of a pleural friction or other signs of chest involvement. There was no case in which the abdominal or other reflexes on the affected side were lost or impaired. There was ordinarily no diminution or exaggeration to hot and cold stimuli, two-point perception or vibratory sense. In a few cases however an exaggerated response, and in some few others a diminished response, to these particular stimuli was noted.

There were only six instances in which the skin was visibly affected. A typical herpes zoster developed in two boys of the more than 250 children in the series. Four others manifested a slight flushing and a peculiar velvety texture of the skin within the pain area.

Perhaps the most significant observation was the discovery of a band of hyperesthesia and hyperalgesia in two boys who had been operated on for appendicitis, the one three years, and the other one and one-half years before the current onset of symptoms. This

Fig 1 (case 1)—Distribution of cutaneous hyperesthesia—a common type

shows as does no other evidence that an appendix is not necessary to initiate the pain, that another mechanism than the viscerosensory reflex can produce cutaneous hyperesthesia.

In a few selected cases, examinations of the blood and spinal fluid, and cystoscopic and roentgenographic studies yielded normal results.

The treatment of the disorder is simple. It consists of the local application of heat, mustard plasters or other counterirritants and the oral administration of the common sedative and analgesic drugs. With such treatment the symptoms subside in from two to four weeks in the majority of instances, without treatment the duration is likely to be longer, from four to eight weeks. A few cases persisted with remissions and exacerbations for from four to eight months. The prognosis, in any event, is always good, the course is apparently self limited.

One boy remarked about the immediate cessation of symptoms following a lumbar puncture, though he had no increase in spinal fluid pressure, globulin or cell content. Two girls had abrupt and complete relief following the removal of infected tonsils. Another girl had similar relief after the extraction of several carious teeth.

Other types of treatment that have been suggested include (1) injection of the posterior nerve roots with alcohol, which I have not tried, (2) the use of light roentgen irradiation over the point of emergence of the affected nerve trunks, which was employed in a limited number of cases with no apparent relief, and (3) the empirical administration of large doses of brewers' yeast by mouth. This too has been done in a small

Fig. 2 (case 3)—The relationship of the area of hyperesthesia in the knee is apparent when the proximity of the affected ganglions is considered

group of cases without any apparent improvement in symptoms. In fact, certain of the patients grew worse while taking the yeast.

It would appear then that the disorder is self limited and not influenced by specific or other therapeutic measures, except as I have noted. One thing further stands out as significant. In spite of statements by certain children that they have had pain for from three to five years, I myself have seen fewer than 5 per cent of them in a second attack. Hence it would seem that immunity is likely to follow after one attack of the disease.

REPORT OF CASES

CASE 1—A girl, aged 13 years, had had recurrent attacks of abdominal pain for about a year. The pain was usually on the right side and ordinarily was accompanied by vomiting. The patient complained of frequency of urination but not of dysuria or hematuria. Recurrent throat infections had preceded the attacks of abdominal pain. In the University Dispensary it was thought that she had some renal disease, and so she was referred to the Pediatric Division for study.

The blood was normal. The tuberculin test and the Wassermann reaction were negative. The spinal fluid was clear and contained no globulin and no cells. Cystoscopic examination, intravenous pyelograms and repeated urine cultures yielded nothing abnormal.

After hospitalization for one month, the segmental distribution of the pain was noted and cutaneous hyperesthesia and hyperalgesia were demonstrated in the affected area. The history of frequent sore throats was thought to be significant and removal of the tonsils was advised. Within one week after tonsillectomy the pain disappeared. After more than one year there has been no recurrence of any of the symptoms.

CASE 2—A girl aged 9 years, was first seen in the University Dispensary, April 16, 1934, complaining of a sharp, burning pain in the left side. After two days the pain disappeared but it reappeared shortly thereafter, this time on the right side. The child complained of nausea and vomited once. The his-

tory brought out the fact that these symptoms had been preceded by a moderately severe sore throat and cough, which, however, had cleared up completely before the onset of the pain.

There was quite definite cutaneous hyperesthesia in the distribution of the seventh to twelfth dorsal segments and in the first lumbar segment, accompanied by slight voluntary spasm and moderate tenderness to light palpation over the entire right side.

It was arranged to hospitalize the child for study, April 23. Examinations of the blood and spinal fluid and roentgenograms of the kidneys, ureters and bladder showed nothing abnormal.

One week after admission, a mild throat infection and moderate nasal discharge developed. Simultaneously exquisite tenderness appeared in the right thigh and knee, accompanied by skin hyperesthesia in the distribution of the second, third and fourth lumbar segments. All treatment was unavailing until the carious teeth were extracted. Within five days the pain in the knee was relieved. In a week all cutaneous hyperesthesia had disappeared. Some months later the child reported that she had had no recurrence of pain in the abdomen or knee.

CASE 3—A boy, aged 13 years, was studied in the hospital for five days in March 1933 because of a dull pain over the left side of his body and in his left shoulder following a sore throat, fever and swollen cervical glands. Occasionally he remarked about sharp, lancinating pains induced by coughing, deep breathing, quick movements of the body and walking. Examination revealed a marked skin hyperesthesia and hyperalgesia in the distribution of the first to the twelfth dorsal segments and in the third and fourth lumbar segments.

All ordinary blood studies yielded normal results. The tuberculin test and the Wassermann test were negative. The spinal fluid pressure was slightly increased. The fluid itself was clear, contained two cells and no globulin.

The patient improved so markedly after lumbar puncture that no medication was administered.

CASE 4—A colored boy, aged 12 years, was first seen April 9, 1935, nine days after the outbreak of a typical herpes zoster. He had almost intolerable "burning" pain in the two or three days preceding the eruption. Inspection revealed the typical vesiculation of herpes zoster in the distribution of the third and fourth dorsal segments on the left side of the thorax. Examination brought out a sharply defined band of hyperesthesia and hyperalgesia extending from the third to the eighth dorsal segments. The lower border of this band was well below any of the evident skin lesions, which suggests a lesser degree of involvement of these particular segments.

Fig. 3 (case 4)—A band of intense hyperesthesia and vesiculation (shown in black) with a nonvesicular area of hyperesthesia beneath April 9, 1935. Six weeks later, May 23, the band of hyperesthesia was reduced to the limits of the area in black showing a probable relation between severe ganglionic involvement and vesiculation.

Six weeks later, May 23, the hyperesthesia was less marked and the band was narrower, having disappeared from the segments that were less markedly involved. Two weeks later, June 6, all evidence of hyperesthesia and hyperalgesia was gone.

CASE 5—In February 1936, shortly after an attack of sore throat, herpes zoster developed in a boy aged 14 years. Vesiculation was limited to the fourth and fifth dorsal segments on the left side. Hyperesthesia and hyperalgesia involved a much

wider area, the fourth to the eighth dorsal segments inclusive. After more than two months (May 4) he still has an indefinite narrow band of hyperesthesia.

CASE 6—This girl, aged 13 years, when first seen was complaining of pain in the abdomen and groin on the left side. The segmental nature of the pain was noted, but it was not until two weeks later, when similar pain developed in the heel of the same side, that the case became of greater than ordinary

Fig. 4 (case 6)—A most unusual remote area of hyperesthesia in the exact distribution of the first sacral segment

interest. The exact correspondence of this area of hyperesthesia to the distribution of the first sacral segment is remarkable.

CASE 7—A boy, aged 14 years, appeared in the University Dispensary complaining of pain in the right side, which had been interpreted as due to appendicitis. Cutaneous hyperesthesia and hyperalgesia were elicited on both sides, involving the ninth to twelfth dorsal segments.

The boy received large doses of brewers' yeast by mouth (3 teaspoonfuls twice a day for three weeks of the Anheuser-Busch Company's most potent powdered yeast). Not only did the abdominal pain become worse but new pain areas developed in the shoulders and arms. The distribution was bilaterally symmetrical, affecting the ulnar and median innervation while leaving the radial free.

CASE 8—A boy, aged 14 years, had had an appendectomy in 1933. In November 1935 he was seen with bilateral segmental pain in the distribution of the tenth, eleventh and twelfth dorsal segments. It was identified as a most exquisite hyperesthesia and hyperalgesia of the skin, which obviously cannot be explained by recourse to the viscerosensory reflex.

CASE 9—A boy, aged 14 years, had had his appendix removed in September 1934. In February 1936 he was seen because of bilateral cutaneous hyperesthesia and hyperalgesia in the distribution of the tenth, eleventh and twelfth dorsal segments. Again it is rather obvious that the pain cannot be explained by disease in the appendix.

CASE 10—A girl, aged 17, was seen in the University Dispensary with a complaint of intermittent pain in the right side. It had disturbed her more or less for three years. Examination revealed a typical segmental band in the distribution of the tenth, eleventh and twelfth dorsal segments—a band of hyperesthesia in contrast to the usual hyperesthesia. All topical sensations were reduced in this area, although the girl complained of tingling and lancinating pains as did the other children.

EXPLANATION

The explanation of this pain syndrome must be independent of the viscerosensory reflex, since no evidence of visceral disease was established in any of the cases. It must take into account the obvious relation of the pain to infections of the upper respiratory tract as well as its segmental distribution, and it must conform to modern medical thought. Consequently, I have been led to conclude that the essential pathology of the disorder is most likely a postinfectious inflammation of

the posterior spinal nerve roots and their ganglions, a radiculoganglionitis, caused by a neurotropic virus associated with the common cold.

The nature of this virus is undetermined, as to whether it may be a specific virus in its own right or identical with the virus of herpes zoster. It seems to me that the latter is quite possible as well as plausible, since the distribution and the peculiar character of the pain are so very similar in the two disorders. The fact that only two children in the entire series had typical herpetic lesions does not necessarily argue that the rest of the group were affected by a different virus. It suggests rather that vesiculation may be unusual in zoster and that subherpetic manifestations may be the rule.

Any other explanation fails of conviction. I have already remarked about the inadequacy of the theory of the viscerosensory reflex to explain the condition observed in these children. It is unlikely that allergy has any part in the disorder, as recovery has been spontaneous and permanent in most of the cases without recourse to the measures commonly employed in allergic disturbance. On the other hand, a neuritis due to vitamin deficiency may not be so easily dismissed—at least as a contributory factor—in spite of the fact that specific vitamin (B_1) therapy apparently failed to influence the course of the disease. The fact that the great majority of affected children are derived from the underprivileged group would seem to have some significance. It is quite possible that infection may be impotent in the production of this syndrome except in those children already "conditioned" through a deficiency of vitamin, even though my own studies thus far fail to provide such evidence.

REVIEW OF THE LITERATURE

In a study of the literature I have found frequent mention of manifestations commonly ascribed to visceral disease which correspond exactly to the cases I have observed. I have found also numerous references

Fig. 5 (case 8)—Girdle of hyperesthesia in a patient who had had an appendectomy three years before

to thoracic and abdominal pain different in character and origin from the syndrome under discussion.

Perhaps the earliest significant observations were those of Ross³ (1888), who postulated a theory of referred somatic pain from an affected viscus to the appropriate spinal segment, thence by a process of diffusion to the sensory fibers of the same segment, whence the pain was referred to the skin. This concept was later elaborated by Mackenzie¹ and by Head²

³ Ross, James. On the Segmental Distribution of Sensory Disorders. *Brain* 10: 333, 1888.

into the theory of the viscerosensory reflex, which has dominated all medical teaching since that time

Sherren,⁴ Cope⁵ and more recently Livingston,⁶ noting exactly the same segmental hyperesthesia and hyperalgesia that I have encountered, have cited clinical cases tending to prove the application of the viscerosensory reflex in this type of pain. Sherren noted the association in forty of 124 cases of appendicitis (26.6 per cent) and Cope in 110 of 185 cases (59 per cent). They both noted that it commonly was absent in cases of gangrenous and ruptured appendixes and in the peritonitis that followed.

Robinson,⁷ on the other hand, another of the early observers, concluded that the "finding of cutaneous hyperalgesia is of slight value in appendicitis" and pointed out that this finding "persists long after other evidences have disappeared."

Livingston (1932) has noted cutaneous hyperesthesia and hyperalgesia in 86 per cent of 400 patients operated on consecutively for appendicitis. He emphasizes particularly a maximal intensity of such pain within the limits of a triangle, which he calls Sherren's triangle. He attaches such importance to this particular finding that he calls it the most pathognomonic sign in acute appendicitis. While he noted the same type of pain covering other and distinctly larger areas than this triangle he apparently did not attach any significance to the wider distribution. Curiously, he too noted that in the presence of gangrenous and ruptured appendixes the skin signs were singularly absent.

He did make observations, however, in a patient with an appendicostomy which would seem to support the validity of the viscerosensory reflex in certain of these cases. He also quotes Campbell, who has noticed skin hyperesthesia along the inner aspect of the upper part of the thigh following ureteral manipulation in the course of cystoscopy.

These observations, of course, make it difficult to discard entirely the theory of the viscerosensory reflex. I am really not interested in doing so but rather in emphasizing another mechanism which, I believe, is operative in a great many of these cases.

Morley⁸ is convinced that the viscerosensory reflex is a doubtful mechanism and that cutaneous hyperesthesia is of little diagnostic importance in appendicitis. He believes that it is derived from stimulation of a sensitive parietal peritoneum.

Boland⁹ doubts the essential relation of skin hyperesthesia to appendicitis but does remark that he has observed herpes zoster occasionally in patients who had symptoms simulating appendicitis. Comroe¹⁰ also mentions, without discussion, herpes zoster as a cause of abdominal pain.

Carnett,¹¹ of all clinical observers in this country, has approached most nearly my interpretation of this type of pain. However, he does not in any way relate it to acute respiratory infections or to a virus etiology. He does not specifically implicate the ganglions but does discuss posterior root pains originating in certain lesions of the spinal cord or vertebrae, such as Pott's disease, carcinoma with metastases and fracture or subluxation of the spine. He also called attention to pressure on the posterior nerve roots from postural trauma. He has endeavored especially to differentiate this type of pain, which he calls "parietal," from the pain of acute and chronic appendicitis, and in so doing questions the application of the viscerosensory reflex in most instances of skin hyperesthesia.

Russetzki¹² in 1934 described a group of 100 cases in which the symptoms and signs are approximately the same that I have observed. He noted that the symptoms of segmental pain appeared generally within a period of from five to ten days after the onset of an infection of the upper respiratory tract, that it ordinarily lasted from twenty to thirty days, that the characteristic disturbances were lancinating pains in the sensory distribution of the spinal segments, paroxysms of coughing and sneezing, difficulty in moving the affected parts, pain on percussion over the corresponding vertebral areas, and a slight increase in the cell count and globulin of the spinal fluid. In his series the pain was localized in the dorsal segments in 60 per cent of the cases, in the cervical segments in 24 per cent of the series and in the lumbar segments in 16 per cent. In 85 per cent of all his cases the involvement was unilateral, in the remaining 15 per cent bilateral. These observations all are reasonably in keeping with those in my own series. His explanation, as well, is essentially the same as the one I had arrived at independently, namely, that segmental pain, associated with hyperesthesia and hyperalgesia of the skin, is due to the action of a neurotropic virus following grippal and influenzal infection.

Additional references to the literature seem unnecessary, since much of it applies only indirectly to this study. However, I should like to mention mesenteric and retroperitoneal lymphadenitis, the "Brennemann syndrome,"¹³ because it brings out the relation between infections of the upper respiratory tract and abdominal pain of another sort. Likewise the studies of Evans¹⁴ and the more recent observations of Freedman¹⁵ have shown that there is a definite relation between infections of the upper respiratory tract and the incidence of acute appendicitis.

COMMENT

It is evident, then, that several symptom complexes may arise in connection with acute infections of the upper respiratory tract and must be considered individually in the differential diagnosis of pain. Yet it is not too much to believe that they may occasionally occur together. Thus the apparent connection between appendicitis and skin hyperesthesia in many instances and the total lack of it in many others may be explained most readily by assuming that they have only an inci-

dental relation to each other—in other words no relation at all except that they happen to occur simultaneously in the same patient

If, then, cutaneous hyperesthesia is divorced from appendicitis and other visceral disease, as the evidence from this study indicates must be done it must be concluded that the viscerosensory reflex does not explain this type of pain. On the other hand, the explanation I have proposed seems to apply to all the cases in the series, including those in which segmental hyperesthesia appeared following appendectomy

The site affected by the attacking virus has not been definitely established. There have been no biopsy or postmortem studies or other localizing evidence. Russetzki¹⁴ apparently looks on the disorder as a primary radiculitis, a variation of the radicular syndrome first described by Dejerine¹⁵ and his pupils and reviewed by Mayer¹⁷ in this country, whereas I am disposed to look on it as a primary ganglionitis with secondary radicular involvement, i. e., as a form of herpes zoster

I feel justified in this conclusion because of the striking resemblance of this disorder to herpes zoster. It explains every feature of the pain, its peculiar character as well as its segmental distribution. The fact that vesiculation occurred only twice in the series would seem to indicate a basic difference between this disorder and herpes zoster. Yet it has occurred to me that we may be dealing with a mild or subherpetic form of zoster, which seems a simpler explanation than to assume that a totally different virus does essentially the same thing as the zoster virus

In its thoracic and upper abdominal distribution it is likely that most observers who are not too completely persuaded by the viscerosensory reflex will recognize in this syndrome the well known intercostal neuralgia. This is probably a sufficiently accurate designation so far as it applies, but it is really only a part of the whole. Other localized neuralgias are frequently encountered. It would seem advisable to include all forms under one general head, especially those forms having a common origin. Russetzki has called the syndrome "post-grippal polyradiculitis." I think his terminology minimizes the probable involvement of the posterior root ganglions. I should suggest, therefore, the term "radiculoganglionitis" as being both more nearly accurate and more descriptive of the true disease state. If it is desired to use a simpler clinical term I should suggest that "segmental neuralgia" seems more nearly to fulfil all the requirements than any other

SUMMARY

1 I have seen more than 250 cases of segmental pain in children during the last five years. This pain was, with rare exceptions, manifest in the form of cutaneous hyperesthesia and hyperalgesia

2 It was characteristically associated with or preceded by some form of infection of the upper respiratory tract

3 The symptoms were relieved by counterirritants and the common analgesic drugs

4 The duration of the pain was variable and unpredictable but the disorder has seemed to be self limited, with an apparent tendency to confer immunity

5 The evidence indicates that the syndrome is not related in any way to visceral disease and that the vis-

cerosensory reflex is not a satisfactory explanation of the manifestations

6 It is suggested that the disorder may be caused by a neurotropic virus with a special predilection for the posterior roots of the spinal nerves and their ganglions. The additional suggestion is offered that the disorder may well be a subherpetic form of herpes zoster

7 The designation radiculoganglionitis is proposed for the syndrome, along with the simpler clinical term segmental neuralgia

10515 Carnegie Avenue

ABSTRACT OF DISCUSSION

DR. JOHN A. TOOMEY, Lakewood, Ohio: Dr. Davis has focused attention on a condition which many pediatricians may have seen often and not recognized. It is my very good fortune to have examined several of his cases, and I can subscribe to the facts described by him in these instances. He speaks truly when he states that this syndrome is common. To my knowledge, his series is the largest on record. I agree that the condition is probably postinfectious in origin, sometimes following so called influenza. Whether the causative factor is a virus entity is not known, but Dr. Davis's suggestion along that line is interesting. It may be the same as the herpes zoster virus, or it might be similar to or identical with that virus first isolated from a common cold and described by Dochez and his associates. It certainly must be neurotropic in nature. I do not think that the term "radiculoganglionitis" is complete. It should be "neuroradiculoganglionitis," but the term proposed by Davis, "segmental neuralgia," is comprehensive. I do not find myself completely in accord with the author with regard to the viscerosensory reflex response. It may be, however, that Dr. Davis did not intend to include the mechanism of production in his presentation. It is true, as he states, that a disease starting in the nerve roots and ganglions would give peripheral symptoms similar to a disease that started in the viscera and would give visceral stimulation with a referred viscerosensory response. Visceral disease is ruled out because no pathologic changes are visible. The absence of recognizable pathologic changes is granted, but, on the other hand, absorption of toxins may occur anywhere along the gastro-intestinal tract without leaving visible traces of its presence. Such neurotropic toxins would be thus taken up and carried from the gastro intestinal tract directly to the somatic nerves. It is my belief that such is the mechanism that produces the subjective and objective symptoms, not only in typhoid but in poliomyelitis and influenza as well, and perhaps even in Dr. Davis's segmental neuralgia. Were this so, one could see how the viscerosensory reflexes might be disturbed by such conditions and yet not give rise to noticeable pathologic evidence. Dr. Davis has collected a vast amount of clinical information that is extremely practicable from the standpoint of differential diagnosis and he deserves our thanks for this careful compilation

DR. HUGH L. DWYER, Kansas City, Mo.: I am sure that all of us have seen just such cases as Dr. Davis has described this afternoon. Not infrequently, one sees in the outpatient departments children who complain of pain in the side of the chest, or in the abdomen, which has been relieved by the local application of heat, by counterirritation or by sedatives. Careful examination of these children may show none of the physical signs of disease in the abdomen or in the chest. The examiner usually suspects that more definite signs will appear in a day or two, but the symptoms disappear without the development of pleurisy, pneumonia, appendicitis or other visceral involvement. With such an experience, I have often thought that the child had magnified his symptoms or, because he had been to the outpatient department many times before, that he liked to visit the clinic. Nevertheless, the sharp, lancinating pains that were present in some cases must have resulted from definite tissue changes. The fact that these symptoms are associated with cutaneous hyperesthesia and hyperalgesia, and that the borders of the involved area can be rather sharply defined by stroking or pinching the skin, suggests involvement of the spinal segments. Dr. Davis's observation of the frequency of this

condition following closely on mild infections of the upper respiratory tract suggests a relationship. It is logical to assume such a relationship because of the similarity of segmental neuralgia to herpes zoster, which presumably is a virus disease, and because Dochez and others have offered evidence that the common cold is due to a filtrable virus. It would seem that if physicians would adopt such means as stroking or pinching the skin in the region of the sharp, sticking pains in those children in whom there are no definite signs of visceral disease, and especially in the absence of fever and toxemia, an explanation would be found for those cases in which one waits for visceral disease that never appears.

DR. JOHN HART DAVIS, Cleveland. Dr. Toomey thinks I have disposed of the viscerosensory reflex somewhat too rapidly. I am sure he does not hold with those who think this type of pain originates in the appendix, but he has suggested that the viscerosensory reflex may operate after all through the gastrointestinal tract. I am not sure that he refers to a true reflex, an impulse transmitted along the reflex path, so much as he refers to a possible absorption of virus from the tract extending along the gray rami communicantes to the ganglions and the posterior roots. I am pleased with the suggestion, because it offers a pathway for virus spread that I had overlooked, but, after all, it is not reflex. I find the probable pathway of the virus less of a worry than suitable proof of its actual existence. I have not seen the virus. No one has ever seen a virus. It may be we are dealing with a soluble toxin instead but something at least that seems to activate the posterior root ganglions in a specific pain reaction. My chief interest with respect to this presentation is that it may enable other practitioners of medicine to differentiate more readily than hitherto between real visceral disease and harmless conditions that simulate visceral disease.

CLINICAL EXPERIENCE WITH AN IMPROVED CRYSTALLINE INSULIN

SAMUEL S. ALTSHULER, M.D.
AND
RUDOLPH LEISER, M.D.
ELOISE, MICH.

Efforts have been made during the past few years to develop an insulin that might in a measure approximate the continuous even internal secretion of the pancreas. Recently Hagedorn¹ has introduced insulin protamine and Root and his associates² as well as Sprague and his associates³ have described clinical experiences with this product. Earlier investigators⁴ have attempted to devise methods to obtain a prolonged or sustained effect from insulin.

Because of the rapid action of the insulin in common use, it has been necessary to administer the amount required in two, three or even four doses daily. Especially in severe cases of diabetes has it been difficult to control the blood sugar level between the extremes of hyperglycemia and hypoglycemia. At best, the life of the diabetic patient who needs insulin is an abnormal one and any improvement that would decrease the number of daily injections, the total number of units required or the entire complexity of insulin therapy would be of inestimable benefit to the patient.

This paper deals with a clinical investigation of an improved crystalline insulin that was developed by Dr. Melville Sahyun of Detroit. Although in the course of preparation this insulin is in a crystalline form, for

Chart 1—Effect on blood sugar of old insulin and crystalline insulin (10 units) average of ten nondiabetic patients. Broken line old insulin, solid line, crystalline insulin.

clinical use it is dissolved in various concentrations and assayed in the usual manner. The technic of administration is the same as that used for standard commercial insulin. For purposes of brevity, throughout this paper the standard commercial insulin will be referred to as "old insulin" and the improved crystalline insulin as "crystalline insulin."

STUDIES OF NONDIABETIC PATIENTS

The comparative action of old insulin and of crystalline insulin on ten nondiabetic patients was first investigated.

After an overnight fast, blood sugar determinations were made, after which 10 units of old insulin was administered to each patient. Samples for blood sugar determination were withdrawn at intervals of three-quarters, one and one-half, three, five and seven hours. No food was taken during the test period. Twenty-four hours later the same procedure was repeated on the same group with an identical amount of crystalline insulin. The curves of the averages of these nondiabetic patients are shown in chart 1, from which it

Chart 2—Fourteen hour study of effect of 10 units of crystalline insulin on blood sugar of a nondiabetic patient.

may be seen that the crystalline insulin lowers the blood sugar more gradually and maintains the low level for a longer period, and that at the end of seven hours the blood sugar is still far below the fasting level.

DURATION OF ACTION

The observation that seven hours after the administration of crystalline insulin the blood sugar still had

not returned to the fasting level led to an investigation of the duration of the effect of this insulin. Consequently, three hours after the evening meal, 10 units of crystalline insulin was given to each of two nondiabetic patients. Blood sugar determinations were made immediately before the administration of the insulin and every two hours thereafter for fourteen hours. No food was taken during the period. The results of this experiment are shown in charts 2 and 3.

In one case (chart 2) the blood sugar returned to the starting level in thirteen hours, the curve of the other patient (chart 3) shows that the starting level had not been regained at the end of fourteen hours.

STUDIES OF DIABETIC PATIENTS

Crystalline insulin has been used in the treatment of twenty-nine diabetic patients whose ages range from 17 to 86 years. These patients have been in the hospital receiving accurately weighed diets for periods varying from two months to five years. All the patients are indigents who have no homes and are kept in the metabolic wards, where they are available for observation over long periods of time.

Comparative studies of old insulin and crystalline insulin have been made in twenty cases. The most equitable comparisons are those made in the cases of

Chart 3—Fourteen hour study of effect of 10 units of crystalline insulin on blood sugar of a nondiabetic patient.

patients with severe diabetes, who are more likely to be sensitive to slight changes in insulin dosage or times of administration.

For this study, the minimum maintenance dose of old insulin required to control the patient was compared with the minimum maintenance dose of crystalline insulin. The criteria of diabetic control were blood sugars between 70 and 180 mg. Below 70 mg was considered the level of insulin reaction, and above 180 the level of glycosuria.

Six blood samples (capillary) were taken during twenty-four hours, at 5 a. m., 10 a. m., 3 p. m., 7 p. m., 12 midnight and 5 a. m. Determinations were made by Folin's method. There were approximately 2,700 blood sugar determinations. Daily qualitative urinary examinations were made by Benedict's method on twenty-four hour specimens.

The diets were kept constant throughout this investigation. Both high and low carbohydrate diets were in use. The carbohydrate content ranged in various cases from 100 to 200 Gm., protein from 60 to 70 Gm., and fat from 80 to 150 Gm. Because of the routine of the institution, breakfast was given at 6 a. m., lunch at 10 30 a. m. and supper at 3 30 p. m. The three meals were equal in available dextrose content.

To allow the patient to become stabilized on certain doses before blood sugar studies were made, changes in insulin dosage were not effected oftener than from five to seven days.

Chart 4—Dosage of insulin and blood sugar level in case 1. Diet carbohydrate, 100 Gm. protein 70 Gm. fat 100 Gm. In the charts old insulin is represented by solid columns and crystalline insulin by shaded columns.

Five cases selected from among our patients with more severe diabetes.

CASE 1 (chart 4)—A girl, aged 17, known to have had diabetes since 1924, was admitted to the hospital in diabetic coma June 7, 1934. She had a juvenile type of diabetes and

Chart 5—Dosage of insulin and blood sugar level in case 2. Diet carbohydrate 170 Gm. protein 70 Gm. fat 80 Gm.

had always been difficult to control. When this investigation was started on February 18 her minimum maintenance amount of insulin was 135 units divided into four doses daily. She was given crystalline insulin on February 19 and the dosage and times of administration were adjusted until the minimum maintenance dose was reached on April 7, when she received 70 units of crystalline insulin in two doses. As a control study, for two

weeks she was put on 70 units of old insulin, given in two doses daily, with a resultant glycosuria and hyperglycemia. A further control period of one week on the original 135 units in four doses still showed glycosuria and hyperglycemia.

CASE 2 (chart 5)—A man, aged 59, known to have had diabetes since 1926, was admitted to the hospital in September 1932. This patient was also difficult to control because of fluctuations between insulin reaction and hyperglycemia. At

Chart 6—Dosage of insulin and blood sugar in case 3. Diet: carbohydrate, 170 Gm. protein, 70 Gm. fat, 70 Gm.

the beginning of the study, February 20, his minimum maintenance dose was 42 units divided into four doses daily. He received crystalline insulin on February 21 and the dosage was gradually adjusted until April 14, when his minimum maintenance dose of 40 units of crystalline insulin given in one dose was reached. A control period of one week followed, when the patient was given 40 units of old insulin in one dose, on which he developed glycosuria and hyperglycemia. During a further control period of one week the original dosage of 42 units in four doses daily failed to free him from the glycosuria and hyperglycemia.

CASE 3 (chart 6)—A man, aged 61, known to have had diabetes since 1921, was admitted to the hospital in July 1932

Chart 7—Dosage of insulin and blood sugar level in case 4. Diet: carbohydrate, 100 Gm. protein 60 Gm. fat 150 Gm.

When the study was begun February 14, he was receiving 55 units of insulin in three doses daily. February 15 he was put on crystalline insulin and the dosage was gradually adjusted until March 24, when he was being given 35 units in two doses daily. A week's control period with 35 units of old insulin in two doses daily showed a glycosuria and hyperglycemia. A second control week on the original 55 units in three doses daily did not abate this condition. However after two consecutive

weeks on the original dosage the glycosuria began to disappear and the blood sugar approached the normal level.

CASE 4 (chart 7)—A woman, aged 50, known to have had diabetes since 1934, was admitted to the hospital in March 1935. At the beginning of this investigation, February 18, she was receiving 70 units of insulin in three doses daily. She was placed on crystalline insulin February 19 and the dosage was adjusted until on April 7 she was able to get along on 30 units of crystalline insulin in one dose. During a control period of one week the patient was given 30 units of old insulin in one dose daily, on which she developed glycosuria and hyperglycemia, which a further control week on the original 70 units in three doses daily did not abate.

CASE 5 (chart 8)—A woman, aged 65, known to have had diabetes since 1932, was admitted to the hospital in July 1934. February 10 she was receiving 20 units of old insulin in two doses daily. The patient was placed on crystalline insulin on February 11 and the dosage gradually adjusted until April 7, when she received 10 units in one dose. During a control week on 10 units of old insulin in one dose she developed a marked hyperglycemia. Another control week on 20 units of regular insulin in two doses daily did not appreciably improve her condition.

COMMENT

Comparative studies show that crystalline insulin controls the diabetes with fewer units of insulin given

Chart 8—Dosage of insulin and blood sugar level in case 5. Diet: carbohydrate, 100 Gm. protein 60 Gm. fat 150 Gm.

in fewer doses. The first control periods, in which comparison is made between the minimum maintenance dose of crystalline insulin and an equal amount of old insulin, indicate that the same effect cannot be accomplished with the use of the latter.

The second control periods, in which the patient was returned to the original dosage of old insulin, did not bring about control of the diabetes as these dosages had at the start of this investigation, because they were minimum maintenance doses and not sufficient to lower the blood sugar within normal levels.

In this entire group of diabetic patients to whom crystalline insulin was given, no untoward effects either local or general were observed. It was found to be satisfactory in controlling the glycosuria in diabetic patients with such infections as abscesses of the neck, gangrene of the feet and infections of the upper respiratory tract. It was efficacious in the treatment of diabetic patients with mild acidosis.

CONCLUSIONS

1 Crystalline insulin has a slower action than old insulin and therefore produces a more gradual and more prolonged effect on the blood sugar.

2 The duration of action on nondiabetic patients is approximately thirteen to fourteen hours

3 In the treatment of diabetes mellitus, blood sugar levels are better controlled with fewer doses or with fewer total units. In many cases both the number of injections and the amount of insulin is less when crystalline insulin is used

David Whitney Building, Detroit

PRIMARY TULAREMIC ULCERS IN PHARYNX

F H McGOVERN, MD
UNIVERSITY, VA

Tularemia is a disease arousing increasing comment. In Virginia alone 105 cases were reported to the state board of health in 1932. Ophthalmologic literature frequently records the oculoglandular form of tularemia. My object in this paper is to review briefly the disease and to report a case in which the primary lesion was located in the pharynx. This case, of especial interest to the otolaryngologist, presents a primary site of infection in a region heretofore unreported in the literature.

Historically, tularemia is the first disease to be worked out entirely by American investigators, and it stands as a monument to the scientists of the United States Public Health Service. In 1911-1912 McCoy and Chapin¹ first discovered and cultivated *Bacterium tularense* in ground squirrels of Tulare County, Calif. Wherry and Lamb² first isolated the organism from a human being (conjunctiva) in 1914. They found the organisms in infected rabbits in their locality and warned of the danger of transmission of the infection from rabbits to man.³ Francis⁴ in 1919 recognized "deer fly fever" of Utah to be caused by *B. tularense* and named the new disease tularemia. Francis further contributed largely to the knowledge of the symptoms, pathology, bacteriology, transmission and diagnosis of the disease.

Tularemia is primarily a fatal disease of rodents, chiefly rabbits, and is secondarily transmitted to man from rodents by the bite of an infected tick and other blood sucking insects, by contamination of the hands with infected material, or by the ingestion of improperly cooked infected meat.

Clinically, of the four main types of tularemia—ulceroglandular, oculoglandular, glandular, and typhoidal—I am dealing here with a form of ulceroglandular tularemia. The ulcers are chronic indurations resembling the primary lesion of syphilis, appearing after an incubation period of from one to nine days, and accompanied by chills, high fever, sweating, headache and prostration. The regional adenopathy, often quite large and frequently suppurative, may appear before the primary lesion is apparent. Pulmonary manifestations⁵ consisting of pulmonic consolidation, bronchitis or

pleural effusion may follow the initial symptoms. A moderate leukocytosis with a distinct shift of the Schilling count to the left is found.

A diagnosis is ordinarily confirmed by a positive agglutination reaction of the serum against *Bacterium tularense*. This reaction becomes positive generally in the second or third week and persists indefinitely. Cross agglutinations with the organisms for undulant fever occur in about 20 per cent of cases and at times lead to confusion. Recently Lee Foshay⁶ has reported satisfactory diagnostic results with an intradermal injection of a suspension of *Bacterium tularense*. This test is said to have the advantage over the agglutination test of becoming positive much earlier in the disease.

General symptomatic treatment is usually instituted, with incision of the lymph node when necessary. The Camps⁷ have reported two cases in which intravenous mercurochrome proved to be of marked benefit. Intravenous neoarsphenamine⁸ and roentgen therapy to the primary lesion⁹ have been recommended. Foshay¹⁰ has urged the administration of his special antitularemia serum. He reports excellent results following this form of therapy: the febrile period is shortened, the symptoms are ameliorated, the prolonged disability is lessened, and the glandular enlargement is decreased. The serum is especially effective when used early in the course of the disease, and an early diagnosis can be made by the use of his intradermal test.

In the current literature are reports of several cases of tularemia presenting pharyngeal lesions. Crawford¹¹ writes of a family that contracted tularemia from the ingestion of insufficiently cooked rabbit. In one member of the family a peritonsillar abscess and enlarged submaxillary lymph nodes developed. The patient died in the fourth week of lung abscess and bronchopneumonia. His blood agglutinated *B. tularense* during the second week in a dilution of 1:80 and during the third week in a dilution of 1:1,280.

Freese, Lake and Francis¹² report three fatal cases of tularemia in which conjunctivitis occurred. The surviving patient had a swollen left eye, marked enlargement of the lymph nodes of the left superior cervical region and a slightly reddened throat. Swabs taken from the nose and throat were used to inoculate culture mediums and guinea-pigs. The guinea-pigs died and showed typical postmortem changes of tularemia in the spleen and liver. The patient's blood serum agglutinated *B. tularense* in a dilution of 1:1,280. A purulent dacryocystitis developed. Four members of the family remained well. They showed that insufficiently cooked infected meat can cause fatal lesions in experimental animals when injected subcutaneously.

Francis¹³ has also seen a case of tularemia with the primary site of infection at a pimple in the nose, which the patient had scratched while dressing a rabbit.

REPORT OF CASE

A white woman, aged 32, married, admitted to the University of Virginia Hospital, July 18, 1934, complained of an extremely sore throat of twelve days' duration. The onset of illness had

been sudden, commencing with chills, fever and sore throat. Her local physician was consulted and made a throat smear and blood culture, both of which were reported negative. Although a definite diagnosis could not be made, the case was treated as Vincent's angina by the administration of neoarsphenamine intravenously and locally to the throat. The temperature at onset had been 104 F and had remained at this height until two days before admission, at which time it dropped to 102 F. The patient's condition did not improve in spite of treatment, and the excessive dysphagia made eating almost impossible. The patient lost 10 pounds (4.5 Kg) in twelve days and felt extremely weak at the time of admission.

The positive changes on physical examination were as follows: There was a large confluent ulceration involving almost the entire right side of the posterior wall of the pharynx, many discrete shallow ulcerations measuring from 2 to 3 cm in diameter, covered with a gray exudate, were scattered over the posterior pharyngeal wall. The cervical glands were bilaterally enlarged and tender. The temperature on admission was 102.4 F. The tonsils had been removed. The eyes, nose, sinuses and ears were normal on clinical examination. No other adenopathy was noted.

The urine was normal. The white blood count was 21,000, with a distinct shift of the Schilling count to the left. A throat culture was negative for diphtheria and showed nonhemolytic streptococci, staphylococci and *Micrococcus catarrhalis*. The blood culture was negative.

Antimony and potassium tartrate intravenously and a gargle of solution of hydrogen peroxide were used immediately on the basis of a preliminary diagnosis of Vincent's angina. On the second day in the hospital a 1 per cent mercurochrome spray was tried, which gave the patient remarkable immediate relief, the pharyngeal pain and dysphagia disappearing almost entirely. Because of the high fever, the atypical course for the common pharyngeal diseases and the marked cervical adenopathy, routine agglutinations for the typhoids, tularemia, typhus and undulant fever were done. The first report showed a 4 plus agglutination against *Brucella abortus* in dilutions of 1:320 and 2 plus in dilutions of 1:1,280. A one plus agglutination against *B. tularensis* was found in dilutions of 1:640. Six days later, i. e., about three weeks after the onset of the illness, a 4 plus agglutination against *B. tularensis* was found in dilutions of 1:1,280, whereas an agglutination against *Brucella abortus* had fallen to 3 plus in 1:20, a week later the *Brucella abortus* agglutination was negative. A specimen of blood was sent to the United States Public Health Service and a complete agglutination for tularemia was found in dilutions of 1:2,560 and partial agglutination in dilutions of 1:5,120. The report on the undulant fever agglutination was negative. An intradermal test with Foshay's suspension of *B. tularensis* was negative, but this might have been occasioned by the fact that the suspension used was nearly a year old. Roentgenograms of the chest revealed a slight increase in density in both hilus zones and descending trunks on each side.

Two days after admission the patient became afebrile, and she was discharged greatly improved after eight days in the hospital. Two months after her discharge she reported by letter that she was enjoying excellent health and that the glands and sore throat had entirely disappeared. She had noticed a considerable falling out of her hair following the illness.

COMMENT

The clinical course was typical of tularemia, there was no evidence of a primary lesion on any part of the body other than the posterior wall of the pharynx and no other than cervical adenopathy was present. A positive agglutination for *B. tularensis* was obtained in the third week of the disease in dilutions up to 1:1,280 in three separate laboratories.

On direct questioning a history was obtained of picking ticks from the ears of her pet dog and crushing them between her fingers one week before the sudden onset of sore throat and high fever. The infection was evidently carried to the mouth on fingers that had

crushed infected dog ticks. Francis¹³ also believes that this is the probable mode of infection. If the organisms can be carried on the fingers to infect other parts of the body, it can probably also be carried to the pharynx. The eating of improperly cooked infected food is another way in which a primary lesion may occur.

The relief of pharyngeal discomfort achieved by the 1 per cent mercurochrome spray is of interest in view of the report by the Camps on the intravenous use of mercurochrome. The result with arsphenamine could not be evaluated because of the inadequate dosage.

Whereas tularemic manifestations in the pharynx are not common either early or late in the course of the disease, the possibility of this disease should be borne in mind in districts such as Virginia, where tularemia is prevalent.

SUMMARY

In a case of tularemia with primary ulcerations in the pharynx and bilateral cervical adenopathy, the inoculation presumably occurred from crushing an infected dog tick and carrying the organisms to the mouth on the fingers.

GONOCOCCIC ENDOCARDITIS

REPORT OF A CASE WITH POSITIVE BLOOD CULTURE

ISIDOR COHN, M.D.

BROOKLYN

Although a number of cases of acute bacterial endocarditis caused by the gonococcus have been reported in the past few years, the proved cases are still few enough, especially in view of the prevalence of gonorrhea, to make this condition a comparative rarity and to justify the report of this case.

Hoffman and Taggart,¹ reporting a case in 1932, reviewed the literature for the past decade and could find only nineteen cases reported, of which they regarded only eight as proved. Their criteria of proof were a positive blood culture *intra vitam* or a post-mortem culture from the heart valve. Positive smear from a heart lesion, without culture, they regard as only presumptive evidence and a positive complement fixation alone as questionable, since the genital infection alone would give this and it is therefore no proof by itself of gonococcal sepsis or endocarditis. Using less rigid standards, Eric Stone² in 1934, in a thorough search of the literature, found 122 cases reported with sufficient data to be critically studied. Of these only eighty-five could be regarded as proved cases in which blood or valve cultures were positive, or cultures were sterile but valve smears positive and there was a concomitant or very recent gonorrhea. In fact, acute bacterial endocarditis is itself an uncommon condition, occurring, according to White,³ as only 1 per cent of all types of endocarditis, and he quotes Thayer's table of 199 cases, of which only 11 per cent were caused by the gonococcus.

In only thirty-four of the cases analyzed by Stone was the blood culture positive, and this is the only proof of diagnosis clinically. However, the diagnosis may

safely be presumed when a patient presents the picture of ulcerative endocarditis and gonorrhea, even though the cultures remain sterile, for blood culture as the sole criterion of diagnosis in this condition is unreliable, owing to the difficulty of growing this fastidious organism on artificial mediums. As on culture mediums, the organism is often fragile on distant foci and is quickly displaced by secondary pyogenic invaders, so that it may not be demonstrable on smear or section of the infected valve. When an ulcerative endocarditis follows or is concomitant with a genital infection, therefore, the diagnosis of gonococcic endocarditis may justly be considered, in fact, sterile blood cultures, ruling out the usual bacteremic organisms, are almost as good evidence of the etiologic agent of the sepsis as a positive culture. In some cases, however, there may be no detectable evidence of genital infection at the time of the endocarditis, and many months may have passed since its occurrence. In such cases the absence of bacteriologic confirmation obviously precludes the possibility of diagnosis, and there are possibly a number of cases so missed.

Gonorrheal endocarditis is always secondary to infection of the genital tract, usually during or shortly after the primary infection. This is often mild, there is apparently little local tissue resistance, so that, instead of a barrier as in the usual case, there is a portal for early dissemination. In only a few of the cases analyzed by Stone could it be determined just when blood stream invasion had occurred, as shown by sudden chill, followed by hyperpyrexia and rapid development of the typhoid state. The usual onset is insidious, being masked by the appearance of some gonorrheal complication, most often polyarthritis. The frequency of association of arthritis and endocarditis forces the assumption that the polyarthritis is itself a manifestation of bacteremia (which is therefore a not infrequent occurrence) and that there is necessary only a locus minoris resistentiae, in the form of a damaged or congenitally defective endocardium, to permit the development of gonococcic endocarditis. It is only in the exceptional case of bacteremia that gonococcic endocarditis develops on a normal endocardium, as there have been reported many cases of gonococcic bacteremia with recovery that gave no previous history of a cardiac lesion and showed none after recovery.

The usual onset of septicemia is in the second or third week of genital infection, although, as previously noted, and as in the present case, it may occur at any time or even when there is no sign of local infection. As about 90 per cent emerge from cases of gonorrheal arthritis, all cases of joint involvement should be watched for this complication. The earliest signs are unduly high temperature during the course of the arthritis, persistence of high temperature while the arthritis is subsiding, or sudden hyperpyrexia with wide fluctuations, with or without chills, as articular symptoms are lessening.

The local endocardial lesions are rapidly destructive, and therefore signs of valvular damage appear early. In some cases, death may follow very soon after the development of the murmurs—within five days, in two cases reported by Peters and Horn.⁴ After vegetations appear, further complications, as in any other form of acute bacterial endocarditis, may arise—embolic phenomena, pneumonia, pleurisy. Nephritis is very com-

mon. Most cases end fatally, usually within a short time, but about one third run a course of two months or more.

REPORT OF CASE

A man, aged 38, was admitted Nov 6, 1935 complaining of fever and joint pains. He had been perfectly well until the onset of the present illness, which began with headache, malaise, slight chill and fever, two and one-half weeks before admission. On the fourth day, while going to the bathroom, he fainted and fell, bruising the right elbow and both knees. Shortly after this he began to have pain in both knees, and pain, redness and swelling of the right elbow. These joint symptoms subsided after a few days of baking, except for occasional recurrence of pain. He remained in bed, the temperature ranging from 101 to 104 F. One week before admission he had a severe chill and a subsequent temperature of 104, a second chill the day before admission, and another on the day he entered the hospital.

His previous history was essentially negative, except for two attacks of peritonsillar abscess and several attacks of grip. There was no knowledge of rheumatism, of any cardiac lesion or of venereal infection.

The patient was well nourished, quite pale, dyspneic, and apparently acutely ill. The pharynx was markedly injected, the tonsils were cryptic and there was no exudate. There was some submaxillary adenitis. The heart was normal in size, the sounds were of fair quality and regular, and there was a questionable impurity of the first sound at the apex. The lungs were clear, the abdomen was moderately distended but otherwise normal. The extremities showed normal articulations and arterial pulsations. The external genitalia were normal, rectal examination revealed a prostate about 50 per cent enlarged, smooth and elastic, and the right seminal vesical distended but soft and not tender.

The urine showed a faint trace of albumin, the white blood count was 22,000, with 87 per cent polymorphonuclears, the red count was 4,000,000. Hemoglobin was 76 per cent. The sedimentation rate was 73 mm in one hour. Blood chemistry figures were normal. The Kline test was negative. Blood culture was sterile.

The patient had a chill lasting thirty minutes the next day, during which he was cyanotic and very dyspneic, the temperature going to 105, and another at 5 p. m. On the fourth night he suddenly complained of numbness and pain in the right leg. Examination showed that the right femoral artery was palpable, but from there down no pulsation was felt and the leg was cold and cyanotic. There had evidently been an embolic closure at the level of the popliteal artery.

The questionable blow at the apex was now noted to be a definite systolic murmur, transmitted upward toward the pulmonic area. The next day the leg had apparently recovered to a great extent, in that it felt warm and the pallor and cyanosis had disappeared. Palpation and oscillometry, however, showed that the artery was still occluded. The surgical consultant saw no threat of gangrene, as there was apparently sufficient collateral circulation, and advised passive vascular exercise, which was instituted.

He continued to have chills at somewhat irregular intervals, usually about forty-eight hours, a temperature of from 101 to 103, with rises as high as 108 after the chills, progressive anemia, and a leukocytosis of from 22,000 to 26,000. Red and white cells and casts began to appear in the urine, coincident with increasing albuminuria. Complement fixation tests for gonorrhea were reported positive November 16 and 27, blood cultures were sterile on several examinations. Agglutination tests for *Brucella melitensis* were negative, but Widal tests were reported positive in a dilution of 1:80 November 23 and December 2. In view of the fact that the patient had been inoculated against typhoid some years before and that in the presence of fever an existing low antibody titer may be increased the test was repeated to higher dilutions and found positive 1:160.

November 26, twenty days after admission, two petechial spots with white centers were noted on the palate and a few days later several were seen on the conjunctivae and trunk. The patient was becoming very much weaker, at times drowsy, and apathetic. December 3 a new embolic area appeared in the left

⁴ Peters, H. L., and Horn, Benjamin. Malignant Ulcerative Gonococcic Endocarditis. J. A. M. A. 102: 1924 (June 9) 1934.

foot, with absent dorsalis pedis pulsation, and the general condition became much worse, with fatal termination December 4

The last blood culture had been taken December 2 and four days later began to show about twenty colonies, examination of which showed gram-negative diplococci, culturally *Neisseria gonorrhoea*

The anatomic diagnosis at the postmortem examination was ulcerative endocarditis of the mitral valve, infarcts in the spleen and kidneys, petechial hemorrhages of the skin, acute bilateral nephritis, dilatation of the right ventricle, and passive congestion of the viscera. The essential changes in the heart were petechial hemorrhages in the pericardium, measurements of 11 cm from apex to base, and 10 cm at the base. The right side was normal. The left atrium contained some clots, the foramen ovale was closed, the auriculoventricular orifice was 8.5 cm in circumference, the valves were thickened, stiff and ulcerated. Attached to the free margin of both cusps were cauliflower-like vegetations. The ventricular wall was 2 cm thick and flabby. The aortic orifice was 6 cm in circumference. The heart weighed 410 Gm.

Microscopic examination disclosed that the myocardial fibers were of good size, the nuclei stained well. Intermuscular connective tissue was not increased. The surface of the mitral valve was covered with fibrin and polymorphonuclear cells. The deeper layers were made up of homogeneous, pink-staining material, in which occasional spindle-shaped cell nuclei were seen. There were accumulations of polymorphonuclear cells in the deeper layers. In the base of the valve and the nearby thickened endocardium there was a dense infiltration of polymorphonuclear and mononuclear cells. In a preparation stained by Gram's method, granules were seen in several of the cells of the exudate, but no definite bacteria.

The seminal vesicles contained a thick, cloudy fluid, the prostate measured 4.5 by 2.5 by 2.5 cm., the cut surface was yellow and homogeneous, microscopic examination was negative.

COMMENT

This case presents several unusual features, which illustrate the difficulties often encountered in arriving at a diagnosis. In fact, were it not for the positive blood culture, in itself a rather rare observation, the diagnosis could not have been made, for there was no history nor anatomic evidence of gonorrhea except possibly the enlarged prostate and seminal vesicle. The positive complement fixation was contradicted by the equally positive Widal, so that the serologic reactions only confused the clinical picture, and the postmortem examination, while confirming the clinical diagnosis of ulcerative endocarditis, gave no hint of etiology.

There was no evidence of previous cardiac damage or defect, so that this is one of those exceptional cases in which gonococci, invading the blood stream, have caused inflammation of a normal endocardium.

Although the demonstration of gonococci in the valve would have been further evidence in this case, the failure to do so is explained by the fact that no active search was made for them until after the report of the last blood culture, by which time these fragile organisms could readily have been replaced by the secondary invaders found on culture—*B. coli* and *Staphylococcus aureus*.

This case also illustrates the importance of repeated blood cultures, and it is interesting that growth was finally obtained on ordinary Savita agar and bouillon, after failure with special mediums.

Clinical Notes, Suggestions and New Instruments

AN UNUSUAL FOREIGN BODY (BONE PEG) IN THE BLADDER

OWSLEY GRANT M.D. LOUISVILLE, K1

A woman, aged 56, fell on the stairs and injured her left hip, Oct. 9, 1934. She had no especial medical attention until October 14, when she was admitted to the hospital. Examination showed inversion and adduction of the left thigh, with some shortening, there was no active motion of the left leg, but passive motion of the hip joint was extremely painful. X-ray examination showed an intracapsular fracture of the left femur. Two days later the left trochanter was exposed, the capsule severed, and under direct vision a beef-bone peg inserted

Fig 1—Bone peg surrounded by calcification in bladder six months after insertion in left hip

through the trochanter and on into the head of the femur, holding the two in apposition. There was no perforation of the acetabulum.

There developed some moderate infection at the operative site. This infection was not severe and did not make itself evident until a week after the insertion of the peg. At that time an abscess about the wound was opened and pus evacuated. The patient remained in the hospital for three and one-half weeks, and the temperature still did not subside to normal. After removal to her home, the patient was under the care of

Fig 2—Bone peg after removal from bladder showing calcareous deposit.

the orthopedic surgeon. Her next symptoms were a very marked gastro-intestinal irritation and distention of the colon. These were so marked at one time as to raise the question of obstruction. This persisted for several weeks but subsided gradually.

Four months after discharge from the hospital, bladder irritation began and blood and mucus appeared in the urine. Two weeks of irrigation did not improve this condition and she was referred for cystoscopy. Because the patient had had some vesical disturbance even prior to operation and considering the character of the urine, a malignant condition was suggested. The bladder capacity was very small, 1½ ounces (45 cc.). The

inflamed walls seemed to surround a large, irregular, fungating mass lying in the center of the bladder. The nature of the surface of this mass was not specifically clear, it appeared to be calcification in some portions and in others that of neoplasm. A roentgenogram was then taken, which revealed the unusual picture seen in figure 1.

The bone peg was pictured migrating apparently on the same axis as that on which it had been inserted in the hip, and on about one-half its length there was evidence of a heavy deposit of salts. The bladder was opened suprapubically and it was found that the pointed end of the peg was just beginning to perforate the right wall of the bladder and that by manipulation the peg could be easily loosened and removed. On the left side a sinus extended from the bladder to the head of the femur, which could be readily palpated from the bladder. No endeavor was made to excise this sinus, which was simply curetted and the bladder then closed about a Pezzar catheter. The patient made an uneventful recovery and has now good use of both legs although the left is a little shorter than the right.

One can only estimate the length of time it took the peg to travel this course. From the amount of calcareous deposit, it must have been in the bladder for some time. Since it was six months between the insertion of the peg and its removal, and about one half of that period had elapsed after insertion of the peg before any bladder symptoms manifested themselves, it would appear that it required about three months for the point of the peg to travel from the left acetabulum to the point where it penetrated the left wall of the bladder.

Special Article

THE PHARMACOPEIA AND THE PHYSICIAN

THE USE OF DRUGS IN THE TREATMENT OF ANEMIA

MAURICE B. STRAUSS, M.D.

BOSTON

This is one of a series of articles written by eminent clinicians for the purpose of extending information concerning the official medicines. The twenty-four articles in this series have been planned and developed through the cooperation of the U. S. Pharmacopoeial Committee of Revision and THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.—ED

The past two decades have witnessed radical changes in the management of anemia. Previously treatment for all types of anemia consisted chiefly in general hygienic measures, fresh air, nutritious food, iron and arsenic to "stimulate" the bone marrow, and transfusion of blood when necessary. Today diagnosis of the specific type of anemia is of primary importance. It is recognized that anemia occurs either because of loss or increased destruction of blood, or because of decreased formation of blood. If anemia results either from acute loss or from increased destruction of blood, drug or diet therapy will be of no avail. Decreased formation of blood may be the result of nutritional deficiency or of other disturbances of the blood-forming organs. If it is due to the former, the administration of the substances specifically lacking will be followed by increased blood formation, if to the latter, such treatment is useless. The successful treatment of anemia, therefore, depends essentially on exact diagnosis. If there is doubt as to the nature of the anemia, the time

to establish the diagnosis is before, not after, the blood picture has been obscured by indiscriminate therapy. The following tabular classification of anemias on an etiologic basis will be adhered to in the consideration of therapy.

CLASSIFICATION OF ANEMIAS

- 1 Anemia due to acute blood loss
- 2 Anemias due to increased blood destruction.
 - (a) Extrinsic causes: chemicals, infections, as malaria, hemolytic streptococci, and so on
 - (b) Intrinsic causes, as hemolytic jaundice, sickle cell anemia and paroxysmal hemoglobinuria
- 3 Anemias due to decreased blood formation from nutritional deficiency
 - (a) Pernicious and related macrocytic anemias (sprue, pregnancy, pellagra, gastro-intestinal disturbance)
 - (b) Hypochromic anemias of all types (including that due to chronic blood loss)
 - (c) Anemia due to deficiency of vitamin C
 - (d) Anemia due to deficiency of thyroid secretion
- 4 Anemias due to decreased blood formation from disturbances of blood-forming organs
 - (a) Toxic: benzene, nitrogen retention, chronic sepsis, and the like.
 - (b) Physical: radiation
 - (c) Mechanical: metastatic carcinoma of bone marrow, Hodgkin's disease, leukemia and other conditions
 - (d) Idiopathic disturbances of blood-forming organs, "aplastic," Cooley's, splenic, hepatic, congenital anemias

ANEMIA DUE TO BLOOD LOSS

The fundamental point in the treatment of anemia of blood loss obviously lies in bringing about the cessation of bleeding, whether this is acute or chronic. In acute hemorrhage the immediate effects are due to the reduction of the blood volume rather than to anemia. The reduction in blood volume varies with the amount and rate of blood loss and, if severe, requires treatment by the prompt transfusion of blood. The immediate intravenous infusion of physiologic solution of sodium chloride or 5 per cent dextrose solution is of value until blood can be obtained for transfusion. However, in any type of chronic blood loss, and in many instances of severe acute hemorrhage, adequate therapy must, in addition, be instituted to promote the formation of new hemoglobin. If a surgical procedure of any magnitude is necessary to stop chronic blood loss, it is desirable at least partially, to alleviate the anemia and associated deficiency state preoperatively. Measures to accomplish this will be considered under the therapy of hypochromic anemia.

ANEMIA DUE TO INCREASED BLOOD DESTRUCTION

The proper treatment of anemia due to blood destruction lies in removing, whenever possible, the cause. If due to chemicals, their ingestion or exposure to them must be stopped. If due to infections, therapy must be directed to the removal of the offending organisms. In sickle cell anemia no therapy other than supportive measures, such as transfusion, is of value. In chronic hemolytic jaundice, particularly of the hereditary type, splenectomy may be of great benefit. In other chronic hemolytic anemias, particularly if splenomegaly is present, the removal of this organ may be of value. Since there is a conservation of blood-building materials in the hemolytic anemias, little or no deficiency of such materials occurs. Therefore therapy with iron or liver preparations is not indicated, although after the cause of hemolysis has been removed the use of iron may possibly hasten the return of the blood to normal.

ANEMIAS DUE TO NUTRITIONAL DEFICIENCY

In the anemias due to nutritional deficiency, therapy properly administered has its most brilliant successes.

(a) *Pernicious Anemia*—In the treatment of pernicious anemia, preparations of liver or stomach are to be employed. The available products are Extract of Liver, U S P XI, Solution of Liver, U S P XI, Stomach (Dried Stomach), U S P XI, stomach-liver combination (Extralain, N N R) and Purified Solution of Liver, U S P XI. The first four are for oral administration only, the last is for parenteral use. Provided an amount of such material can be and is employed which is adequate for the individual case, it is a matter of little moment as to which preparation is used. Normal erythropoiesis is possible only when the necessary building stones supplied by such preparations are available. None of these substances have any general "stimulating" effect on the bone marrow. Before prescribing one of the preparations in any given case it is therefore of paramount importance to determine that it is the type of material needed. "Shotgun" therapy is to be deplored for a number of reasons. Most mixtures of substances fail to contain enough of any one ingredient to give maximal effects. The patient must pay not only for the material he needs but also for nonessentials. Mixed therapy may so cloud the clinical picture that accurate evaluation of subsequent therapeutic needs becomes impossible. Most patients with Addisonian pernicious anemia require lifelong treatment, whereas the majority of patients with anemia due to iron deficiency, once well, will remain well unless the original cause is reestablished. Therefore, if a patient, not definitely known to have pernicious anemia, receives both liver and iron and recovers, no conclusion can be drawn as to which was the effective substance. If both should now be stopped, the patient, should he have pernicious anemia, will sooner or later relapse. In addition, he runs the risk that his relapse may be essentially neurologic and may advance to the stage of irreparable spinal cord injury before the nature of the condition is recognized. On the other hand, if the anemia is of the iron deficiency type and therapy with both liver and iron is continued, the patient is subjected to the expense and inconvenience of taking an unnecessary liver preparation.

It has been stated that it matters little which of the materials effective in pernicious anemia is employed in treatment if the amount used is adequate. Adequate therapy does not mean usual or average. It implies that a sufficient amount of material be administered not only to restore to and maintain the blood at normal in all respects but also to relieve or arrest all the signs and symptoms of the deficiency state. Pernicious and the related macrocytic anemias are diseases that may involve not only the hematopoietic but also the gastrointestinal and neural systems. Vague "indigestion," soreness of the mouth or tongue, diarrhea, even attacks closely simulating gallbladder disease may be symptoms of the deficiency state of pernicious anemia. Minot has shown that in one third of all patients with pernicious anemia it is these symptoms which are prominent at the onset. Anemia may be slight or absent at this stage. Furthermore, when relapse occurs because of inadequate treatment the symptoms may be predominantly gastro-intestinal with minimal blood changes. The neural changes of pernicious and the related anemias may simulate tabes dorsalis, spastic paralysis or simple polyneuritis. They may occur in the absence of anemia. It is obvious from a consideration of the

nature of lesions within the central nervous system that repair of completely degenerated neurons is impossible. However, adequate therapy should and does completely arrest the progress of the lesion. Reeducation in muscular coordination may enable remarkable improvement in function to appear.

The precise procedure to be followed when the diagnosis of pernicious anemia has been established depends on the factors present in the individual case. Transfusion of blood is indicated if "air hunger" or signs of circulatory failure are present at rest in the severely anemic patient. There should immediately be injected intramuscularly 10 units¹ of Purified Solution of Liver. This should be repeated on the next two days and then at weekly intervals until the blood values are normal. It is immaterial whether the 10 units is administered in a single injection or in divided doses. If transfusion is not required, the same routine of liver therapy should be followed for the severely anemic patient. When the patient with pernicious anemia first presents himself with relatively high blood values, i. e., 3,000,000 red blood cells per cubic millimeter or higher, the weekly intramuscular administration of 10 units of Purified Solution of Liver will generally suffice to bring about complete remission of the anemia. In general, parenteral therapy is preferable for the severely anemic patient, particularly as it may be exceedingly difficult to administer an adequate amount of potent material by mouth. Once the erythrocyte response has been well established, however, or if the patient is only moderately anemic when first seen, oral therapy may be employed. A minimum of 10 units of potent material should be given weekly in divided daily dosage until the blood values reach normal. Not infrequently it will be found that the red blood cells will rise steadily from low levels to the neighborhood of 4 million per cubic millimeter with such dosage but that larger amounts of potent material must be administered in order to raise the count to 5 million per cubic millimeter.

Therapy, whether oral or parenteral, with a minimum of 10 units a week should be continued in all cases for at least six months after the blood values have been normal and all other symptoms of the deficiency state have disappeared. Following such a period, one may cautiously proceed to determine the maintenance dose. It is to be emphasized that treatment must never stop in pernicious anemia. Frequently after twelve months of entirely normal existence and blood values it is safe to reduce the dose by half, that is, to 5 units weekly. If injections are employed, the most convenient practice is to administer 10 units every fortnight. If at the end of twelve months on such dosage the patient remains in perfect health, the erythrocytes number 5 million per cubic millimeter or more, and the color index and mean corpuscular volume are normal, one may try a further reduction to 10 units in three weeks or, in some cases, in four weeks. Although many patients may continue satisfactorily with as little material as this, it is to be emphasized that this does not generally occur.

When there is definite evidence that subacute combined degeneration of the spinal cord is present, therapy must be directed at this lesion. It is, of course, essential that sufficient potent material be administered to maintain the blood in an entirely normal condition, but this

1. The Committee of Revision of the U. S. Pharmacopeia has approved the labeling of antianemic preparations in terms of units. A unit is the amount of material which when given daily either by mouth or by injection has been shown in the opinion of the Advisory Board to produce satisfactory reticulocyte rises and increases in erythrocytes and hemoglobin in patients with Addisonian pernicious anemia.

is not the factor which should determine the amount to be given. A considerable number of patients will show advancing cord lesions in spite of normal blood levels. These patients must receive sufficient material to arrest completely all progress of the cord degeneration. It has been unequivocally established that such arrest can be achieved if sufficient amounts of liver extract are employed. For this purpose certain individuals may require as much as 5 units daily, an amount that it is almost impossible to administer over a period of months and years by mouth. Accordingly intramuscular injection of Purified Solution of Liver is the treatment of choice. A minimum of 35 units should be injected during the first week and at least 10 units a week thereafter. If arrest of the degeneration is not evident within a month this weekly dose should be doubled. The dose that is found adequate to arrest the lesion should be continued for at least a year and then reduced only with great caution since relapse may be rapid in onset and result in irreparable neural damage before increased therapy again controls the degeneration. It must be borne in mind that patients with pernicious anemia without neural involvement may develop cord degeneration at any time. This may occur even during treatment if insufficient material for the particular individual is being given. Careful neurologic examinations should therefore be made at frequent intervals, and any change for the worse in even a single symptom or sign should be a signal for immediate increase in the amount of therapy.

A certain number of patients presenting themselves with classic pernicious anemia will show definite evidences of iron deficiency during adequate therapy for their primary condition. This manifests itself usually after the erythrocytes have reached 3 million or more per cubic millimeter by a lag in hemoglobin production, the color index falling below unity. Treatment as outlined under hypochromic anemia should then be given in addition to therapy with liver or stomach preparations.

Macrocytic Anemias Related to Pernicious Anemia

Macrocytic anemia of the tropics encountered in association with sprue and pregnancy is to be treated essentially as has been outlined. However since iron deficiency is so common in both these conditions adequate therapy for this should be instituted as soon as evidence for its presence is manifest. The same is true for the pernicious (macrocytic) anemia of pregnancy of the temperate zone, and the macrocytic anemia of pellagra. In all these conditions dietary measures alone may suffice to bring about relief of the anemia, because many such patients retain their ability to secrete Castle's gastric factor and hence lack only the dietary or extrinsic factor. As it is a difficult procedure to determine the exact mechanism in an individual case, and as the therapy outlined is satisfactory no matter what the exact mechanism of the deficiency, it is to be recommended for all such patients. In most cases of sprue it appears advisable to continue lifelong treatment as in pernicious anemia. This is likewise true for the macrocytic anemias associated with pathologic conditions of the gastro-intestinal tract such as idiopathic steatorrhea, stenoses and anastomoses, and chronic ulcerative colitis. In the other types of macrocytic anemia, treatment may frequently be omitted following recovery, provided the precipitating factors do not recur (as pregnancy or faulty diet). In all of these anemias much larger amounts of liver or stomach preparations than the usual requirement in pernicious

anemia are frequently necessary. In certain instances of sprue an original dosage for a week or more of 10 or more units daily given by intramuscular injection may be necessary to control alimentary tract symptoms. In any type of macrocytic anemia discussed resort to parenteral therapy may turn failure or partial success with oral therapy into a satisfactory result because of the convenience of giving large dosage of active principle by the former method.

(b) *Hypochromic Anemia*—Iron in suitable form is the essential and most useful therapeutic agent in these conditions irrespective of whether prolonged faulty diet, improper assimilation or chronic blood loss is the chief etiologic agent bringing about the condition. Copper and other metals have not been proved of clinical value. Some of the official preparations of iron with the approximate daily dose necessary to secure maximum effects are Reduced Iron 3 Gm (45 grains), Mass of Ferrous Carbonate 4 Gm (60 grains), Pills of Ferrous Carbonate 4 Gm (60 grains), Iron and Ammonium Citrates 6 Gm (90 grains) and Ferrous Sulfate 1 Gm (15 grains) the dose calculated on the weight of the anhydrous salt.

The first three are relatively insoluble the last two freely soluble. When these doses are employed there is little difference in the efficacy of the various preparations although it is possible that in the presence of achlorhydria the soluble forms are superior. From the point of view of convenience to the patient the smaller effective dosage provided by ferrous compounds is an advantage. Preparations can be administered in capsules or coated tablets. Elixirs and syrups are useful vehicles for the treatment of small children. Iron should be administered daily in divided doses immediately after meals in order to minimize gastric irritation. It is rarely if ever necessary to administer iron parenterally. Should disturbances of the enteric tract be so severe that iron cannot be given by mouth from 0.1 to 0.2 Gm of Green Iron and Ammonium Citrates, U. S. P. XI, may be injected intramuscularly daily. However, marked local and systemic reactions not infrequently occur. Smaller doses of this or any other iron compound are of no significant value. Since the maximum gain in hemoglobin following the injection of iron is limited by the amount injected calculated as metallic iron organic compounds of iron offer no advantages. The smaller dose of Green Iron and Ammonium Citrates given corresponds to 16 mg of Fe and can contribute to the manufacture of but 0.6 per cent of hemoglobin in an average size adult. Thirty such injections must therefore be given to raise the hemoglobin by 20 per cent. It is to be emphasized again that iron, like liver, has no "stimulating" effect on blood formation and accordingly such injections will raise the hemoglobin only if the anemia is due to a deficiency of available iron within the body.

In certain cases of "iron deficiency" anemia there appears to be an inability on the part of the patient to obtain sufficient iron from an adequate intake of food iron. Such individuals and those with constant losses of iron (chronic bleeding, pregnancy and so on) should continue maintenance doses of iron, approximately one-third to one-half the amounts stated. Other patients ordinarily require no further therapy after the blood values are normal. Certain patients with hypochromic anemia may suffer from a partial deficiency of other materials necessary for the manufacture of the hemoglobin molecule. There is evidence that the daily administration by mouth of 200 Gm of whole liver or

the Whipple "secondary anemia fraction" derived from such an amount of liver will cause blood regeneration in certain cases of hypochromic anemia, especially when chronic blood loss is the dominant etiologic factor. However, the amount of material necessary for effectiveness comparable to that of iron preparations in small quantity makes the use of either whole liver or the Whipple fraction of little clinical value. In combination with iron such a liver fraction can be regarded only as a relatively inert and bulky component of the preparation.

(c) *Anemia Due to Deficiency of Vitamin C*—The daily administration of 6 ounces of orange juice or 100 mg of cevitamic acid (N N-R) is sufficient to alleviate the type of anemia due to deficiency of vitamin C, which occasionally occurs in association with scurvy.

(d) *Anemia Due to Deficiency of Thyroid Secretion*—This usually mild anemia is relieved by the administration of the amount of thyroid substance that will raise the basal metabolic rate to the normal range. In certain instances more severe anemias occurring with associated deficiencies of either iron or liver extract may require treatment as outlined in the preceding sections.

ANEMIA DUE TO TOXIC INHIBITION, PHYSICAL INJURY OR MECHANICAL INTERFERENCE WITH THE BLOOD-FORMING ORGANS

In all anemias due to toxic inhibition, physical injury or mechanical interference with the blood-forming organs, therapy must be directed essentially at the underlying cause of the anemia. Transfusion of blood may be of significant temporary benefit but has no specific effect. Iron, liver, stomach and so on are usually of no value but may be employed in maximal doses in order to alleviate any associated deficiency state. If the daily intramuscular injection of 5 units of Purified Solution of Liver for ten days does not produce a significant reticulocyte response, the possibility of pernicious anemia being present is minimized.

IDIOPATHIC DISTURBANCES OF THE BLOOD-FORMING ORGANS

In general, idiopathic disturbances of the blood-forming organs are not amenable to drug therapy. Certain types of congenital anemias of infants are cured by repeated transfusions. Cooley's anemia and "aplastic anemia" may be temporarily benefited by transfusion of blood. The macrocytic anemia of liver disease does not respond to any form of therapy unless there is an associated deficiency either of iron or of liver extract. It is accordingly worth while to employ a therapeutic test with each of these substances in such cases.

Splenic anemia (Banti's syndrome) very frequently is hypochromic in variety and due to a virtual deficiency of iron, in which case iron therapy is of distinct value. In many instances, however, no treatment is of any avail.

CONCLUSION

Anemias may be divided for therapeutic purposes into two main groups, those due to nutritional deficiency and those due to other causes. The anemias of the first group respond brilliantly to the administration of the proper therapeutic agents, whereas for those of the second group there is no specific drug therapy. Diagnosis is of primary importance in defining the nature of the treatment and the results to be expected from it.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
HOWARD A. CARTER, Secretary

ULTRATHERM, MODEL G, ACCEPTABLE

Manufacturer: Adlanco X-Ray Corporation, New York

The Ultratherm, Model G, is recommended for medical and surgical diathermy. It is a one-tube machine with a fixed wavelength of about 6 meters. The output of the machine is controlled by means of a rheostat to govern the voltage on the filament. There is a tuning condenser in the patient's circuit so that it can be brought into resonance. For the treatment of patients, different sized electric field electrodes with different air-gap distances or felt layers are used and are provided as regular equipment.

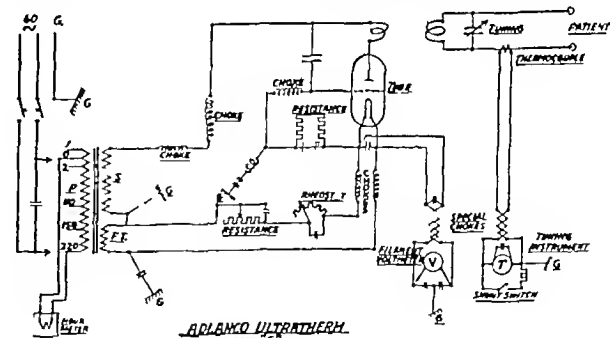

When this machine is operated under full load it draws approximately 1,000 watts. Since no reliable method has been proposed to measure the output of energy available to the patient, the value is not given.

The manufacturer submitted evidence intended to substantiate the claims made for the unit. Five-inch glass air-gap electrodes were anteriorly applied to determine whether these electrodes used on the machine were effective in producing heat within the tissues of a thigh of a human subject.

Three vigorous adult male medical students ranging from 150 to 180 pounds were used for the experiments. Two trocars placed in hard rubber cannulas were inserted into the thigh. One was inserted midway between Poupart's ligament and the knee and straight down into the depth of the muscular tissue until the instrument was at an approximate depth of 2 inches, or until the femur was encountered. The second was introduced as nearly parallel to the skin as possible and subcutaneously at an approximate depth of one-eighth inch. The trocars were removed, leaving the rubber cannulas in situ. Temperature measurements were then taken by means of thermocouples of the hypodermic needle type and introduced through the cannulas. The constant junction was immersed

Adlanco Ultratherm Model G

Schematic diagram of circuit.

in ice enclosed in a quart vacuum bottle. The electromotive force due to the difference in temperature of the junctions was read in millivolts from the Leeds and Northrup portable potentiometer. The thermocouples were calibrated in degrees Fahrenheit against a Bureau of Standards certified thermometer. Initial temperatures were taken and then each subject was submitted to a twenty minute application of maximum current intensity consistent with skin comfort. At the end of this period temperatures were again recorded until the temperature began to drop. The highest temperature attained was recorded as final temperature in each instance. Oral temperatures also were taken.

The glass air-gap electrodes were placed anteriorly (in the same plane) on the thigh equidistant from the cannulas. The

distance between electrodes, center to center, was about 9 to 11 inches. The distance from the skin to the metallic electrode (inside the glass) was about $1\frac{1}{4}$ inches.

Each reading that follows is the average of six observations obtained on the glass air gap electrodes, applied anteriorly, that is, in the same plane.

Deep Muscle Temp F		Subcutaneous Temp F		Oral Temp F	
Init	Final	Init	Final	Init	Final
98.9	106.6	97.4	105.2	98.7	99.1

It is interesting to note that application of the electrodes on the upper surface showed a substantial rise in temperature, whereas the application of the electrodes posteriorly to the thigh—one distal to the buttocks and the other proximal to the knee—did not show as high a temperature rise. With the electrodes adjusted laterally, i. e., one on the medial aspect of the thigh and the other on the lateral aspect the temperature rises were not as high as those obtained with the anterior application.

The results indicate that the temperature rise, with use of the aforementioned method of application, is considerably above what can be expected from the application of conventional diathermy—with a metal electrode on the medial aspect of the thigh and another metal electrode on the lateral aspect of the thigh—the method of application that has been adopted as a minimum standard of acceptance.¹

The temperature rise of the transformer after the machine had been operated at full load for two hours, came within the limits of safety prescribed by the Council. The shipping weight of the apparatus is about 200 pounds. Burns may be produced but may be avoided by ordinary precaution. Their likelihood to occur is much less than with conventional diathermy.

The machine was installed in a clinic acceptable to the Council and operated under actual clinical conditions. It was reported as giving satisfactory service. In view of the favorable report based on the performance of this unit when glass air-gap electrodes, applied anteriorly, were used the Council on Physical Therapy voted to include the Ultratherm, Model G, in its list of accepted devices.

Council on Foods

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COUNCIL ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

FRANKLIN C. BING, Secretary

LIBBY'S LOGANBERRY JUICE, DILUTED AND UNSWEETENED

Manufacturer—Libby, McNeill & Libby, Chicago

Description—Canned loganberry juice

Manufacture—Mature loganberries are washed and the juice is extracted mechanically, clarified, and sugar syrup is added. The sweetened juice is filled into cans, processed under vacuum, and cooled.

Analysis (submitted by manufacturer)—Moisture 83.1%, ash 0.2%, fat (ether extract) 0.01%, protein (N \times 6.25) 0.2%, total sugars 15.0%, crude fiber a trace, carbohydrates other than crude fiber (by difference) 15.3%, total acidity (as malic acid) 1.2%, pH 3.02, sodium (Na) 0.024%, potassium (K) 0.084%, calcium (Ca) 0.008%, magnesium (Mg) 0.009%, iron (Fe) 0.0004%, phosphorus (P) 0.005%, sulfur (S) 0.002%, chlorine (Cl) 0.013% and iodine (I) 0.02%.

Calories—0.62 per gram, 17.6 per ounce

Claims of Manufacturer—A wholesome canned fruit juice

¹ Mortimer Bernard and Osborne S. L. Tissue Heating by Short Wave Diathermy J. A. M. A. 104:1413 (April 20) 1935

SEXTON BRAND WHOLE BEETS, WATER PACKED

Manufacturer—John Sexton & Company, Chicago

Description—Canned whole beets, packed in water

Manufacture—Beets are washed, graded, precooked to loosen the skins, mechanically peeled, inspected again graded and filled in cans. The cans are filled with water, sealed and processed at 113 C.

Analysis (submitted by manufacturer)—(Analysis of entire contents including liquid) moisture 87.2% total solids 12.8%, ash 0.51%, fat (ether extract) 0.1%, protein (N \times 6.25) 1.5%, crude fiber 0.92%, carbohydrates other than crude fiber (by difference) 9.8%.

Calories—0.46 per gram, 13 per ounce

Claims of Manufacturer—Choice quality whole beets packed in water without added sugar or salt. For use in special diets in which sugar or salt is proscribed or in quantitative diets of calculated composition.

- (a) LIBERTY BRAND CRYSTAL WHITE SYRUP
- (b) LIBERTY BRAND GOLDEN SYRUP

Distributor—G. H. Wetterau & Sons Grocer Company, St. Louis

Packer—Union Starch and Refining Company, Granite City, Ill.

Description—(a) A table syrup, corn syrup sweetened with sucrose flavored with vanilla extract—the same as Pennant Crystal White Syrup (THE JOURNAL, Jan. 30, 1932, p. 403).

(b) A table syrup, corn syrup flavored with refiners' syrup—the same as Pennant Golden Table Syrup (THE JOURNAL, Jan. 30, 1932, p. 403).

Claims of Manufacturer—For table use and as a carbohydrate supplement for milk modification in infant feeding.

FAULTLESS BRAND TOMATO JUICE

Distributor—The L. E. Elliott Brokerage Company, Salina, Kan.

Manufacturer—Marshall Canning Company, Marshalltown, Iowa

Description—Tomato juice seasoned with salt, retaining in high degree the natural mineral and vitamin values. The same as Faultless Brand Tomato Juice (THE JOURNAL, July 18, 1936, p. 213).

DODGE BRAND VEG-ALL

Distributor—Haas Brothers Company, San Francisco

Packer—The Larsen Company, Green Bay, Wis.

Description—Mixture of carrots, potatoes, celery, green beans, cabbage, peas, corn, lima beans, onions, sweet peppers, salt and water prepared by efficient methods for retention in high degree of the natural mineral and vitamin values, the same as the accepted Larsen's Veg-All for Soups, Salads, Vegetable Dishes (THE JOURNAL, Aug. 12, 1933, p. 525).

DOWNING BRAND EVAPORATED MILK

Distributor—Downing Brothers Dairy, Rock Island, Ill.

Packer—Amboy Milk Products Company, Amboy, Ill.

Description—Canned, unsweetened evaporated milk, the same as Amboy and Melody Brands Unsweetened Evaporated Sterilized Milk (THE JOURNAL, May 7, 1932, p. 1655).

RED TURKEY BRAND HAWAIIAN PINEAPPLE TID-BITS

Distributor—J. B. Maltby Company, Corning, N. Y.

Packer—Hawaiian Pineapple Company, San Francisco

Description—Canned pineapple packed in concentrated pineapple juice with added sucrose. The same as Dole canned pineapple (THE JOURNAL, April 8, 1933, p. 1106).

SATURDAY, NOVEMBER 14 1936

THE NOBEL PRIZE IN MEDICINE

The Nobel prize in medicine and physiology for 1936 has been awarded jointly to Sir Henry Dale of London, England, director of the National Institute for Medical Research at Hampstead, and Prof Otto Loewi of the University of Graz, Austria for their work on the transmission of the nerve impulse. Sir Henry Dale is 61 years of age. He was born in London and was educated in that city. From 1904 to 1914 he was director of the Wellcome Physiological Research Laboratories. He has been secretary of the Royal Society of Medicine since 1925 and a member of the General Medical Council since 1927. He came to the United States in 1919 and delivered the Herter Lectures at Johns Hopkins University, Baltimore, and again in 1933 to deliver the Charles Dohme Lectures, the subject being at the latter time 'Progress in Auto-pharmacology, A Survey of Present Knowledge of the Chemical Regulation of Certain Functions by Natural Constituents of the Tissues.' His Linacre Lecture on "Chemical Transmission of the Effects of Nerve Impulses" was published in the *British Medical Journal* May 12, 1934, his Dixon Memorial Lecture on "Pharmacology and Nerve Endings" was published in the *Proceedings of the Royal Society of Medicine* in January 1935. Among numerous other publications Sir Henry Dale and his associates published a paper entitled

"Release of Acetylcholine at Voluntary Motor Nerve Endings," in the *Journal of Physiology* May 4, 1936.

Prof Otto Loewi is 63 years of age. He was born in Frankfort-on-the-Main, Germany, and graduated at Strasbourg in 1896. After working for a time at Frankfort under von Noorden, Dr Loewi entered the Pharmacologic Institute at Marburg in 1896. He went to Vienna as a professor in 1906 and since 1909 has been director of the Faculty of Pharmacology at the University of Graz. Among his numerous writings was a paper written in collaboration with E. Pichler, entitled "Glycogen Metabolism in Muscle and Its Nervous Control, Proprioceptive Glycogenetic Reflex," published in 1933. Dr Loewi came to New York in 1933 to deliver a Harvey Lecture on "The Humoral

Transmission of Nervous Impulses." He has published papers also on diuresis, the vegetative nervous system, diabetes, and other subjects.

In 1895 Alfred Nobel gave several millions of dollars to found the Nobel Commission, which he directed to award the interest each year among the five persons who in the preceding year had contributed the greatest work in medicine and physiology, in physics, in chemistry, in literature, and for the peace of the world. The final selection of the individual to receive the Nobel prize in medicine and physiology rests with the faculty of the Caroline Institute in Stockholm. The prize consists of a medal, a diploma and about \$40,000 in cash. The medical prize was awarded to persons living in the United States or Canada in 1912 (Carrel) in 1923 (Banting and Macleod) in 1930 (Landsteiner) and in 1934 (Minot, Murphy and Whipple).

BIG BABIES AND DIABETES

Repeatedly the observation has been noted in medical literature that diabetic mothers have large babies. Joslin has pointed out that fat babies born dead suggest examination of the parents for diabetes. Bowcock and McCord¹ have reported an instance of a mother giving birth to babies said to have weighed 12, 15½, 14 pounds, and 12 pounds 2½ ounces (5,443, 7,030, 6,350 and 5,514 Gm). In her sixth pregnancy, after normal gestation, she bore a baby weighing 12 pounds 2 ounces (5,500 Gm). In her seventh pregnancy she developed diabetes and, when labor was induced, gave birth to dead twins weighing a little over 3 pounds (1,360 Gm) each. By the use of insulin and diet she was made sugar free. When she next became pregnant she was kept sugar free without insulin, on a restricted diet and gave birth at term to a baby weighing 13 pounds 7½ ounces (6,109 Gm). All the babies were oversize in respect to height and weight.

In a record of large babies born in Great Britain, Dr W. F. Christie² indicates that infants heavier at birth than 10 pounds (4,535 Gm) may be postmature rather than obese and does not indicate any relationship to possible diabetes. The largest babies born, according to American medical records, include a case described by Dr D. P. Belcher³ of a woman who gave birth to a baby girl (stillborn) that weighed 25 pounds (11,340 Gm). There is also an authentic record of a baby born in Italy weighing 24½ pounds (11,294 Gm), and Birnbaum discusses the case of a child weighing 11,300 Gm at birth.

A most comprehensive recent consideration of the subject is that of Kaern⁴. Weight of the new-born above 6,000 Gm is apparently found once in 200,000

¹ Bowcock, Harold and McCord, J. R. The Occurrence of Diabetes During Pregnancy in a Woman Bearing Large Babies. *J. A. M. A.* 94: 1917 (June 14), 1930.

² Christie, W. F. Prodigious Infants. *Brit. M. J.* 1: 373 (Feb. 23) 1935.

³ Belcher, D. P. A Child Weighing Twenty Five Pounds at Birth. *J. A. M. A.* 67: 950 (Sept. 23) 1916.

⁴ Kaern, T. On the Birth of Abnormally Big Children. *Acta obst. et gynec. Scandinav.* 10: 169-201 1916.

births, while weight exceeding 4,000 Gm is met in every thirty births. Surgical intervention usually becomes necessary when the child weighs more than 4,500 Gm. Kaern considers protracted pregnancy the chief factor responsible for increased fetal growth. The race, constitution and heredity of the parents, the age of the mother, the previous childbirths, and particularly pregnancy in diabetic women not treated with insulin are also important etiologically. In the delivery of large babies, the difficulties concerned with the shoulders are especially significant. The death rate among large babies is 14.9 per cent, in contrast to the average death rate of 3.2 per cent. Kaern is convinced that when there is a suspicion of giant birth it is not only justifiable but even indicated to induce delivery at a time when the fetus is deemed to have acquired normal birth weight. The suspicion of a giant child arises particularly in cases in which the woman has previously given birth to large children or the pregnancy lasts too long. Obviously, the presence of diabetes demands immediate control by restricted diet and insulin. The classic contribution on this subject by Randall and Rynearson,⁵ published recently in *THE JOURNAL*, merits most careful consideration by every physician interested in obstetrics, metabolism and the care of the child.

LIFE EXTENSION INSTITUTE ENJOINED FROM PRACTICING MEDICINE

The Life Extension Institute, a New York corporation, has been enjoined from practicing medicine in that state. Since its organization in 1914, this corporation has been engaged in promoting and conducting periodic medical examinations on a nation-wide scale. It has had contracts with large insurance companies for the annual examination of policyholders through local cooperating physicians paid by the corporation. It has made similar services available to individuals. While the medical examinations were made by local physicians, the reports were forwarded to the central office of the corporation and there reviewed by its medical staff. Suggestions with respect to needed medical treatment were outlined by the home office and transmitted to the examinees. Urinalyses four times each year constituted a part of the services rendered by the corporation to examinees. For making these physical examinations and for reporting to the examinees, the institute made a charge considerably in excess of the amount paid by it to local examining physicians. In 1935 the state instituted proceedings in the Supreme Court of New York, New York County, to dissolve the corporate status of the corporation and to revoke its charter on the ground that its activities constituted the practice of medicine, in which practice it could not lawfully engage. By consent of the parties, the Supreme Court appointed a referee to determine the issues.

After a number of hearings but before the state had finished presenting its evidence against the Life Extension Institute, the hearings were suspended because of negotiations between the Life Extension Institute and the state's attorney general to effect a settlement out of court. A stipulation was signed by the institute and by the attorney general in which the institute voluntarily assented to the entry of a decree against it, to embody the prohibitions and other provisions contained in the stipulation. The decree was thereafter entered enjoining the corporation from "practicing medicine and/or from holding itself out as being able to diagnose, treat, operate or prescribe for any human disease, pain, injury, deformity or physical condition and/or from offering or undertaking, by any means or method, to diagnose, treat, operate or prescribe for any human disease, pain, injury, deformity or physical condition." Furthermore, the decree specifically denies to the corporation the right to engage, directly or indirectly, in making physical examinations or reports and recommendations based on such examinations and from employing any physician to perform these activities for it. The corporation is permitted, under the decree, to maintain laboratories and to employ physicians to perform such services as may be legal and proper in connection with the operation of such laboratories. The corporation may, for compensation, supply "services" to physicians and others, when such services do not constitute the practice of medicine. It may not, however, receive any part of the compensation paid to physicians for the rendition of medical services. The corporation may not direct, supervise or control the medical services rendered by any physician who has been furnished any "services" by the corporation. The corporation may furnish to any physician who is interested in and specializes in life extension work "offices, laboratory facilities, work or services, financial assistance, clerical and other lay help, files, records, data, statistics and any other utilities or services not of a medical character." It is expressly stipulated, however, that the corporation may in no event receive from such physicians compensation constituting "an interest, direct or indirect, in fees to be paid said physician or group of physicians for professional services in the practice of medicine." In view of the stipulation and the decree that was based thereon, no judgment was rendered dissolving the corporation.

Under the decree, the Life Extension Institute may continue to exercise corporate powers but may not practice medicine, directly or indirectly, in any form. The referee, in the opinion that he filed along with the entry of the decree, emphasized the fact that a statute prohibiting the corporate practice of medicine serves a wholesome purpose, because the relation between a physician and his patient is and must be a personal and confidential one, which can exist only when the physician is a natural person.

Current Comment

MORTALITY FROM TUBERCULOSIS

The New York Tuberculosis and Health Association has recently summarized in an easily understandable form the deaths occurring from tuberculosis in the larger cities of the United States during the years 1934 and 1935. The total mortality of forty-six large American cities was 71.4 per hundred thousand in 1934 and 69.6 per hundred thousand in 1935. The third largest city in the group, Philadelphia, showed one of the largest declines, 12 per cent. The largest percentage decline was, however, that of Oklahoma City, which showed a 40 per cent reduction from 1934 to 1935 and gave in 1935 the lowest death rate for tuberculosis of any city in the list. The Negro tuberculosis mortality was given for forty-three cities during these years. In all instances the death rate among the Negroes was markedly higher than among the white population of the same cities. In many instances it was four or five times as large. The trend of mortality was also not as favorable among the Negroes as among the white population, though this might possibly be due to factors such as migration, which cannot be estimated from the gross figures given. Thus, the figures cited revealed a gross increase in deaths from tuberculosis among Negroes 0.4 per cent higher in 1935 than in 1934. As has been repeatedly pointed out, however, gross figures are difficult of analysis other than to show a general trend.

SULFHYDRYL IN DIBENZANTHRACENE CARCINOMA

A number of compounds containing the sulfhydryl group have been shown to increase the rate of cell division under certain conditions. Also it has been repeatedly demonstrated that a number of phenanthrene derivatives, including 1,2,5,6-dibenzanthracene, are carcinogenic when repeatedly applied to the skin of mice. Questions logically arise regarding the effect of applying the two substances sulfhydryl and dibenzanthracene simultaneously. One might expect that a synergistic effect would be produced and that there would be a greater percentage of tumor incidence in the treated animals and perhaps also that a shorter period would be required for the development of the growth. This possibility has been subjected recently to an experimental study.¹ Large numbers of white mice were treated daily, six days a week, for as long as twelve to fifteen months with either dibenzanthracene alone or with this substance and the sulfhydryl compound parathiocresol, applied either singly or in combination on alternate days or during alternate periods of several weeks each. The time of appearance of tumors was recorded and the growth was examined histologically. Contrary to what might be expected there was a decided decrease in the incidence of tumor formation and, in those animals in which a tumor did appear, there was an increase in the length of the period required for the development of the growth. A microscopic examination revealed rather characteristic

changes in the skin of the treated animals. The skin of the mice treated with parathiocresol alone was characterized by the presence of larger numbers of epithelial cells than normal skin and the various layers of the epiderm and the basement membrane were defined more clearly. There was little or no inflammatory reaction in the epiderm itself or in the underlying tissues. The skin of the animals treated with dibenzanthracene alone was also thickened and the layers were well defined but to a less extent than those in the skin to which parathiocresol had been applied. In contrast to the response to the sulfhydryl compound, however, inflammatory reactions were nearly always observed and keratinization of the skin was much more pronounced. Both types of histologic response were usually observed in the skin of the animals treated with the combinations of sulfhydryl and dibenzanthracene. According to the authors, the apparent anticarcinogenic effect of the sulfhydryl compound is not due to a simple, direct chemical "neutralization" of the two compounds but is exerted by way of the animal itself and specifically involves the skin.

THE TREATMENT OF MALARIA

The multiplicity of therapeutic agents now available for the treatment of malaria and the conflicting claims of efficacy made for them create much therapeutic confusion. To date the most authoritative consideration of the question is the report of the Malaria Commission published in the *Quarterly Bulletin* of the Health Organisations of the League of Nations.¹ The extensive review of the action and value of the various drugs embodied in this report is based on numerous laboratory and clinical observations. The status at the time of the report is summarized thus: "The new synthetic remedies now available are still in the experimental stage, and they [members of the commission] consider that the time has not yet come when any of these drugs can be recommended as substitutes for, or in preference to, quinine and other preparations of cinchona bark." The commission believed that quinine is effective for the purpose of clinical prophylaxis and that it remains the best drug to use. It is not good practice, according to the commission, to treat attacks of malaria in the acute stage with more than one of the specific drugs available. For treatment of an acute attack of benign tertian and quartan malaria, quinine and atabrine seem to be about equally effective. Atabrine, however, is definitely superior to quinine for the treatment of acute attacks of malignant tertian malaria. For the treatment of relapses the commission felt that no drug or combination of drugs seems yet to be available which will sterilize all the parasites in the human host and thus prevent the possibility of relapse. Plasmochnin, unlike quinine and atabrine, has a powerful action against the gametocytes of malignant tertian malaria. The problem therefore retains some characters of confusion, much of which, however, can be eliminated by knowledge of the indications and limitations of the more widely used preparations.

THE ATLANTIC CITY SESSION

Application Blanks Now Available for Space in the Scientific Exhibit

Application blanks for space in the Scientific Exhibit at the Atlantic City session are now available. The Committee on Scientific Exhibit requires that all applicants for space fill out the regular form. Applications close Feb 1, 1937.

Blanks may be obtained from the Director, Scientific Exhibit, American Medical Association, 535 North Dearborn Street, Chicago.

RADIO BROADCASTS

The American Medical Association and the National Broadcasting Company are presenting the second series of dramatized health broadcasts under the title *Your Health*. The first broadcast in the new series the thirty-second dramatized cooperative broadcast under the title *Your Health* was given October 13. The theme for 1936-1937 differs slightly from the topic in the first series, which was "medical emergencies and how they are met." The new series is built around the central idea that "100,000 American physicians in great cities and tiny villages who are members of the American Medical Association and of county and state medical societies stand ready, day and night to serve American people in sickness and in health."

The program will go out on the Blue network instead of the Red as originally announced. The announcement cards that were sent out when the program was planned for the Red network can be changed simply by substituting the word "Blue" for "Red" where it occurs.

The topics are announced monthly in advance in *Hygiene*, the Health Magazine, and three weeks in advance in each issue of *THE JOURNAL*. The topics and speakers for the next three programs are:

November 17	Football Injuries	Morris Fishbein M.D.
November 24	Be Thankful	W. W. Bauer M.D.
December 1	Smog	W. W. Bauer M.D.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ALABAMA

Society News—Dr Charles LeBaron, Gulfport, Miss. was chosen president of the Gulf Coast Clinical Society at its meeting in Mobile, October 16. Other officers are Drs. Herbert L. Brvans, Pensacola, Fla., and James H. Dodson, Mobile vice presidents, and Mozart A. Lischkoff, Pensacola, secretary.

CALIFORNIA

Plague Infection in San Bernardino County—According to *Public Health Reports*, plague-infected fleas were found in San Bernardino County recently. Fleas collected from ground squirrels were inoculated into a guinea-pig and the animal showed typical plague infection on the fifth day. In 1933 a human case of plague was suspected to have originated in San Bernardino County and during the present year positive plague agglutination was found in the blood of another person after a mild illness that occurred while camping in this county.

Society News—Dr Maude E. S. Abbott, Montreal, Canada, addressed the San Francisco County Medical Society, November 10 on "Congenital Heart Disease."—Comdr Joel T. Boone, San Diego chief medical officer of the fleet marine force, U. S. Navy presented "Reflections of a White House Physician" before the Hollywood Academy of Medicine November 5.—At a joint meeting of the Los Angeles Society of Neurology and Psychiatry, the Southern California Society for Mental Hygiene and the California branch of the American Eugenic Society, November 9, a symposium on some medical

aspects of mental hygiene was presented by Drs. Arthur R. Timme, Rupert B. Raney, Eugene Ziskind and Samuel D. Inghram. All are from Los Angeles.

Scope of Chiropractic Practice—According to a decision recently handed down by the superior court of California city and county of San Francisco in *McGranaghan v. Berger et al* chiropractors in California may not prescribe or administer drugs, use electrotherapy, hydrotherapy or other forms of physical therapy, may not practice surgery or obstetrics, may not treat the eye, ear, nose and throat and may not reduce fractures generally. The chiropractic initiative measure, said the court in authorizing chiropractors to practice chiropractic 'as taught in chiropractic schools and colleges' does not confer on chiropractors the right to employ any agency the use of which may be taught in chiropractic schools. The agency must constitute chiropractic and must not fall within the field of the practice of medicine and surgery. The measure in further permitting chiropractors to use all necessary mechanical and hygienic and sanitary measures incident to the care of the body 'permits chiropractors in the opinion of the court to use roentgen rays for diagnostic but not for therapeutic purposes.'

CONNECTICUT

Meeting of Alumni Association—Dr Arthur M. Yudkin, clinical professor of ophthalmology, Yale University School of Medicine, New Haven, was elected president of the Association of Yale Alumni at its recent annual meeting. He succeeded Dr. George Blumer. David P. Smith, clinical professor of medicine at Yale. Other officers include Dr. Clyde L. Deming, New Haven, chairman of the executive committee and Dr. Philip Frank, Brooklyn, N. Y., chairman of the literary committee, succeeding the late Lafavette B. Mendel, Ph.D.

DISTRICT OF COLUMBIA

Request for Health Centers—A request of Dr. George C. Ruhland, health officer of the District, for two new health centers was endorsed by the Medical Society of the District of Columbia at a meeting October 7. Dr. Ruhland has asked for \$1,250,000 to construct five medical centers over a period of years, the first two to be started next year, newspapers reported.

Society News—The Medical Society of the District of Columbia was addressed, November 11, by Dr. Edmund Horgan on 'New Technic for Thoracoplasty' and Mr. J. E. Curtis, superintendent, 'Purification of the Water in the Washington Filtration Plant.' The society will be addressed November 18, by Drs. George Louis Weller, Jr. on 'Bone Marrow Findings in the Diagnosis of Certain Blood Dyscrasias' and Robert E. Moran, 'Plastic Surgery Around the Orbit.'

Campaign Against Diphtheria—The department of health of the District launched a diphtheria immunization campaign October 5, to continue six weeks. It is aimed to reach pre-school and kindergarten children, clinics to be conducted in designated public schools. Public interest will be stimulated through the radio and press. The staff of the health department will be augmented on a temporary part time basis this increase in expenditures to be financed by social security funds.

GEORGIA

Georgia's Health—There were 34,313 deaths reported in Georgia in 1935, giving a death rate of 11.3 per thousand of population as compared with 11.8 in 1934. Deaths from automobile accidents showing a gradual increase since 1921, jumped from 774 deaths in 1934 to 903 deaths in 1935, giving respective rates, per hundred thousand of population, of 25.7 and 29.8. Heart disease accounted for 5,071 deaths in 1935 and a rate of 167.3, as compared with a total of 5,019 deaths and a rate of 166.9 in 1934. A decrease was noted for cancer, 1,715 deaths being registered in 1935 with a rate of 56.6 as compared with 1,762 deaths in 1934 and a rate of 58.6. The department of health reports that for many years smallpox was an important cause of death in Georgia. In the past five years however, there has not been more than one death annually attributed to this cause. In 1935 there were 365 deaths from pellagra giving a rate of 12, while in 1934 there were 351 a rate of 11.7. Malaria accounted for 387 deaths and a death rate of 12.8.

Society News—The Thomas County Medical Society was addressed at Thomasville recently by Drs. Chapman Q. Dikes, Carrabelle, Fla., on treatment of pneumonia, and Simeon E. Sanchez, Barwick, cancer.—At a recent meeting of the Muscogee County Medical Society in Columbus, Dr. Daniel C. Elkin, Atlanta, spoke on 'The Surgical Treatment of Tuber-

culosis," and Dr William C Warren Jr, Atlanta. The Intracranial Complications of Otitis and Mastoiditis"—A symposium on syphilis was presented before the Seventh District Medical Society at its meeting in Marietta, September 30.—Dr Thomas F Harper, Coleman, addressed the Randolph County Medical Society in Cuthbert, October 1, on pellagra.—The Ware County Medical Society at its meeting in Waycross, October 7, heard Dr Wilbur C Hafford discuss inguinal granuloma.—Among others, Dr Charles D Bowdon, Atlanta spoke on 'The Present Status of Malaria and Its Treatment' before the Eighth District Medical Society in Douglas, October 13.

ILLINOIS

Society News—Dr Eric Oldberg, Chicago, addressed the Sangamon County Medical Society, Springfield, November 5, on 'The Cerebrospinal Fluid'.—Dr Willard Van Hazel, Chicago, addressed the Winnebago County Medical Society in Rockford, October 13 on 'Surgery of the Lungs and Pleura'.—Drs John P O'Neil and Joseph A Jerger, both of Chicago discussed artificial fever therapy before the Kane County Medical Society in Elgin, October 14.

Chicago

Society News—Dr Charles Gordon Heyd, New York, President, American Medical Association, will address the Chicago Medical Society, November 18, on 'Liver Deaths' and the Complications of Gallbladder Surgery,' and Dr Ralph C Sullivan clinical professor of surgery, Loyola University School of Medicine 'The Operating Room Diagnosis of the Gallbladder'.—Dr George W Crile, Cleveland, addressed the North Side Branch of the society, November 5, on 'Comparative Anatomy of the Energy Controlling System'.—Among others, Drs Harry P Ritchie, St Paul, and Otto W Yoerg Minneapolis, discussed 'Another Suggestion in the Technic of Cholecystectomy for the Selected Case' and 'Fracture of Os Calcis' respectively before the Chicago Surgical Society, November 6.—At a meeting of the Chicago Council of Medical Women, November 6 Dr Marie Ortmayer discussed 'Clinical Values of Gastrosocopy'.—The Chicago Pathological Society was addressed, November 9, by Dr Paul R Cannon and George Hartley Jr on 'The Inadequacy of Allergic Inflammation as Protection Against Infection with Virulent Pneumococci'.—Prof Bernhard Dattner of the University of Vienna addressed the German Medical Society of Chicago, November 3, his subject was 'Modern Therapy of Neurosyphilis'.—Dr Dattner gave a lecture at Michael Reese Hospital, November 2, on 'Nervous Manifestations of Alimentary Hypersensitivity'.—At a meeting of the Chicago Gynecological Society, November 20, papers will be presented by Drs William C Danforth, Evanston, Ill, on 'Carcinoma of the Cervix During Pregnancy', William B Serbin, Splenomegaly in Pregnancy', and Julius E Lackner and Leon Krohn, 'Effect of Ovarian Hormones on the Human (Nonpuerperal) Uterus'.—The Chicago Orthopaedic Society was addressed, November 13 by Drs W Eugene Wolcott Des Moines, Iowa, on 'The Circulation of the Hip with Practical Suggestions Regarding Prognosis in Certain Types of Fractures of the Neck of the Femur' and Frank G Murphy, 'Osteochondritis Dissecans'.

INDIANA

The Service of Dr Wishard.—At the October meeting of the board of trustees of Indiana University, resolutions were passed in commemoration of the many years of service to the medical school of Dr William N Wishard, who recently retired as professor and chairman of the department of genito-urinary surgery. He had occupied this position since 1897 (THE JOURNAL, August 22, p 592).

Society News—Dr Frank C Walker will discuss "Bladder Symptoms Secondary to Cervical Lesions" before the Indianapolis Medical Society November 17 and Dr Dudley A Pfaff, 'Pancervical versus Supracervical Hysterectomy'. The society will be addressed, November 24 by Drs Edwin W Dyar Jr on 'Eye Problems in Childhood' and Francis C Smith 'Dermatology in Pediatrics'.—Dr Harrison S Martland Newark, N J, spoke on the relation of medicine to crime November 10.—The Wayne-Union Counties Medical Society was addressed in Richmond October 22 by Dr George S Bond, Indianapolis on cardiology.—At a meeting of the Montgomery County Medical Society in Crawfordsville, October 22, Dr James F Balch Indianapolis discussed urology.—Dr Rollin H Moser, Indianapolis addressed the Henry County Medical Society in Newcastle October 15 on treatment of diseases of the stomach.—Dr John C Davis Logansport

discussed complications in the second and third stages of labor before the Cass County Medical Society, October 15.—At a meeting of the Fayette-Franklin County Medical Society in Connersville, October 13, Dr Clifford J Strachley, Cincinnati spoke on the treatment of heart disease.—Dr Jacob Meyer, Chicago, addressed the Tippecanoe County Medical Society in Lafayette October 13, on peptic ulcer.

IOWA

Rural Health Meetings—The extension service of the Iowa State College of Agriculture and the state department of health will hold health meetings in fifty three counties beginning the week of November 7, for residents in rural areas. The program will include a get-together meeting in each quarter of the county from Monday through Thursday. On Friday and Saturday of the same week a county-wide conference of farm leaders will be held at the county seat, under the direction of the state department of health, to discuss what organized groups can do to improve and extend local health services.

Basic Science Certificate and Reciprocity—The basic science act of Iowa authorizes the board of examiners in the basic sciences, in its discretion, to issue a certificate without examination to an applicant who has passed an examination in anatomy, physiology, chemistry, pathology, bacteriology and hygiene, given by a board of examiners in the basic sciences or by a licensing board in another jurisdiction, provided the examination passed by the applicant was as comprehensive and exhaustive as the examination required under the Iowa act. On October 13, the Iowa board promulgated a regulation that hereafter no applicant will be exempt from examination unless he has successfully passed an examination in the subjects named given by a 'board of examiners in the basic sciences in another state with which reciprocity relations have been established.' This ruling apparently makes it impossible for a physician licensed in a jurisdiction in which the basic science requirement is not in effect to obtain reciprocity with Iowa without passing the Iowa basic science examination.

KANSAS

Society News—Dr Erastus S Edgerton discussed 'Malignancies of the Colon' before the Sedgwick County Medical Society, Wichita, November 17, and Dr Fred J McEwen conducted a cardiac clinic. Drs Wirt A Warren and Joseph S Reifsneider, Wichita, among others, addressed the society, November 3 on 'Treatment of Chronic Arthritis' and 'Safety Line in Acute Otitis Media'.—The Pratt County Medical Society was addressed, October 23, by Dr Willard J Kiser, Wichita, on 'Carcinoma of the Breast'.—At a meeting of the Butler-Greenwood County Medical Society, October 16, Dr George B Morrison, Wichita, spoke on 'Statistical Comparison and Practical Considerations of Transurethral Prostatic Resection'.—Dr Chester H Warfield, Wichita, discussed 'Bone Tumors and Allied Bone Lesions' before the Sumner County Medical Society, October 22.—Dr Edgar A Pickens, Wichita, read a paper on 'Prostatic Resection' before the Meade-Seward County Medical Society, November 6.—Dr Lee V Hill, Kansas City, gave an anatomic demonstration on infections of the foot before the Wyandotte County Medical Society, November 3, and Dr Fred E. Angle, Kansas City, discussed coronary disease.

MARYLAND

Child Health Conferences—More than 2 800 children were examined during the fifteen weeks of the annual tour of the healthmobile of the state department of health. Nine counties in southern Maryland and the eastern shore were visited. Of the children examined 2,170 needed follow-up care, 1,224 had not been vaccinated, about 397 were underweight, 333 had unhealthy tonsils and eighty-one were 'mouth breathers.'

MASSACHUSETTS

New Society of Gastro-Enterology—The Boston Society for the Advancement of Gastroenterology was organized at a meeting in the Harvard Club September 24 to stimulate interest in the relation of gastro-enterology to the practice of general medicine and the various specialties and in the relation of other fields of medicine to gastro-enterology. Meetings will be held from October to May, and dues will be \$5. The society is a local chapter of the National Society for the Advancement of Gastroenterology. Officers are Drs Charles W McClure president, William R Morrisson vice president,

and Lester R. Whitaker, secretary-treasurer. The affairs of the society will be administered by an executive committee consisting of two elected members and the officers ex officio. The elected members are Drs. Henry Baker and Louis F. Curran. A clinical meeting was held at the Boston City Hospital, November 10.

"Eye Specialist" Bernstein Pleads Guilty—Samuel Bernstein, New Orleans, pleaded guilty in Middlesex Superior Court, East Cambridge, October 14, to a charge of conspiracy and larceny of \$500. In the meantime, he has been turned over to other authorities in Massachusetts who wanted him for the same type of fraud. Bernstein was said to be one of three men traveling about the country representing themselves as "eye specialists." In this instance his companions were said to be Ernest Mandell and Jack Shaw. The general procedure of "eye specialists" has been described at various times in THE JOURNAL. "Liquid rindum" is dropped into the eye, the substance congeals and is then removed with the claim that it is a cataract. Bernstein was identified through a police picture and returned voluntarily after he was located in New Orleans, not, however, until he was threatened with extradition. A man involved in a similar swindle in 1934 gave the name S. Bernstein (THE JOURNAL, March 17, 1934, p. 849). He and another man giving the name E. J. Mandell or Mendell were arrested but were released for want of proof on condition they would return the \$300 involved.

Society News—Dr. Israel M. Rabinowitch, Montreal, Canada, addressed the Greater Boston Medical Society, November 10, on "Effects of Protamine-Zinc-Insulin and Other Mixtures of Zinc and Insulin in Diabetes Mellitus."—The health developments in Massachusetts under the social security program was the theme of the Massachusetts Conference of Social Work, November 7, in Boston, speakers were Drs. Henry D. Chadwick, state health commissioner, Mary Louise Diez, director, division of child hygiene of the state department of public welfare, and Edward G. Huber, assistant director, division of administration.—Among speakers before the New England Heart Association in Boston, November 9, were Drs. Ashton Graybiel on "The Effect of Inhalation of Tobacco Smoke on the Electrocardiogram," and Paul D. White, "The Growing Importance of Cardiac Neurosis."—Dr. Thomas B. Quigley, Boston, discussed "State Medicine in Sweden" at a meeting of the Essex South District Medical Society, November 4.—Samuel Eliot Morison, Litt D, professor of history, Harvard University, presented high lights in Harvard medical history before the Harvard Medical Society, November 10.

MICHIGAN

Dr. Byington Accepts New Position—Dr. Garner M. Byington, Battle Creek, for four years medical director of the W. K. Kellogg Foundation, has resigned to become director of medical relations in the Detroit Department of Health, newspapers report. In his new position Dr. Byington will carry out a child health program in Detroit similar to that sponsored by the foundation in rural districts. Dr. Byington is a graduate of Wayne University College of Medicine, Detroit.

Changes in Faculty at Wayne University—Dr. Charles G. Johnston, Harriet M. Frazier, fellow in research surgery, and instructor in surgery, University of Pennsylvania School of Medicine, Philadelphia, has been appointed professor and head of the department of surgery at Wayne University College of Medicine, according to an announcement. Dr. Warren O. Nelson, formerly research assistant in anatomy, Yale University School of Medicine, New Haven, Conn., has been named professor and head of the department of anatomy. Dr. Gordon B. Myers has been appointed professor and acting head of the department of medicine. Dr. Ward F. Seeley, professor of obstetrics and gynecology, has been made also acting head of the department, and Dr. Thomas B. Cooley has been named professor and head of the department of pediatrics. Dr. Seeley succeeds Dr. H. Wellington Yates, who becomes professor emeritus. The appointment of Dr. Hugo A. Freund as professor of clinical medicine was also announced.

MINNESOTA

One Year at Hard Labor—Mels White, alias Mike Roller, alias Marion Roller, alias Marion Royle, pleaded guilty to a charge of practicing healing without a basic science certificate, October 8, at Rochester, and was sentenced by Judge Vernon Gates to one year at hard labor in the Olmsted County Jail. White, who claims to be a full blooded Osage Indian from Oklahoma, has spent most of the past ten years in the state prison on various charges.

Health at Minneapolis—Telegraphic reports to the U. S. Department of Commerce from eighty-six cities with a total population of 37 million, for the week ended October 31, indicate that the highest mortality rate (1933) appears for Minneapolis and that the rate for the group of cities as a whole was 111. For the corresponding period last year the mortality rate for Minneapolis was 89 and for the group of cities, 109. The annual rate for eighty-six cities for the forty-four weeks of 1936 was 121 as against a rate of 113 for the corresponding period of the previous year. Caution should be used in the interpretation of these weekly figures, for they fluctuate widely.

MISSOURI

Society News—The St. Louis Medical Society was addressed, October 27, by Drs. Lex G. McCutchen on "Comparative Values of Radium and Contact X-Ray Therapy in the Treatment of New Growths," Thomas P. Findley, Jr., "Observations on the Mechanism of Urine Formation," and John W. Thompson, "Results in the Surgical Treatment of Carcinoma of the Gastro-Intestinal Tract."—The Boone County Medical Society was addressed in Columbia, October 6, by Drs. William T. Coughlin and James L. Mudd, St. Louis, on "Malignancies That Involve the Mouth and Jaws" and "Chronic Lung Suppuration" respectively.—Dr. Gervais D. Smith, Bolivar, among others, addressed the Dallas-Hickory-Polk County Medical Society, October 6, on "Recognition and Treatment of Menopausal Disturbances."—Dr. George Kirby Sims, Bolivar, read a paper entitled "Forceps: Their Uses, Abuses, Indications and Contraindications" before the Jasper County Medical Society, October 27.—Common Diseases of the Skin and Their Treatment" was discussed before the Perry County Medical Society, October 1, by Dr. Norman Tobias, St. Louis.

NEBRASKA

New Division of Maternal Health—Dr. John Warren Bell, Olean, N. Y., has been appointed director of a new division of maternal and child health in the state department of health set up under the social security plan. The committee on maternal health of the Nebraska State Medical Association met with Dr. Bell September 18 to establish a basis of coordination with the new division. Basic maternal now being gathered and analyzed on a regional basis will be presented to the committee and to the councilor districts.

District Meetings—The Seventh Councilor District Medical Society held its annual meeting at Friend, October 22. The speakers were the following physicians of Lincoln: Drs. Charles H. Arnold, "Management of Complicating Factors in Hyperthyroidism," Harry E. Flansburg, "Atypical Hyperthyroidism," Floyd L. Rogers, "Diagnosis and Treatment of Hyperthyroidism," and Sidney O. Reese Jr., "Clinical Problems Associated with Malignancy of Thyroid," and Drs. Albert F. Tyler and Francis L. Simonds, Omaha, "Treatment of Malignancies," a film in color.—The Ninth and Tenth Councilor District Medical Societies held a joint meeting at Kearney, October 15. The speakers were Drs. Charles R. Spicer, Hastings, on "Insulin in Infant Feeding," Abram E. Bennett, Omaha, "Results Obtained in Neuropsychiatric Disorders with Artificial Fever," Lee W. Rork, Hastings, "Observations in Early Pulmonary Tuberculosis," and Albert F. Tyler, Omaha, "Treatment of Accessible Malignancies of the Head, Face and Neck."

NEW JERSEY

State Tuberculosis Meeting—The thirtieth annual meeting of the New Jersey Tuberculosis League was held in Newark, October 22-23. Among the speakers was Dr. James Alexander Miller, New York, on "Vignettes from Tuberculosis History." Dr. Charles I. Silk, Perth Amboy, was elected president of the league.

Society News—Dr. George W. Crile, Cleveland, addressed the New Jersey Gastro-Enterological Society, October 5, on "Pathologic Physiology of the Sympathetic System with Special Relation to Peptic Ulcer and Spastic Colitis."—Dr. Sigmond S. Greenbaum, Philadelphia, addressed the Newark Dental Club, October 1, on "Oral Medicine with Special Reference to Diagnosis."—Dr. John A. O'Regan, New York, addressed the Bergen County Medical Society, October 13, on obstetrics. A round table discussion of maternal welfare in New Jersey was presented by Drs. Spencer T. Snedecor, Hackensack, William K. Pudney, Montclair, Henry d'Agostin, Cliffside Park, and Lyman Burnham Englewood.

NEW YORK

Graduate Lectures—A graduate course of lectures was presented in Wayne and Cayuga counties beginning September 24 and continuing on Thursdays through October. Dr Russell L. Cecil, New York, gave the first, speaking on pneumonia, subsequent speakers, all of New York, were Drs Ralph G. Stillman, on "Significance of Laboratory Tests and Methods", Edward M. Livingston, "General Aspects of Abdominal Surgical Diagnosis", William Goldring, "Physiology of Kidney Diseases," and Robert T. Frank, "Practical Endocrinology."

New York City

Second Harvey Lecture—Dr Eugene M. Landis, Philadelphia, will give the second Harvey Society Lecture of the season at the New York Academy of Medicine, November 19, on "The Passage of Fluid Through the Capillary Wall."

Brickner Lecture—Dr George R. Minot, professor of medicine, Harvard University Medical School, Boston, will deliver the sixth Walter M. Brickner Lecture at the Hospital for Joint Diseases, November 19, on "Anemia: Etiology, Diagnosis and Treatment."

Personal—The advisory council of the department of hospitals is sponsoring a dinner in honor of Dr Mark L. Fleming, who recently retired as general medical superintendent of the department. The dinner will be at the Waldorf-Astoria, Wednesday evening, November 18.

Diabetes Meeting—Insulin protamine was the subject of discussion at a clinical meeting of the New York Diabetes Association, November 13, at the New York Academy of Medicine. The speakers were Drs Henry Rawle Geyelin and Herman O. Mosenthal, New York, and Howard F. Root, Boston.

Public Health Training for Medical Students—Students at Long Island College of Medicine are to be trained in public health administration in cooperation with the Red Hook-Gowanus health center now under construction by the department of health, it was announced October 1. The plan calls for student participation in the actual work of the health center, with lectures, laboratory practice and field trips. It is expected that the center will be completed about May 1937.

Sentenced for Insurance Fraud—Dr Rubin Klein, 92 Humboldt Street, Brooklyn, was sentenced to two months in city prison, October 19, on a plea of guilty to conspiracy in a fraudulent accident insurance claim, the New York Times reported October 20. It was said that Klein signed a report to an insurance company that he attended a man for injuries received in an automobile accident when the injuries had actually occurred previously and the man had already received an award of \$2,000 from another company. According to the newspaper report, the man admitted the conspiracy but denied receiving the money. This case was one of several revealed by an investigation of accident frauds perpetrated on insurance companies by a so-called "Hurwitz gang," of which one Jacob Hurwitz, an insurance broker, was said to be the leader. The case was prosecuted by Assistant District Attorney Bernard Botwin, in charge of a new accident fraud bureau.

OHIO

Personal—Dr Abram L. Van Horn, chief of the bureau of child hygiene of the state department of health since 1934, has been appointed a regional consultant for the Children's Bureau, U. S. Department of Labor effective November 15. Dr Van Horn will supervise the maternal and child health program of the bureau in Maryland, Delaware, District of Columbia, Virginia, North and South Carolina, Georgia and Florida.

District Meeting—The fall meeting of the Eighth Council District, Ohio State Medical Association, was held in Athens November 12. The speakers were Drs Clyde L. Cummey, Cleveland, on "Syphilis the Great Masquerader," Louis J. Karnosh, Cleveland, "Psychoses Associated with Disturbances of the Endocrine System" and Leslie L. Bigelow, Columbus, "High Lights in Medicine." The motion picture "Treatment of Breech Presentation," produced by Dr Joseph B. De Lee, Chicago was shown.

Society News—Dr Emil Novak, Baltimore, will address the Academy of Medicine of Cleveland November 20 on "Endocrinology and Organotherapy in Gynecology."—At a meeting of the Wayne County Medical Society in Wooster, October 23 the speakers were three Orrville physicians: Drs Otto P. Ulrich on "Care of Accident Cases," Orrin C. McDowell "Treatment of Hemorrhoids" and George H. Irvin

"Obstetric Anesthesia"—Dr Harry G. Armstrong, U. S. Army, Wright Field, Dayton, addressed the Montgomery County Medical Society, Dayton, November 20, on "Physiologic Effects of Flying."—Dr Soma Weiss, Boston, addressed the Academy of Medicine of Cincinnati and the Heart Council of Greater Cincinnati at a joint meeting November 10, on "The Relation of the Cardiovascular System to the Nervous System." Dr Isidor C. Rubin, New York, will address the academy November 17 on "Tubal Insufflation and Sterility: Diagnostic and Therapeutic Aspects."—Dr James G. Carr, Chicago, addressed the Stark County Medical Society, Canton, November 12, on diseases of the heart. Drs Howard A. Power, Charles E. Ziegler and David B. Martinez, all of Pittsburgh presented a symposium on obstetrics before the society October 15.

OREGON

Annual Registration Due December 1—All practitioners of medicine and surgery holding licenses to practice in Oregon are required by law to register annually on or before December 1 with the secretary of the Board of Medical Examiners and at that time to pay a fee of \$5. A practitioner failing to register is subject to a penalty of \$1 for each thirty days or part thereof of default, and his failure to reregister within ninety days after December 1 is a misdemeanor.

PENNSYLVANIA

Society News—At a meeting of the Fayette County Medical Society in Uniontown, November 5 the speakers were Drs James K. Everhart, Pittsburgh, William W. Briant Jr., Mount Lebanon, and Ellsmer L. Piper, Pittsburgh. This was the second pediatric institute of the series of three being presented throughout the state under the auspices of the state department of health and the Medical Society of the State of Pennsylvania.—Drs Louis H. Clerf and Charles E. G. Shan non, Philadelphia, addressed the Western Pennsylvania Eye, Ear, Nose and Throat Society, Indiana, October 15, on "Differential Diagnosis of Diseases of the Larynx and Practical Points in Their Treatment" and "The Relationship Between Paranasal Disease and Retrobulbar Neuritis" respectively.

Philadelphia

Illegal Practitioner Jailed—The state board of medical education and licensure recently investigated the "Medical Research Laboratories" Thirtieth and Market streets. One Adolph Quesada pleaded guilty to practicing medicine without a license, received a suspended sentence and was fined \$100 and costs. Being unable to pay the fine and costs, he was placed in jail.

Personal—Dr. George M. Dorrance, professor of maxillo-facial surgery, Thomas Evans Institute, University of Pennsylvania and surgeon at the American Oncologic Hospital received the medal of achievement awarded by the Poor Richard Club, an advertising club, of Philadelphia, October 6.—Dr Brooke M. Anspach received the honorary degree of doctor of science at the Founders Day exercises at Lafayette College, Easton, October 16.

In Memory of Dr. Anders—The Philadelphia County Medical Society will devote its meeting of November 25 to the observance of the annual Pennsylvania Health Day and a memorial to Dr. James M. Anders, who was a leader in the movement to establish the public health day. Dr. Roderick Heffron, Boston, will speak on "The Control of Pneumonia" and Dr. George E. Pfahler will pay tribute to Dr. Anders. Dr. Baldwin L. Keyes will present the report of the society's noise abatement committee, whose work was almost the last activity sponsored by Dr. Anders before his death August 29.

Annual Dinner of Ex-Residents—The Association of Ex-Resident and Resident Physicians of the Philadelphia General Hospital will hold its fiftieth annual meeting and dinner December 1. Clinics will be given in the auditorium of the hospital in the afternoon by Drs. Edward A. Schumann, Emily P. Bacon, Ross V. Patterson and Russell S. Boles. The dinner will be at the Art Club with Major Gen. Charles R. Reynolds, surgeon general of the U. S. Army, presiding. General Reynolds is president of the association. Guests will be Dr. George E. Pfahler, Hon. S. Davis Wilson, mayor of Philadelphia, Dr. William C. Hunsicker, director of public health of the city, Dr. William G. Turnbull, superintendent of the Philadelphia General Hospital and Dr. John G. Meharg, president of the Blockley Medical Society. Ex-residents who have not received announcements are asked to send their names to Dr. George Wilson, secretary of the association, 133 South Thirtieth Street.

SOUTH CAROLINA

Specialty Society Elections—Dr Roger H DuBose, Roanoke, was elected president of the Virginia Pediatric Society at its annual meeting during the convention of the Medical Society of Virginia in Staunton in October Dr W Ambrose McGee, Richmond, was reelected secretary Dr Austin I Dodson, Richmond, was elected president and Dr Linwood D Keyser, Roanoke, secretary of the Virginia Urological Association, which met at the same time The Virginia Orthopedic Society elected Drs John Blair Fitts, Richmond, and Bernard H Kyle, Lynchburg, president and secretary respectively At the meeting of the Virginia Society of Obstetricians and Gynecologists Dr Marvin Pierce Rucker, Richmond was elected president and Dr Eugene S Groseclose, Lynchburg, secretary

WEST VIRGINIA

Dr Schwinn Honored—A bronze bust of Dr Jacob Schwinn was recently unveiled at the Ohio Valley General Hospital, Wheeling, as a tribute from the Jacob Schwinn Study Club Dr Schwinn, a native of Switzerland, came to the United States at the age of 25, and has practiced more than fifty years in Wheeling He has for many years been a member of the staff of the Ohio Valley General Hospital and has served as president of the Ohio County Medical Society and the West Virginia State Medical Association He is 81 years old.

Society News—Dr Albert H Hoge Bluefield, addressed the Fayette County Medical Society at Oak Hill, October 6, on "Gastro Intestinal Allergy" The Kanawha and Raleigh county medical societies were guests—Dr Leopold Clarence Cohn Baltimore, addressed a joint meeting of the Harrison, Marion and Monongalia county medical societies in Clarksburg, October 1, on diagnosis and treatment of cancer—Drs Abraham Seletz and Howard A Swart Charleston, addressed the Kanawha Medical Society October 13, on "Relationship of Nasal Accessory Sinus Infections to Certain Obscure Chest Involvements" and "Internal Derangements of the Knee Joints" respectively—Dr Isaac A Bigger, Richmond Va addressed the Ohio County Medical Society, Wheeling, October 9 on "Surgery of the Heart and Pericardium"

WISCONSIN

Personal—Dr William E Grove, associate clinical professor of laryngology rhinology and otology, Marquette University School of Medicine, Milwaukee, has been appointed to succeed Dr Charles J Coffey, clinical professor and director of the division of laryngology, rhinology and otology, who has retired after thirty-six years of teaching at Marquette to devote his time to private practice. Dr Coffey was honored at a

testimonial dinner at the Hotel Schroeder, October 22 Dr Francis D Murphy, head of the department of medicine at Marquette, was chairman and speakers were the Rev William M Magee, president of the university, Rev Anthony Berens, regent and Dr Eben J Carey, dean—Dr Ralph M Waters Madison addressed the section of anesthetics of the Royal Society of Medicine of London, October 2, on carbon dioxide absorption from anesthetic atmospheres

GENERAL

Campaign Against Cancer—The national enlistment campaign of the Women's Field Army in the cancer control movement will be held March 21-27, 1937, the fee to be \$1 In the distribution of funds, 70 per cent will be given to the states for their activities, 20 per cent to the central office in New York City for expenses and 10 per cent to a contingent fund All funds will be allocated from the central office

Medical Section of Accident Boards—At the recent annual meeting of the International Association of Industrial Accident Boards and Commissions in Topeka Kan, a resolution was adopted by the medical section urging the continuance of separate medical programs in subsequent years The resolution has been accepted by the association's executive committee The 1936 session of the association was the first in which a medical section convened

Rocky Mountain Medical Conference—The first Rocky Mountain Medical Conference will be held in Denver, July 19-21 1937 The conference is to be a joint meeting of the Colorado State Medical Society, the New Mexico State Medical Society, the Utah State Medical Association and the Wyoming State Medical Society and will be open to members of the recognized societies of adjoining states According to the present plan, the conference will be held every three years with a different state acting as host.

Railway Associations Elect Officers—Dr William J Connolly, Carnegie, Pa, was elected president of the Association of Surgeons of the Pennsylvania Railroad at its convention in Philadelphia in October Dr Frank P McCarthy, Erie, Pa, was made vice president—Dr Wade H St Clair, Bluefield, W Va, was elected president of the Association of Physicians and Surgeons of the Norfolk and Western Railway, at the annual meeting in New York, October 7-8

Plans for Congress on Gastro-Enterology—The United States National Committee of the International Society of Gastroenterology has been formed by representatives of the various gastro-enterologic organizations in this country, it is announced Those who are interested in joining are invited to apply to the president, Dr Anthony Bassler, 121 East Seventy-First Street, New York The second International Congress on Gastroenterology will be held in Paris, Sept 13-15, 1937

Changes in Status of Licensure—The Pennsylvania State Board of Medical Education and Licensure recently reported the following actions dated August 28

Dr Eugene Hamborszky Millersville license restored It was revoked Oct 18 1934

Dr David A Rupert Donora license suspended because of conviction of narcotic addiction

The New Jersey State Board of Medical Examiners has reported the following

Dr Francesco Verdighione Camden license revoked automatically through his failure to present evidence of having become a citizen of the United States within six years after declaring his intention to do so

Dr John J Kashkevich Newark license restored it was revoked in 1923

Meeting of Radiologists—The twenty-second annual meeting of the Radiological Society of North America will be held at the Hotel Netherland Plaza, Cincinnati, November 30-December 4 The preliminary program lists the following speakers, among others

Drs Henry Snure and George D Maner Los Angeles Roentgen Ray Evidence of Metastatic Malignancy in Bone

Dr Hugh F Hare Boston Cancer of the Thyroid in Children

Drs Wendell G Scott and Sherwood Moore St Louis Roentgen

Kymographic Studies in Clinical Cardiac Conditions

Dr Louis H Clerf Philadelphia Carcinoma of the Bronchus

Drs Richard Manges Smith and Austin T Smith Philadelphia Osteopetrosis

Dr Carleton B Pearce Ann Arbor, Mich Pulmonary Pneumocoele

Certain Considerations in Cystic Disease of the Lung

Drs Eugene T Leddy and Walter C Popp Rochester Minn Use of Pentobarbital Sodium (Nembutal) for Roentgen Sickness Report of 175 Cases

Several symposiums have been planned diseases of the stomach and gallbladder, the female pelvis therapy, gastroscopy, the chest and physics Clinics will be held every afternoon except Thursday

Society of Tropical Medicine—The American Society of Tropical Medicine will hold its annual convention at the Fifth Regiment Armory, Baltimore, November 18-20. The presidential address will be delivered by Dr. Henry E. Meloney, Nashville, on "The Problem of Malaria Mortality in the United States," and the first Charles Franklin Craig Lecture on Tropical Medicine will be presented by Dr. Ernest Muir, general and medical secretary, British Empire Leprosy Relief Association, London, England, on "The Control of Leprosy." The speakers on the program will include

Dr. Wilbur A. Sawyer, Director International Health Board Rockefeller Foundation, A History of the Activities of the Rockefeller Foundation in the Investigation and Control of Yellow Fever
 Carl M. Johnson, Sc.D., Panama and Raymond A. Kelsler, Ph.D., Ancon, C. Z., Incidence of Chagas Disease in Panama as Determined by the Complement Fixation Test
 Dr. Ellis H. Hudson, Deir ez Zor, Syria, The Significance of Bejel.
 Dr. Thomas B. Turner, International Health Board, New York, Studies on the Relationship Between Yaws and Syphilis

At the luncheon of the society, November 19, Walter Reed medals will be presented to Mrs. Walter Reed and to the Rockefeller Foundation, the latter for meritorious achievement in the study and control of yellow fever.

Society News—Dr. Elliott P. Joslin, Boston, was chosen president of the Interstate Post-Graduate Medical Association at the annual meeting in St. Paul, October 12-16.—Dr. Paul Titus, Pittsburgh, was chosen president-elect of the American Association of Obstetricians, Gynecologists and Abdominal Surgeons at the annual meeting in Bretton Woods, N. H., September 14-16, and Dr. James W. Kennedy, Philadelphia, was installed as president. Dr. Willard R. Cooke, Galveston, Texas, was elected vice president and Dr. James R. Bloss, Huntington, W. Va., reelected secretary. The 1937 meeting will be at The Homestead, Hot Springs, Va.—Dr. Arthur T. McCormack, Louisville, Ky., was chosen president-elect of the American Public Health Association at the annual meeting in New Orleans in October and Dr. Thomas Parran, Surgeon General, U. S. Public Health Service, Washington, D. C., was installed as president. Vice presidents elected were Drs. Angel de La Garza Brito, Mexico City, and Robert E. Wodehouse, Ottawa, Canada.—Drs. Andrew L. Glaze, Birmingham, Ala., and Herbert S. Alden, Atlanta, Ga., were elected president and secretary respectively of the Southeastern Dermatological Association at its meeting in Atlanta, September 6.—Dr. Byrl R. Kirklm, Rochester, Minn., was chosen president-elect of the American Roentgen Ray Society at the annual meeting in Cleveland and Dr. Charles A. Waters, Baltimore, was installed as president. Dr. Eugene P. Pendergrass, Philadelphia, was reelected secretary. The 1937 session will be held in Chicago, September 13-17.

FOREIGN

Society News—Dr. Henry G. Bugbee, New York, was elected president of the International Urological Association at its recent meeting in Vienna. The next meeting will be in New York in 1939.—The International Congress of Ophthalmology will be held in Cairo, Egypt, Dec. 8-14, 1937. The official subjects for discussion will be "Arterial Hypertension of the Retina" and "Endocrinology and the Eye." Correspondence should be addressed to the secretary general, Dr. M. Tewfic, Postoffice Box 2001, Cairo.

The Jerusalem Medical Center—Ground was broken on Mount Scopus, overlooking the city of Jerusalem, October 20, for a medical center to be erected under the auspices of Hadassah, the women's Zionist organization of America, and the Hebrew University in Jerusalem (THE JOURNAL, May 16, p. 1744). Funds for the medical center, which is to consist of a hospital, a graduate medical school and a school for nurses, have been raised principally by Hadassah and the American Jewish Physicians Committee.

Government Services

Centennial Celebration of Army Library

The one hundredth anniversary of the founding of the Army Medical Library will be observed with ceremonies at the library, November 16. The principal address will be delivered by Sir Humphry D. Rolleston, Haslemere, Surrey, England, formerly regius professor of physic at the University of Cambridge, former president of the Royal Society of Medicine and the Royal College of Physicians and physician extraordinary to the king. Other speakers will include Col. Harold W. Jones, librarian, and Surg. Gen. Charles R. Reynolds. Visitors will inspect the library; its operation will be described by the staff, and rare books and manuscripts will be on display.

The Decline of Population

The fall of the birth rate is a phenomenon, in varying degree, of all western Europe and North America. It is at last beginning to receive some attention in this country. Statisticians such as Professor Carr-Saunders, D. V. Glass and R. Kuczynski, have written on the subject. In a lengthy editorial the *Times* points out that between 1821 and 1921 the population of England and Wales was trebled, and that from 26 million in 1850 the white population of North America rose to 137 million in 1933. Now everywhere, in the new countries as well as the old, the trend is turning. The great increase of the British population during the last century was due chiefly to a fall in the death rate, not to a rise in the birth rate. The persistent decline in that death rate is still concealing the imminent decline of population. In England and Wales the mean expectation of life in the middle of the last century was about 39 years, now it is 59 years. At the most fertile period, between 1851 and 1860, the natural increase of our population was 151 per cent a year; now it is 3 or 4 per cent. It has been proved statistically that our present birth rate is not sufficient to maintain the population. Professor Carr-Saunders in his recent book "World Population" has warned us that there is evidence that the numbers of the British race will certainly fall, perhaps catastrophically, during the next fifty years.

Kuczynski has introduced a new and most important unit for the study of population, called "the net reproduction rate." This may be defined as the average number of females that will be born to each new-born girl according to fertility and death rates of the women living in a particular year. If this rate is unity, the female population is being exactly replaced and the population will remain stationary. If the rate is above unity, the population will increase; if below it, the population will decrease. In only three countries of Europe—Bulgaria, Russia and Italy—is the rate above unity. In England and Wales the rate (1933) was 0.734, in France 0.82, in Germany (1930) 0.70, in Italy 1.18.

Estimates have been made of future populations. Assuming that the British birth rate declines at the same rate as during the period 1924-1931 and that mortality continues to fall, Dr. Lejbourn calculates that our population forty years hence will be 32,700,000, a decline of 12,000,000. Another estimate, with different assumptions, puts our future population at 38,500,000 in 1975 and 20,000,000 a hundred years hence. For other countries similar estimates have been made. France has been given 29,000,000 for 1980, Germany 50,000,000 for 1975 (this estimate was made in 1930). There may be differences as to the exact figures, but there is none as to the tendency they reveal. Some qualification must be made as to what are called "the totalistic countries," which might be defined as those which have totally abolished the liberty of the individual. For military reasons, in spite of their poverty, Russia, Germany and Italy are all endeavoring to increase population by monetary inducements. In Germany the birth rate fell from 39 per thousand in 1876 to 15 in 1932 and the net reproduction rate to 0.75, which is about the same as in England. Statisticians prophesied a decline of population of over 20,000,000 by the year 2000 and all agreed that after 1960 a decline would begin. Alarmed at this prospect, the government passed an act in 1933 to provide loans for young couples wishing to marry, a fourth of which would be canceled on the birth of each child. It is too soon to judge of the success of this scheme or of a similar one in

Italy. But marriages have increased in Germany from 509,591 in 1932 to 701,431 in 1934, births in the same period by 181,772. However, there was also an increase in classes not benefiting by these grants and therefore how far the increase is due to economic recovery remains a question. The government also took drastic measures to check the practice of abortion. In his book "The Struggle for Population" Mr V. D. Glass calculates that if the rise of the German birth rate is maintained the present population will be replaced but with a smaller proportion of potentially fertile women. Thus decline has been postponed, not averted. In Italy Mr Glass can find no "significant positive result of the attempt to encourage marriage." Although the birth rate has hardly responded to official encouragement, infant mortality has shown a remarkable decline. The two dictatorships, with all their resources of power and propaganda, have not been able to destroy the menace of depopulation. In France and Belgium propaganda and family allowances have been tried. But an inquiry made for the Eugenics Society (of England) revealed little to show any result. In neither of these countries has there been such a sharp decline in the birth rate as in England, where it has fallen from 22 to less than 14 per thousand in twelve years. It is reckoned that a man needs an addition of 120 per cent to his income to maintain an infant and four children. The highest allowances on the continent cover little more than half the cost of raising three children.

What causes have brought about the position in England where the birth rate is now only two thirds of that necessary for replacement and in the professional classes only one half? The *Times* suggests that modern housing, modern ways of spending leisure, social and educational ambitions for children, the concentration of population in towns, educational and economic opportunities opened to women, and the tendency to put the comfort and independence of the individual before the interests of the community play their part and have more to do with the decline than economic considerations. But it might be objected that some of these causes are of an economic nature. The *Times* adds that most influential of all in the opinion of many authorities is the widespread knowledge of contraceptive measures. It asks: Can we hope to hold a large proportion of the thinly populated parts of the earth when our stock is dwindling? It does not suggest a remedy, but says that the first step toward action is an easy one: publicity for the problem and full and authoritative investigation.

Atmospheric Pollution by Smoke

An interesting smoke abatement exhibition, organized by the National Smoke Abatement Society in conjunction with certain government departments was opened at the Science Museum, South Kensington, by the minister of health. The president of the society, Dr H. A. Des Voeux, recalled the fact that the society was founded thirty six years ago, when London used to have from thirty five to forty thick fogs every winter, some of them lasting a week. If the conditions continued London would have become uninhabitable. The minister of health, Sir Kingsley Wood said that smoke was an insidious enemy and cost the nation many millions a year. In Elizabeth's reign proclamations were issued forbidding the use of coal in London while parliament was sitting. Conditions were better now than at the end of the last century, in spite of the fact that over four million houses had been built since 1901. The increased use of gas and electricity had helped this improvement. But there was little reason for complacency today and much had still to be done. He thought that in the future legislation would be less important than prudent administration and cooperation between public authorities, manufacturers and voluntary organizations. Domestic smoke was now the largest part of the problem.

The exhibition is designed to illustrate three things—the nature and effects of smoke, the methods of measuring air

pollution and how the nuisance can be abated. A fine series of photographs show the great smoke pall over London and the blackened clouds over Epping Forest after a London fog as well as views of Edinburgh, Manchester and other cities. There are photographs as well as specimens of stonework and bricks damaged by smoke. To demonstrate the effects on human life there are specimens of contaminated and uncontaminated lungs and a diagram showing that, while there were 137 deaths from respiratory diseases in Manchester in December 1930 a month without a fog, there were 592 in January 1931 when there were nine days of fog. An effective display came from Kew (the botanic gardens just outside London). A branch of evergreen as picked showed a great contrast from one that had been washed. There is a diagram showing how a Londoner if he lives at Kew, loses every year ninety-nine hours of sunshine through smoke, 233 hours if he lives at Westminster and 340 if he lives in the city. There is a poster of a pair of scales, which teaches that the average English family every year creates more than its own weight of smoke.

Oct 12, 1936

French Surgical Congress of 1936

The forty-fifth annual meeting of the French Surgical Association was held during the week beginning October 5 at Paris. Owing to the inability of Prof. Victor Pauchet, who had been elected president last year, to be present the surgeon general of the army, General Rouvillois, acted as president.

It is the custom at all the important French congresses to appoint two members to review a subject chosen by vote and to submit the report at the next meeting. The subjects for this year's congress were (1) the results of ovarian grafts, (2) surgery in diabetes and (3) pneumonectomy.

RESULTS OF OVARIAN GRAFTS

The reporters for the subject 'Results of Ovarian Grafts' were Dr Moequot of Paris and Dr Cotte of Lyons. Their monograph is an exhaustive critical review and worthy of study in the original by all those interested in the subject. Dr Moequot's paper took up the results of experimental work on animals, which must form the basis of clinical observations. He reported the methods of grafting: autoplasty, homoplasty and heteroplasty, as follows:

A. Autoplastic grafts. In earlier experiments the transplantation of ovaries was especially studied from the point of view of the reestablishment of the faculty of procreation, but this is less important than the question of the power of the graft to furnish internal secretions. In order to leave a portion of the surface of the graft free, it was placed on the surface of the parietal peritoneum, mesentery or omentum. When this idea was discarded, the graft was placed in cellular tissue, muscles, viscera or isolated segments of veins. Transplantations into the anterior chamber of the eye have yielded valuable information on the growth of the follicles and formation of the corpus luteum. A graft composed of the entire ovary offers resistance to the penetration of blood vessels, whereas minute fragments offer little resistance to absorption by the tissues. The best results were obtained by Pettinaria in transplanting a bisected ovary. Successful grafting is favored by the hormone effects of other endocrine organs, especially the hypophysis. When there is a lack of ovarian secretion in the organism, a functional stimulation of endocrine secretions results which favors development of the graft. Too long an interval must not elapse (not more than from five to six months in guinea-pigs) between the castration and grafting; otherwise the organism adapts itself to a newly established endocrine equilibrium with resultant suppression of the functional stimulation needed for growth of the graft. The more highly developed

elements, i. e., the follicles and corpora lutea, are the first to die if the graft is unsuccessful. Ovaries of younger are far more resistant when transplanted than are those of older animals. Even when the graft survives, the question arises whether one is not dealing with a tissue culture in a living medium.

B Homoplastic grafts Numerous experiments have shown that an ovary transplanted into an animal of the same species conserves its vitality with the formation of follicles, development and expulsion of ova. All the manifestations of the genital cycle reappear, even fecundation and gestation can follow. Homoplastic grafts, however, are less apt to be successful than the autoplasmic variety. The best results for homoplasty are obtained in animals of the same age. When the transplantation is done on castrated animals the genitalia of which show a retarded development as a result, the uterus, tubes and vagina resume their interrupted evolution and the genital cycle is reestablished.

C Heteroplastic grafts Transplantation experiments between different races of mice, guinea-pigs, rabbits, cats and dogs have been attempted. In but few cases did the grafts survive. When this did occur there was great skepticism regarding the interpretation of the histologic picture. As a rule, heteroplastic grafts die, the changes being those of either a sclerotic or an inflammatory type.

Dr. Cotte of Lyons discussed the clinical application of ovarian grafts. His conclusions, from a study of the literature and his own results, were as follows:

1 Ovarian autografts There are two principal indications: (a) In the treatment of sterility of ovarian origin. The occluded tubes present lesions that will not be improved by conservative operations, and only a salpingectomy is indicated. Instead of trying only to save the uterus and one ovary, it seems indicated, if the patient so wishes, to try to conserve the power of conception by transplanting the ovary into the uterus. He reported 200 cases in which this had been done, with twenty-one subsequent pregnancies, of which about 30 per cent terminated in miscarriage during the third or fourth month. From the point of view of technique, one should not attempt a free graft but rather implant the ovary with its pedicle attached in the uterine cavity.

(b) In the prophylactic treatment of disturbances after castration. If one admits that castration is always followed by more or less important disturbances and that the transplantation (autografts) of fragments of the ovary suffices to prevent such disturbances, this indication would hardly merit further discussion, but surgeons are far from being in agreement on this question. Hence it is difficult to formulate conclusions that will be generally accepted. As to the therapeutic value of the grafts the good results are not as constant as has been claimed. On the other hand it is true that in a certain number of cases the graft has sufficed to prevent the disturbances following castration. Cotte's observations include ninety-two cases in which the ovary was transplanted into the omentum and the uterus conserved. Of seventy-four end results, menstruation was reestablished in sixty-five (88 per cent). The ovarian function is resumed at the end of three months, a little later (seven months) in cases of acute salpingitis. Ovarian autografting hence is indicated in cases in which oophorectomy is of no avail. Every effort should be made to perform conservative gynecologic operations. The surgeon ought not to perform total or subtotal hysterectomy with the idea in mind that transplanting the ovary into the labium majus will suffice to prevent the disturbances following castration. If the uterus can be conserved there is a prospect that an ovarian autograft will prevent such sequelae. Cotte believes the uterus should be conserved far more frequently than is at present the case. If this is not done, one will find few indications for ovarian autografts.

2 Ovarian homografts The results obtained at the present time with ovarian and anterior hypophysis hormones have greatly lessened the indications of ovarian autografts, especially since their biologic value is far from being proved.

3 Ovarian heterografts Their utilization in revitalizing the organism has shown that the effect is only transitory, even with pluriglandular grafts.

In the discussion, Dziembowski of Poland said that the majority of gynecologists in his country felt that the effects of ovarian grafts were only transitory and that they were either absorbed or became sclerotic in a few months, hence oophorectomy continues to be the treatment of choice, following castration.

Douay of Paris reported 167 ovarian grafts observed from 1928 to 1934, of which 128 have been followed to the present time. This permits one to evaluate the end results. There were 11 per cent complete failures and 72 per cent permanent good results. The average duration (53 per cent of the cases) of ovarian activity following grafting is two years. In all his patients, autografts were employed. If the ovary is normal, it is advisable to leave it in situ. If it is diseased it is necessary to remove a portion that can be used for grafts, contrary to current opinion. The patient need not be young. One is as apt to be successful in women just prior to the menopause. Douay believes that his method, placing the graft in the labium majus, will give the best results.

Senechal of Paris maintained that there are very few cases in which it is impossible to conserve a small portion of the ovary, sufficient to prevent the disturbances of the artificial menopause.

SURGERY IN DIABETES

The first paper on the second subject was by Fredet of Paris on general aspects, and the second by Jeanneney of Bordeaux on surgical disorders in diabetic patients. Fredet first took up cases presenting only a hyperglycemia and not requiring immediate operation. The objective in the first subgroup (hyperglycemia only) should be to reduce the high blood sugar content to the normal figure. This is comparatively easy if the hyperglycemia is of alimentary origin, i. e., a diet too rich in carbohydrates. Often it is necessary to employ insulin in addition to diet. One must begin with small doses to avoid a hypoglycemia and continue until the day of operation. In the second clinical subgroup, cases are encountered in which there is both a hyperglycemia and a glycosuria. Here the same treatment, diet and insulin, is indicated as in the patients with hyperglycemia alone. Insulin is not always efficacious in reducing the glycosuria, especially if the latter is very marked. In such cases the large doses of insulin that are necessary to influence the glycosuria must be supplemented by a diet relatively rich in carbohydrates. In ordinary cases from 10 to 30 units of insulin, one half to be given before the two principal meals is indicated. In a third subgroup can be placed cases of hyperglycemia, glycosuria and acetonuria. These constitute the most serious cases from the surgical standpoint, because of the danger of coma, hence the necessity of energetic measures to reduce the acetonuria. This can often be accomplished by a two or three day diet of green vegetables and, if successful, the next task is to treat the glycosuria. In general, the problem is not so simple. The ketones have decreased but have not entirely disappeared, hence it is necessary to give a diet poor in ketone-producing substances (especially animal more than vegetable proteins) and in addition employ insulin in doses of 40 units a day for the ordinary case in which a diet rich in carbohydrates is unnecessary. When the ketones have disappeared the proteins can be increased followed by treatment of the glycosuria and hyperglycemia. Diabetic patients in this third subgroup must be adequately nourished and not given too large doses of insulin lest a hypoglycemia result. The patient

must be weighed every day. The role of insulin in such cases is not only to combat the acetoneuria but also to allow one to give a diet that will prevent starvation.

Preoperative purgation of patients with diabetes has been criticized, but Fredet maintained that, if castor oil is employed instead of saline cathartics forty-eight hours before operation, supplemented by alkalis by mouth and by hypodermoclysis, the loss of liquid is compensated for and the bowel will be in more favorable condition. He was opposed to starving diabetic patients before operation. As postoperative measures the administration of sodium chloride in large amounts of fluid, carbohydrates (sugar by mouth or dextrose intravenously or by hypodermoclysis) and insulin are to be especially mentioned. The injection of insulin is to be immediately followed by a solution containing both dextrose and sodium chloride. If the patient becomes comatose, 20 units of insulin should be given intravenously every half hour and then at longer intervals (from one to two hours) as soon as the patient becomes conscious. Large doses of insulin are harmless as long as they are accompanied by administration of carbohydrates.

In diabetic patients, when immediate operation is indicated, the chief objective is to prevent coma and hence to consider the patient in a precomatose state. From 20 to 30 units of insulin must be given immediately, depending on the results of the urine examination for sugar and acetone and of the blood for the sugar content. The intravenous injection of insulin is compensated for by intravenous administration of 300 cc of a 3 per cent solution of dextrose.

Fredet quoted the statistics of the Mayo Clinic (3 per cent mortality in 2,000 operations) as showing how greatly the mortality had been reduced as the result of the use of insulin and preoperative preparation.

Jeanneney spoke of the diminution of local and general resistance in diabetic patients, which favors infection and necrosis. Infections are often followed by acidosis. Even though rendered "sugar free," the person with diabetes can never be regarded as a normal individual by the surgeon. The most to be feared are carbuncles in diabetics, 50 per cent of which ended fatally, before the discovery of insulin.

A crucial incision is advisable except in cases in which gangrene is present, in which early excision is indicated. The treatment of the diabetes should be supplemented by autohemotherapy.

In cases of moist gangrene of the extremities in diabetes, an energetic medical treatment is essential. If the arterial circulation is occluded, early amputation in healthy tissue is indicated.

In the discussion of these two papers, Jentzer of Geneva reported two cases of diabetic gangrene of the lower extremity in which diet, insulin and even periarterial sympathectomy had been of no avail. A removal of the adrenal of the same side was followed by healing of the local lesions, without amputation. On following up these patients, a disappearance of the glycosuria and acetoneuria was noted, but one of them still has a marked hyperglycemia in spite of prolonged insulin therapy.

Ducuing of Toulouse found that the hyperglycemia was the most important of the three (glycosuria, acetoneuria and blood sugar content) to watch.

Fontaine, Weil and Mandel of Strasbourg said that they have studied the relation of diabetes to adrenalectomy at the suggestion of Leriche. After removal of the pancreas in animals the adrenal also was removed. They found that the latter procedure had no influence on the diabetes, being only of transitory character. The question as to whether the cortical secretions of the adrenals have an influence on the pancreas merits further study.

Leriche of Strasbourg also believes that the hyperglycemia is of more importance clinically than the glycosuria. In diabetic gangrene of the lower extremities, the question of whether an

arteritis is present or not is of vital interest. Oscillometry is subject to error, but this is not true of arteriography. If this does not reveal an arteritis, it is not necessary to remove as much tissue. If an arteritis exists, only a high amputation is of any avail. One should never be in too much of a hurry to amputate.

Mayer of Brussels was able to avoid amputating in a case of diabetic gangrene of the foot by performing a periarterial sympathectomy, associated with preoperative and postoperative insulin therapy.

Rathery of Paris places more reliance on the glycosuria than on the sugar content of the blood. It is essential to avoid both dehydration and starvation in the preoperative preparation. During the postoperative period, dextrose solution by rectum and insulin are to be especially recommended, also heart tonics and sodium bicarbonate. He does not favor wide removal of carbuncles. As to gangrene of the lower extremities, one should not operate too soon. If amputation is indicated, it should be at as high a level as possible. Oscillometry does not give accurate information, and arteriography is too dangerous a diagnostic procedure in diabetes.

PNEUMONECTOMY

The reporters on the third subject were Monod of Paris and Bonriot of Grenoble, who said that the term "pneumonectomy" ought to be applied only to operations in which either the entire lung (total pneumonectomy) or one or several lobes (lobectomy) were removed, with ligation of the pedicle. To atypical, i. e. partial, removal the term fragmentary pneumoresection should be applied. After a review of the history of the subject, they stated that two problems—the technical and the clinical, presented themselves. The technical problem included our present knowledge of the anatomy, physiology and pathology of the lungs. The last named is the most important from the surgical standpoint, because of the great risks due to infection which it is necessary to prevent. The authors next reviewed the various methods of performing pneumonectomy and their indications. These methods could be divided into (a) cases in which there were no pleural adhesions and (b) those presenting them. As to lobectomy, the one-step method should be reserved to aseptic or slightly infected cases. Two-step operations had a much lower mortality. Not only close team work between the surgeon and the internist is essential, but the surgeon must have trained assistants and special apparatus. It is preferable to operate in a relatively large room, in air that is conditioned and sterilized.

The clinical problem involves a study of the three indications for pneumonectomy that exist at present: (a) primary cancer of the lung, (b) bronchiectasis and (c) pulmonary abscess. The first of these constitutes from 7 to 8 per cent of all cancers; the outcome has been hitherto always fatal and at present no other method of treatment than pneumonectomy is available. In the latter, removal can be successful if the neoplasm involves only the first 2 cm. of the main bronchus and if no metastases exist in the pleura, chest wall, diaphragm or mediastinal lymph nodes. Cases without recurrence in which operation was performed five, six, seven and nine years ago show that the cited essentials of success can be fulfilled. The types most suitable for operation fortunately include cases in which an early diagnosis is possible. Only total pneumonectomy, with separate ligation of the various components of the pedicle, should be attempted.

As to the second indication, bronchiectasis, the question is: In which cases is one justified in performing pneumonectomy or lobectomy? It is the general opinion that a bronchiectasis is a relatively benign condition, while pneumonectomy or lobectomy is a serious procedure. Now the prognosis of bronchiectasis is still an unsolved problem. If it could be shown that the majority followed a benign course, only the severe

complicated cases could be considered as calling for operative measures. This, however, would limit surgery to hopeless cases, thus limiting the field in the future to cases with a potential high operative mortality. But if the clinician could learn to distinguish mild from severe cases at an early period, pneumonectomy would be able to forestall much future trouble.

As to abscess of the lung, the only indication for pneumonectomy or lobectomy is in cases that do not improve under other forms of treatment. This would include single old centrally located abscesses and those which are complicated by bronchiectasis.

The discussion was opened by Professor Sergent who reviewed the indications for pneumonectomy. A progressive fragmentary pneumonectomy or even a simple pneumotomy will suffice for the majority of lung abscesses if carried out early, but if one waits until a progressive pyosclerosis complicated by secondary bronchiectases develops and the lobe or lung is transformed into a veritable purulent sponge more radical measures are needed. As to chronic fetid bronchiectases whatever their origin, nothing except operative removal can have an influence on a sclerotic mass of tissue penetrated by large dilated bronchi. Before a lobectomy is performed however a thorough exploration with iodized oil must be carried out to ascertain the condition of the other lobe or of the other lung, in the case of a pneumonectomy.

As to cancer of the lung the chief problem is early diagnosis, because in addition to the serious operative risks the post-operative complications in the form of overlooked metastases cannot be underestimated.

Professor Bezançon another internist who specializes in pulmonary disorders, said that much remains to be learned concerning bronchopulmonary suppuration. It is only through frequent radiographic examinations with and without iodized oil, as well as a study of the pathology and bacteriology that one can gain a more accurate idea of the clinical picture. Every case must be considered individually so that the chances for spontaneous recovery can be weighed as opposed to operation.

Another internist, Dr. Leon Kindberg said that the principal indication for lobectomy is in cases of bronchiectasis if possible at an early stage. The classic theory "progressive sclerosis of the entire respiratory tract following recurrent little understood infections" can be applied to only the minority of cases. The two groups that ought to be borne in mind as suitable for operation are (1) acquired dilatation of chronic nature or following a bronchiectatic abscess and (2) superinfected congenital dilatation, a localized lesion. The prognosis in such cases is not a favorable one (from eight to ten years of life) and life soon becomes intolerable. Hence it is logical to undertake a radical treatment in such cases. Bronchiectases with a benign clinical course, aged patients or generalized lesions are to be excluded as potential operative cases. Kindberg is very enthusiastic with regard to lobectomy for these two groups of cases.

Edwards of London prefers a one-step operation independent of the condition of the pleura. For bronchiectasis he has performed 113 lobectomies (one bilateral) with 14 per cent (sixteen deaths) mortality. Of ninety-seven patients who survived the operation, twelve died (of intercurrent disorder or tuberculosis) from one to five years after the operation. Sixty-four patients are alive from one to seven years after operation. Thirty-five of these are free from any evidence of bronchiectasis. Seven total pneumonectomies have been done for bronchiectasis with two (28 per cent) deaths. As to cancer he has performed sixteen lobectomies with three operative deaths (19 per cent) eight recurrences and six (37 per cent) cures dating back two, six, seven and nine years since the operation. Six total pneumonectomies were done on patients from 31 to 63 years of age with two operative deaths, one metastasis and three survivals.

Maurer, Rolland and Dreyfus-Le Fover of Paris emphasized the great value of local anesthesia for certain cases, the necessity

of ample drainage in lobectomies for infected lesions and the fact that less radical operations than lobectomy should be given a thorough trial in cases of pulmonary abscess. Under the last named they include, from personal experience, (a) pneumotomy with resection of the external wall of the cavity for superficial localized abscess, (b) phrenicectomy for low junctional lesions with ample drainage through a bronchus and (c) partial superior thoracoplasty in suppurating high lying lesions. It is difficult in cases of cancer to determine radiographically whether or not the mediastinal lymph nodes are involved.

Race, Marriage Problems and Eugenics

To the long list of discussions of race that have appeared in present-day Germany, a new study has recently been added that distinguishes itself from many another printed utterance on the same topic by its scientific character. It is in the form of a lecture on ethnological questions given by Prof. Rudolf Fick, Berlin anatomist, before the Prussian Academy of Science. Many persons who, following the present fad set themselves up as authorities on questions of race would be surprised to know that an exact determination of race from the shape of the skull requires no less than 4,000 measurements. However, even if one approaches the question in its most fundamental aspect, any study of cranial characteristics will present difficulties since the nations of today represent not separate racial entities but rather ethnic mixtures. As Fick stated the antiquity and the origin of the individual races are still controversial questions, despite the discoveries of prehistoric skeletal remains and the results of geological research on the history of the development of plants and animals. Our knowledge of the racial migrations still treads on rather uncertain ground. The abstract concepts of race and type are in need of more precise definitions. One ethnological question, namely, that of the invariable character of hereditary predisposition, is greatly complicated by the phenomena of mutations, a race of men undergoes modification even in the absence of interbreeding with outsiders. Finally it should be remembered that estimates of the extent of the Nordic racial element that has gone into the formation of the German nation exhibit wide differences. So it will be seen that there is still no dearth of unsolved ethnological problems.

The foregoing outline of Fick's discussion may be supplemented by a few remarks on developments in Germany with reference to racial questions. A recent report has it that the National Center for Racial Research has been swamped with inquiries with reference to the best means of maintaining accurate genealogical data. The members of many professions (writers, for example) must furnish the so-called great proof of their ancestry to the year 1800. For most persons however, less formidable proofs are sufficient. For ordinary usage officialdom has devised a small genealogical passport known as a mirror of ancestry. This document contains official genealogical data through the holder's grandparents and further space is provided for notations concerning the great grandparents and future marriages. Moreover, it is interesting to note that the national führer of medicine Dr. Wagner has recently deprecated the fact that an increasingly large number of incompetent persons are concerning themselves with questions of race and as a consequence causing inferiority complexes to develop among our people. It is not proper that such and such persons should be set down as of higher or lesser value to the community on the basis of any sort of imaginary characteristics and of erroneous ideas about various races that compose the nation.

To go from the general to the specific Stettin has been the first German city to undertake an official genealogical card index designed to contain hereditary-biologic data on all the 270,000 inhabitants. In order to lay the groundwork for this project, questionnaires were distributed among the schools. The first 3,000 blanks already filled out have been received at the municipal bureau of health. There the data will be further coordinated, formed into genealogical tabulations and kept down to date. Also of interest is a suggestion appearing in the *Frankfurter Zeitung*, one of the most prominent German newspapers, that even now the extant literature of the racial question, as a perusal will show, fails to conform to the opinions of experts on racial policies. The principal trouble may be that a combination of political and scientific views is not yet evidenced by the majority of authors.

On the question of mixed marriages with Jews a decision has recently been handed down by the supreme court. Many of the so-called German blooded wish to have their own such marriages dissolved, in part for economic reasons in part as a consequence of the new officially propagated views. Although the legislator subscribes to the principle that mixed marriages, which have existed for long periods (and which frequently, till a short time ago, were quite happy) cannot be lightly dissolved the supreme court has decided that such mixed marriages, since the relationship is qualified by racial dissimilarity, may be destroyed more easily than other marriages and that their continued existence is no longer to be expected.

Racial dishonor through sexual intercourse with Jews or partial Jews is recognized in Germany as a valid legal concept. According to a communication of Dr. Kuhn from the national ministry of justice, of all persons legally sentenced for this offense to date 17.8 per cent were of German blood and 82.2 per cent were Jews. Of the defendants in such cases, seven eighths of the Germans and four fifths of the Jews were charged with offenses committed prior to the enactment of the Nuremberg laws.

According to the latest statistics on insanity compiled by Professor Rudin there are from 200,000 to 250,000 cases of schizophrenia in Germany and quite as many cases of epilepsy. At least 1 per cent of the total population must be classed as feeble-minded, but since various investigators have not agreed as to where the border between feeble-minded and normal should be drawn, one must place the figure at from 1 to 4 per cent of the entire population.

At a meeting of the National Socialist League of Physicians, Dr. Wagner, the national führer of medicine, cautioned against the philosophy that all persons who appear to present bad heredity must submit to sterilization. Negative hereditary factors should not, as all too frequently happens, be shoved to the fore. The discussion of these questions is by no means yet at an end. A court in Frankfurt-on-the-Main has recently decided that the marriage contract between a eugenically healthy person and a person with defective heredity is not permissible even if the latter consents to sterilization. It is not right that a healthy person capable of reproduction should be bound to a sterile person. On the other hand, a man was recently sentenced to two months' imprisonment for an insult to a person of defective heredity. The insult had to do with the sterilization of the complainant's son, which had been performed on account of congenital feeble-mindedness. In a recent far-reaching decision the Munich superior court dismissed as trivial objections to sterilization based on religious grounds. The concept of sterilization as an undeserved punishment is erroneous.

The charge for a sterilization by roentgen irradiation, including the fee of the physician who administers the treatment is fixed at 50 reichsmarks, for sterilization by irradiation with a radioactive substance the charge is 40 reichsmarks and this includes the initial examination and the medical measures necessary for a proper arrangement of the radium deposit.

ITALY

Sept 15 1936

Social Administration of Medical Care

Regulations have been given for the establishment of insurance societies for the administration of medical care to workers of different social standing in all Italian provinces. The societies will function under regulations which differ only in relation to the amount of prizes given when one marries and at the birth of children and as to the expenses of funerals. The insured has his medical care paid for and he is free to select his own physician. If he needs hospitalization the insurance company is obliged to provide it. The Cassa Nazionale Malattie for department store employees has been functioning for several years, and about 200 firms have their employees insured with this society. Branches of the society were established at Libia last July. The benefits of rural insurance for maternity cases which, up to now, was given only to women working in rural industries is now being given also to women working on farms. Farm mothers will be given a fixed cash amount of 100 lire (\$5) for each delivery aside from the necessary hygienic and medical service during pregnancy, delivery and the puerperium. The expenses made by the insurance society on farm mothers are met with a fund from contributions of the employers at a rate of 5 lire (\$0.25) a year for each insured farm woman, an annual payment from the insured farm women of 2 lire (\$0.10) and a contribution from the state. The new insurance society will insure about 1,500,000 farm women and will give services in about 100,000 deliveries a year. All women between the ages of 15 and 50 working on farms have to be registered. Insuring farm mothers became a need from the high mortality rate (3,000 women a year) in pregnancy, labor and the puerperium in those women. The annual mortality of new-born infants in Italy is as follows 20,000 infants die from obstetric complications during the first five days of life, and 40,000 are born dead. By adding the figures from abortions and of infants who die in the first month of life, there is a loss of 160,000 lives for each million infants born.

Plans are being made for the establishment of an insurance society for administration of medical care to artists and professionals.

"Synthetic Wool," a Possible New Suture Material

Professor Mozzetti, in a lecture recently delivered before the Società Medico-Chirurgica of Venice, reported results on the use of synthetic wool in surgery, especially in laparotomy. Synthetic wool is the precipitate of milk casein. It can be spun into a fine thread, about 30 microns thick, which can be wound and woven. The product can be sterilized. The speaker left small wads of unwoven sterilized synthetic wool within the peritoneal cavity of one lot of rats and rabbits. In rats and rabbits in another lot he introduced synthetic wool threads through the abdominal wall and left the threads in the subcutaneous tissues, between the aponeurosis and the muscles and within the muscles. Later he made microscopic studies of the tissues of all the animals. The speaker exhibited moving pictures showing the tolerance that living tissues have to this synthetic material also that the latter, when in contact with living tissues, especially the peritoneum induces a polymorphonuclear neutrophil leukocytosis of short duration followed by progressive reabsorption of the material by the tissues. The reabsorption is slower in the spaces of the aponeurosis than in the other spaces but its tolerance to the material is the same in all the tissues. The speaker points out the possible surgical value of synthetic wool, which might later perhaps, be a substitute for catgut and silk. The product is made up of nucleo albumins.

Marriages

ALFRED G. GRUNWELL, Surg. Lieut. Commander, U. S. Navy, retired, Punta Gorda, Fla., to Miss Hattie Griffin at Black Mountain, N. C., September 3.

ROBERT BRECKINRIDGE WARFIELD, Lexington, Ky., to Dr. EMILY ELIOT STURGIS of Chevy Chase, Md., September 26.

ALBERT F. HARDT, Williamsport, Pa., to Miss Edythe Marie Black of Elmira, N. Y., in Glencaryn, Va., August 31.

KENNETH BROWN ROTHEX, Spring Lake, N. J., to Miss Barbara Asquith Scott of Charlotte, N. C., August 14.

EDWIN BELL VAN NESS, Gulfport, Miss., to Miss Charlotte Allen of Bloomington, Ill., in August.

CHARLES FLOYD GRIFFITH, Griffin, Ga., to Miss Mary Riviere of Barnesville, in Macon, August 16.

JOSEPH J. GRAMLING JR., Wauwatosa, Wis., to Miss Marcy Walsh of Chicago, August 29.

LOYD HISRICHE, Batesville, Ind., to Miss Ella Whipple of Mount Vernon, August 16.

CLINTON A. HARDESTA, Paragould, Ark., to Miss Mildred McDaniel, September 1.

Deaths

William Buchanan Wherry, Cincinnati, Rush Medical College, Chicago, 1901, professor of bacteriology and hygiene at the University of Cincinnati College of Medicine, formerly known as the Ohio-Miami Medical College of the University of Cincinnati, where in 1909 he was assistant professor of bacteriology and associate professor from 1910 to 1913, assistant in bacteriology at the University of Chicago from 1901 to 1902, and associate from 1902 to 1903, professor of bacteriology, Oakland (Calif.) College of Medicine and Surgery in 1907, bacteriologist for the board of health of San Francisco and acting assistant surgeon on plague duty for the U. S. Public Health Service from 1907 to 1909, bacteriologist for the United States government laboratories in Manila, P. I., from 1903 to 1905, for many years member of the city board of health, member of the American Society for Experimental Pathology, visiting professor at the School of Hygiene, Manila, P. I., from 1929 to 1930, director of service, Cincinnati General Hospital, consultant in the U. S. Public Health Service, in 1914 with others reported the first case of tularemia in man which was proved bacteriologically to be due to *Bacterium tularense*, aged 60, died, November 1, in the Holmes Hospital, of cerebral embolism.

Wade Wright of Roxbury, Conn., Harvard University Medical School, Boston, 1914, formerly lecturer in pharmacology at the Columbia University College of Physicians and Surgeons and instructor of industrial medicine at the Harvard School of Public Health, served during the World War, for several years in charge of the industrial clinic operated by Harvard as a department for clinical research in occupational disease problems at the Massachusetts General Hospital, at one time assistant medical director of the Metropolitan Life Insurance Company, aged 46, died, August 25, in Wallingford of pulmonary tuberculosis.

John Shade Turner, Dallas, Texas, Louisville (Ky.) Medical College, 1889, member and past president of the State Medical Association of Texas, served during the World War at one time professor of mental and nervous diseases at Baylor University College of Medicine and professor of neurology at the Southern Methodist University Medical Department, formerly member of the city board of health, medical director of the Southland Life Insurance Company, aged 70, died August 29, in the Ozark Mountain range, near Fayetteville, Ark.

Robert Bland Grubbs of Lieut. Colonel, U. S. Army, retired, Los Angeles, Columbian University Medical Department, Washington, D. C. 1899, entered the regular army as an assistant surgeon in 1901, was made a captain in the medical corps in 1906, a major in 1910 and retired with rank of lieutenant colonel in 1917 for disability in line of duty, served during the World War, aged 64, died August 18, in Stockholm of diabetes and arteriosclerosis.

Schuyler Weston Hammond of Rutland, Vt., University of Vermont College of Medicine, Burlington 1895, member of the House of Delegates of the American Medical Association

in 1905, past president and vice president of the Vermont State Medical Society, past president and member of the Vermont State Board of Medical Registration, on the staff of the Rutland Hospital, aged 69, died, September 22.

Henry Beckles Chandler, Arcadia, Calif., University of Bishop College Faculty of Medicine, Montreal, Que., Canada, 1880, member of the Massachusetts Medical Society and the American Ophthalmological Society, professor of ophthalmology emeritus, Tufts College Medical School, Boston, formerly consulting surgeon to the Massachusetts Eye and Ear Infirmary, Boston, aged 81, died, October 7.

Robert Spear, East Chicago, Ind., Trinity Medical College, Toronto Ont., Canada, 1897, member of the Indiana State Medical Association, served during the World War, formerly member of the school board, fellow of the American College of Physicians, aged 68, on the staff of St. Catherine's Hospital, where he died, August 23, of lobar pneumonia and osteomyelitis of the left humerus.

Carl Philip Bauer of Chicago, Rush Medical College, Chicago, 1922, assistant clinical professor of obstetrics and gynecology at his alma mater, member of the Central Association of Obstetricians and Gynecologists, fellow of the American College of Surgeons, assistant attending obstetrician and gynecologist to the Presbyterian Hospital, aged 40, died September 19, of coronary thrombosis.

Lewis Stanton Ramsdell, Manistee, Mich., Rush Medical College, Chicago, 1900, member of the Michigan State Medical Society, fellow of the American College of Surgeons, veteran of the Spanish-American and World wars, formerly mayor and member of the board of education, aged 61, on the staff of the Mercy Hospital and Sanitarium, where he died, October 3, of cirrhosis of the liver.

Riley Moore Waller, St. Joseph, Mo., Washington University School of Medicine, St. Louis, 1920, member of the Missouri State Medical Association, on the staff of the Missouri Methodist Hospital, fellow in surgical pathology at the Mayo Foundation from July 2, 1923, to January 1, 1927, aged 40, was found dead of an accidental bullet wound in August.

Eugene Arthur Stanley, Waterbury, Vt., Jefferson Medical College of Philadelphia, 1904, member of the Vermont State Medical Society, the American Psychiatric Association and the New England Society of Psychiatry, aged 61, medical superintendent of the Vermont State Hospital for the Insane, where he died, August 19, of arteriosclerosis.

Frank Herbert Smith, Amherst, Mass., University of Pennsylvania Department of Medicine, Philadelphia, 1898, member of the Massachusetts Medical Society, for seven years physician to the Amherst College, formerly a member of the school committee, and member of the state legislature, aged 65, died, August 23, of coronary thrombosis.

William Henry Buskirk of Los Angeles, University of Michigan Department of Medicine and Surgery, Ann Arbor, 1904, fellow of the American College of Surgeons, served during the World War, for many years on the staff of the Hollywood Hospital, aged 55, died, August 7, of pneumonia following an operation for duodenal ulcer.

Albert Wilkinson of Dallas, Texas, University of Nashville (Tenn.) Medical Department, 1900, fellow of the American College of Surgeons, member of the staffs of the Methodist, Parkland and St. Paul's hospitals and associate member of the staff of the Baylor Hospital, aged 63, died, August 19, of hypertension and cerebral hemorrhage.

William Joseph Allen, Orange, N. J., Fordham University School of Medicine, New York 1920, member of the Associated Anesthetists of the United States and Canada, member of the staffs of the Orange Memorial Hospital and St. Mary's Hospital, aged 42, died, September 2, in Asheville, N. C., of pulmonary tuberculosis.

Leroy Stewart Townsend, Beaver Falls, Pa., Western Pennsylvania Medical College, Pittsburgh 1895, member of the Medical Society of the State of Pennsylvania, served during the World War, aged 65, on the staff of the Beaver Valley General Hospital, where he died, August 24, of cerebral hemorrhage.

Peter Bachman Witmer, Abilene, Kan., Jefferson Medical College of Philadelphia 1896, member of the Kansas Medical Society, past president of the Dickinson County Medical Society, formerly on the staff of the Dickinson County Memorial Hospital, aged 67, died, August 24, of coronary thrombosis.

John Percy Wade, Baltimore, College of Physicians and Surgeons, Baltimore, 1891, member of the American Psychiatric Association, at one time superintendent of the Spring Grove State Hospital, Catonsville Md. aged 65, died, August 27 in the West Baltimore General Hospital, of a gunshot wound.

Joseph Graham Mayo @ Rochester, Minn., State University of Iowa College of Medicine Iowa City 1927, son of Dr Charles Horace Mayo on the staff of the Mayo Clinic aged 34 was killed near Alma Wis. November 9, when the automobile in which he was riding was struck by a train.

Ross Elliot Black, New London, Conn., Columbia University College of Physicians and Surgeons, New York 1905 member of the Connecticut State Medical Society, served during the World War, health officer of Waterford on the staff of the Home Memorial Hospital, aged 56 died September 27.

Robert Whitehead, Victoria, Va., University College of Medicine, Richmond 1913 member of the Medical Society of Virginia, formerly secretary of the Lunenburg County Medical Society, served during the World War, aged 46, died, August 14 in Richmond of cirrhosis of the liver.

Robert George Barekley @ Milford Pa. Jefferson Medical College of Philadelphia 1891 formerly county medical director, on the staff of the Deepark Sanitarium, Port Jervis N Y, aged 76, died September 26 in the Jefferson Hospital Philadelphia, of carcinoma of the lip and neck.

George F Washburne, Glen Ellyn Ill., Chicago Homeopathic Medical College 1885, formerly health officer for the board of health of Chicago at one time physician in charge of the Spring Hill Sanitarium Hastings-on-the-Hudson, N Y, aged 81 died, August 12, of arteriosclerosis.

Ralph Henry Spencer, Grand Rapids, Mich. University of the City of New York Medical Department 1879 member of the Michigan State Medical Society, for many years on the staff of the Butterworth Hospital aged 82, died suddenly, August 7, of cerebral hemorrhage.

Charles S Bendure, Baxter Springs, Kan., College of Physicians and Surgeons Medical Department of Kansas City University, 1897, member of the Kansas Medical Society, formerly mayor of Baxter Springs, aged 76, died September 12 of carcinoma of the rectum.

David Benjamin Tuholski @ Brockton, Mass. University of Pennsylvania Department of Medicine, Philadelphia 1907 past president of the Plymouth County Medical Society, at various times health officer of Brockton, aged 56, died, August 31 of coronary thrombosis.

John James Wharton, Washington D C., George Washington University School of Medicine Washington 1905, member of the Medical Society of the District of Columbia, aged 63 died August 14 of hemiplegia, cerebral hemorrhage and arterial hypertension.

Alfred R. Warden, Grafton, W Va. Western Reserve University Medical Department Cleveland 1886 member of the West Virginia State Medical Association, formerly member of the state board of health and county health officer, aged 78 died, August 20.

Joseph B Shaw @ Trenton N J., University of Pennsylvania Department of Medicine, Philadelphia 1885 formerly mayor of Trenton for many years on the staff of the Mercer Hospital aged 75 died August 14 of arteriosclerosis and cerebral hemorrhage.

William Bowen Seull @ Philadelphia University of Pennsylvania Department of Medicine Philadelphia 1885 member of the House of Delegates of the American Medical Association in 1911 and 1920, aged 73, died October 1 in the Episcopal Hospital.

Harry Percival Woley @ Chicago College of Physicians and Surgeons Medical Department of Columbia College New York 1890 for many years connected with the New York Life Insurance Company aged 72, died, August 12, in a hospital at Evanston Ill.

Frederick Ellsworth Sweetser @ Merrimac Mass., Medical School of Maine, Portland, 1888 for many years member of the school committee on the staff of the Amesbury (Mass.) Hospital aged 69, died September 29, of angina pectoris and myocarditis.

Ralph Allen Smith, Tiffin Ohio Western Reserve University School of Medicine 1935, resident on the staff of the Women's and Children's Hospital Toledo aged 26 died August 10 in the Miami Valley Hospital, Dayton of cerebral hemorrhage.

Frank L Truitt @ Indianapolis, Medical College of Indiana Indianapolis 1904 medical director, second vice president and secretary of the Reserve Loan Life Insurance Company, aged 55, died, August 13, in the Methodist Hospital, of coronary thrombosis.

William Scaif Beaty, Poplar Grove, Ark., University of Louisville (Ky.) Medical Department, 1892 member of the Arkansas Medical Society, aged 73, died, September 2, in a hospital at Memphis, Tenn., of prostatic retention and coronary occlusion.

Katharine Anne Corey Ford, Van Buren, Ind., University of Michigan Department of Medicine and Surgery, Ann Arbor, 1883, for many years a medical missionary in China, aged 80, died, August 11, of fracture of the hip due to a fall and paralysis agitans.

John Somers Wimberly, Branchville, S C., Medical College of the State of South Carolina Charleston, 1901 served during the World War, aged 56, died August 26, at his summer home in Hendersonville, N C., of nephritis and hypertension.

Ernest Payne Van Arsdall, Danville, Ill., Loyola University School of Medicine Chicago, 1916, past president and secretary of the Cass County Medical Society, aged 48 died, August 14 at the Lakeview Hospital, following a herniotomy.

Jesse Lee Mitchell, San Antonio, Texas, Tulane University of Louisiana Medical Department, New Orleans, 1905 member of the State Medical Association of Texas, aged 55, died, August 2, of encephalitis and pulmonary tuberculosis.

Howard Louis Wilkinson, Hamilton, Ohio, Ohio State University College of Medicine, Columbus, 1911 member of the Ohio State Medical Association, served during the World War, aged 51, died, August 29, of cerebral hemorrhage.

Charles Ignatius West, Washington, D C., Howard University College of Medicine Washington, 1895 professor emeritus of topographical and clinical anatomy at his alma mater, aged 67, died, August 4, of coronary thrombosis.

James Amasa Hampton Webb @ Wichita, Kan. Kansas Medical College, Topeka 1899 member of the Radiological Society of North America, served during the World War, aged 58, died, August 4, of carcinoma of the left lung.

Paterno C Pavino, Manila P I., University of the Philippines College of Medicine, Manila, 1932, member of the Philippine Islands Medical Association, junior resident to the Philippine General Hospital, aged 31, died, July 23.

William Hay Young @ Fredonia, Kan. Eclectic Medical University, Kansas City, 1904, past president of the Wilson County Medical Society, for many years county health officer, aged 63, died, August 13, of mesenteric thrombosis.

Jesse H Beekman, Sayreville N J., Hahnemann Medical College and Hospital, Chicago 1888, member of the Medical Society of New Jersey, for many years school physician, aged 81, died, September 24, of chronic myocarditis.

Frank Elmer Phillips, North Chelmsford, Mass. College of Physicians and Surgeons, Baltimore, 1903, member of the Massachusetts Medical Society aged 65, died, August 27, of coronary occlusion and cerebral hemorrhage.

James Freeman Williamson, Pleasantgrove, Miss., University of the City of New York Medical Department 1878 aged 82, died, August 24, in the Baptist Memorial Hospital Memphis Tenn., of bacillary dysentery.

Milton Steiner, New York University and Bellevue Hospital Medical College New York 1933 intern at the Mount Sinai Hospital, aged 27, died, August 10, in the Desert Sanatorium, Tucson, Ariz., of heart disease.

Almond G Phillips, Cleveland Eclectic Medical Institute Cincinnati 1888 at one time coroner of Lake County aged 83 died, August 25, in the City Hospital, of benign hypertrophy of the prostate and pyelonephritis.

Milton Dallas Van Horn, Churchville N Y. Medico-Chirurgical College of Philadelphia, 1891, for many years member of the board of education, aged 70, died, August 25 of chronic nephritis and myocarditis.

John Silas Lankford @ San Antonio, Texas, University of Louisville (Ky.) Medical Department 1882, past president city board of health and city board of education, aged 77, died, September 21 of myocarditis.

Willis S Watson, Okmulgee Okla. Missouri Medical College, St Louis 1882 member of the Oklahoma State Medical Association aged 81, died August 9, in a local hospital, of cerebral hemorrhage.

James Edwin Smithwick ☉ Jamesville N C, University College of Medicine, Richmond, Va, 1897, aged 66 died August 24, in a hospital at Durham, of lymphosarcoma and bronchopneumonia

Frances Lewis Bishop ☉ St. Louis University of Michigan Department of Medicine and Surgery, Ann Arbor, 1893, aged 72 died, September 11, in a hospital at Cleveland of bronchopneumonia.

Gerhard Kaemmerling, San Diego Calif, National University of Arts and Sciences Medical Department, St Louis 1915, aged 55, was found dead, August 7, of myocardial degeneration

William C Thomson, Detroit, Detroit College of Medicine 1896, aged 70, died August 17, in the Tolfree Memorial Hospital, West Branch Mich of injuries received in an automobile accident

Charles Frank Werner ☉ St. Cloud Wis, College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1905, aged 62 died August 26, of angina pectoris

Benjamin Robert Benson Jr, Cockeysville, Md University of Maryland School of Medicine, Baltimore, 1907, aged 51, was killed instantly, September 22, in an automobile accident

Wilfred Lorne Atkinson, Selkirk, Manit. Canada Manitoba Medical College, Winnipeg, 1911, aged 50, died, September 15, of myocardial fibrosis, arteriosclerosis and hypertension

Fred Gilbert Vosika, Wilber, Neb John A Creighton Medical College, Omaha, 1918, member of the Nebraska State Medical Association, aged 46, died, August 26, of myocarditis

Torstein A Lid, Marinette, Wis, College of Physicians and Surgeons, Chicago, 1896, aged 68, died, August 15, in the Marinette and Menominee Hospital, of myocardial degeneration

William Obie Dodson ☉ Willow, Okla, Louisville (Ky) Medical College, 1904, past president of the Greer County Medical Society, aged 55, died, August 5, of angina pectoris

THE SHOW MUST GO ON

How an Eminent Comedian Survived Gas Pains by Using Van-Tage

Cinema addicts will rejoice that a great tragedy of the American theatre (theatre to you) has happily been averted. Mr Robert Woolsey "of the famous Wheeler and Woolsey team" has just broken down and confessed in an "unsolicited" three-column advertisement for the package medicine "Van-Tage" that he often thought he would have "to quit pictures and retire." "Only a few people have known about it," but Mr Woolsey suffered from "a gaseous stomach disorder and sluggish bowel complications." My food set up a gaseous disturbance in my stomach, causing gas cramps and pains.

Which just goes to show how seldom an audience realizes the tragedies behind the Pagliacci of the silver screen. Those

I get the full good out of my food and have more strength for my Movie Work. "Imagination fails when we try to visualize the Woolsey comedy after three bottles of Van-Tage.

It is a shame Mr Mosby did not know of actor Woolsey's gaseous stomach before, because Mr Mosby was the originator of another notable discovery, "Indo-Vin," which a few years back, was "banishing poisons that foster stomach troubles."

And, Mr Woolsey, if Mr Mosby had given you a shot of his "Konjola," which had thirty-two ingredients, we tremble to think what contortions you might have achieved. Alas Mr Mosby isn't plugging Konjola any more although in 1930 he was enthusiastic over it and flooded the newspapers with testimonials. A testimonial from a Mr A R Sheckler appeared in an eastern newspaper on August 20, 1929 stating "Another victory for Konjola in a seemingly hopeless case after all the others failed." The only thing that was wrong with this, Mr Woolsey, was that the unfortunate fellow died three weeks before the testimonial appeared.

So far as we are able to learn, Mr Mosby has never claimed to be a pharmacist, chemist or physician. Yet, by some esoteric process he is able to conjure up a shotgun cure-all every so often. Konjola was reported to contain

Caramel	Sarsaparilla Root	Angelica Root
Cascara Sagrada Bark	Yellow Dock Root	Boneset Leaves and
Glycerin	Senna Leaves	Tops
Gentian Root	Black Cohosh Root	Potassium Iodide
Queen Meadow Root	Oil of Sweet Orange	Blue Cohosh Root
Pipsissewa Herb	Wild Ginger Root	Colden Seal
Calangal Root	Burdock Root	Spikenard Root
Salicylic Acid	Pink Root	Aletris Root
Poplar Bark	Sodium Benzoate	Lady Slipper Root
Pepsin (Fluffy)	Senega Root	

Some time ago the A M A Chemical Laboratory made some cursory tests of Van-Tage, and it appeared from these that the essential drugs in it were laxatives and iodides.

We all rejoice in your remarkable recovery, Mr Woolsey, and we feel mean for ever having criticized your comedy. But how were we to know it was gas pains?

MISBRANDED "PATENT MEDICINES"

Abstracts of Notices of Judgment Issued by the Food and Drug Administration of the United States Department of Agriculture

[EDITORIAL NOTE The abstracts that follow are given in the briefest possible form (1) the name of the product (2) the name of the manufacturer shipper or consigner, (3) the composition, (4) the type of nostrum (5) the reason for the charge of misbranding and (6) the date of issuance of the Notice of Judgment—which may be considerably later than the date of the seizure of the product.]

Syn O Scope and Synex—Syn O Scope Laboratories Los Angeles Composition Synex consisted essentially of volatile oils including eucalyptus a trace of an alkaloid alcohol (20 per cent) and water (the Syn O Scope was the accompanying device) For sinus troubles hay fever asthma etc. Fraudulent therapeutic claims—[N J 2294 May 1935]

Bullock's Husk Dressing—Bullock Walker Mfg Co South Orange N J Composition Essentially calomel (53 3/4 per cent) zinc oxide (37 1/2 per cent) bismuth subnitrate (141 per cent) aluminum sulfate (01 per cent) and phenolic substances including resorcin and salicylic acid (a trace) in an ointment base For syphilis hemorrhoids ulcers cancer boils etc. Fraudulent therapeutic claims—[N J 2297 May 1935]

Woolford's Sanitary Lotion—Kells Co Newburgh N Y Composition Calcium sulfide (18 per cent) and sulfur (25 per cent) and water For mange and other skin disorders Misbranded because falsely labeled Sodium Chloride 64 Per Cent whereas it contained no sodium chloride (common salt) Fraudulent therapeutic claims—[N J 2328 May 1935]

Mentholated Chest Rub—Hance Bros & White Inc Philadelphia Composition Essential oils including menthol camphor and eucalyptol in petrolatum For sore throat coughs tonsillitis asthma muscular rheumatism etc. Fraudulent therapeutic claims—[N J 2398 May 1935]

Brumfield's Asthma and Cough Remedy—J P Brumfield Galena Kan Composition Essentially chloroform an antimony compound a fatty oil alcohol glycerin gum sugar and water. Fraudulent therapeutic claims—[N J 2392 May 1935]

ROBERT WOOLSEY

Of the Famous Wheeler & Woolsey Team of Hollywood Screen Stars

Tells What

VAN-TAGE

Did for Him!

UNSOLICITED!

This is an Unsolicited Testimonial, Given Freely to the Makers of Van-Tage, Without Any Payment of Any Kind Being Made Therefor.

Robert Woolsey of the Famous Wheeler & Woolsey Team of Hollywood Screen Stars is the latest Prominent American to publicly endorse VAN-TAGE!

This is the "Amazing New Medicine" for Ulcer Stomach, Irritable Bowels, Liver Bile Congestion, and Stagnant Kidneys, which has gained such Spectacular Success in the past few months, with sales of Hundreds of Thousands of Bottles its first year in The West.

It is now being introduced to large crowds daily here by Special Van-Tage Representatives, direct from The Van-Tage Laboratories, in LOS ANGELES at THRIFTY Drug Store, 514 S. Broadway in HOLLYWOOD at THRIFTY Drug Store Santa Monica and Western in PASADENA at THRIFTY Drug Store, Colorado and Euclid and in LONG BEACH at THRIFTY Drug Store 4th and Pine.

At Hollywood, Capital of the Motion Picture World, Van-Tage is a Sensation. This medicine is made here. The Immense Van-Tage Laboratories are located at Hollywood. So the Stars of the Screen are intimately connected with this Great Command and

grimaces of Mr Woolsey's which we mistook for comedy gestures were, in reality, gas pains. I went for days without any food at all! Going without food is not unknown to many thespians. Bob Burns of "bazooka" fame freely admits missing a meal during his vaudeville days. But Mr Woolsey suffered in silence, preserving the age old tradition of the theatre, "The show must go on." They did not know of his Daily Struggle!

Now, however the Shadow has been removed. The Daily Struggle has come to an end. So the story can be told. It's hard work in the movies.

So, from the start, I found pictures a severe physical strain. Sometimes I felt so weak I could hardly get to the

studio. I guess "Something saw me through—sheer will power,

Poor Mr Woolsey! Sitting in the lap of Hollywood luxury turning out smash hit after smash hit and about to give up the drama (drama this time!) But then came the dawn. Mr Woolsey was introduced to a Mr Gilbert H Mosby, "owner of a Medical Compound." And—but let Mr Woolsey tell us in his own words "I was amazed to discover that this medicine was what I had needed all the time. I have taken 3 bottles of Mr Mosby's Van TAGE

Now And

TRYPARSAMIDE AND OPTIC ATROPHY— TREATMENT OF SYPHILIS

To the Editor—H C a widower aged 37 came to my office complaining of difficulty in starting the urinary stream. Fifteen years ago he had gonorrhea but never noted a sore. The gonorrhea was apparently cured. Six years ago he married and he has a son 5 years of age apparently normal. Two years ago his wife died of a ruptured appendix. The difficulty in starting the stream started ten years ago and for the past year has been worse. He has noted a change in gait e. g. it is slightly different from ever before. He never had a rash. His weight is about 185 pounds (84 Kg). The eyes do not react to light but react to accommodation. The eye grounds show a clear cut view of the disk, sharply outlined. The Romberg test discloses slight swaying but no loss of balance with an accompanying dizzy feeling (heel and toe together and eyes closed). The knee jerks are absent. The genitalia are normal. Rectum examination discloses the prostate moderately enlarged baggy and markedly tender with loss of contour and no palpable vesicles. A prostatic smear was loaded with pus and clumps. Passage of a bougie did not disclose a stricture. A No 22 F steel sound passed with ease. Cysto-urethroscopy revealed the bladder mucosa and orifice normal. In the posterior lateral dome of the bladder was a fine trabecular like area of about 5 cm diameter. The trigon is slightly injected. The vesical neck shows no irregularity or encroachment of prostate there is no basal fold. The posterior urethra is covered with a gray white plastic exudate. The prostatic gland orifices appear markedly golf cupped. The vein is markedly enlarged irregular and boggy and bleeds readily. The blood Wassermann reaction was 3 plus and 4 plus. The spinal Wassermann reaction was positive (degree not known) the fluid clear and limpid. The colloidal gold test was 5433200000. The diagnosis is (1) tabetic dementia paralytica with vesical involvement and possibly optic nerve involvement (2) chronic prostatovesiculitis and urethritis. The plan of treatment adopted was that the patient should receive prostatic massage two times a week and later posterior instillations once a week with silver nitrate from 0.5 to 1 per cent. He has received iodides by mouth as much as 50 grains (3.25 Gm) each day with intervals of rest to obviate toxic results. He has received sodium iodobismuthite 2 cc twice a week for ten doses. He is to get for two weeks twice a week a mercurial solution 1 grain (0.06 Gm) followed by tryparsamide 0.2 Gm for first dose and then 0.3 Gm once a week interspersed with mercurial solution 1 grain for from ten to fifteen courses. Before the tryparsamide injections are started he will be seen by an eye physician and one week after the injections for eight visits to obviate a toxic effect on optic nerve. Between courses I intend to continue with the bismuth compound for from six to eight weeks as described. After each course I intend to take a spinal and blood Wassermann test. Should this fail I will then proceed with malarial treatment. Since I began treatment he has felt more 'peppy' and sharp but his vesical difficulty is still present. No definite changes of sight have been elicited before or since treatment and there has been no history of loss of sight acuity at any time. Have you any suggestions to improve this scheme of treatment? Should it be found that tryparsamide cannot be used what course should I take? Is this scheme adequate? Kindly omit name. MD New York.

ANSWER—So far as the syphilologic aspect of the case is concerned, the information furnished is inadequate so far as spinal fluid data and diagnosis of a possible primary optic atrophy are concerned. So long as physicians use the phrase or are willing to content themselves with spinal fluid Wassermann, clinical laboratories will not supply the necessary information for the interpretation of a patient's neurosyphilis from the serologic standpoint. An adequate diagnosis by competent ophthalmologists of the condition of this patient's optic nerves is absolutely necessary to treatment decision here. In discussing his plan of treatment the questioner evidently fears toxic results from a daily 50 grain dose of iodide by mouth—a fear which in general is unjustified. He does not state what type of mercurial solution he intends to employ, plans to begin tryparsamide without adequate ophthalmologic control and speaks of from ten to fifteen courses of tryparsamide and the mercury preparation without specifications as to the length of each course. The dosage of tryparsamide as given in the inquiry is either a typographical error or a complete miscomprehension of the standard dosage for this drug which ranges from 1 to 3 Gm instead of from 0.2 to 0.3 Gm. Not knowing the length of the tryparsamide course or the number of mercurial injections intended it is rather difficult to judge whether or not this patient will have the opportunity to eliminate accumulated heavy metal either mercury or bismuth, while he is following this regimen. So far as one can judge the intention is to make heavy metal treatment continuous over a long period which would in all probability lead to serious accumulation and toxic effect.

Tryparsamide should not be employed if, before treatment is begun, there is definite objective evidence of primary optic atrophy. Significant changes in the optic nerve likely to contraindicate the use of tryparsamide are more frequent in the taboparetic syndrome than in the preparetic states as such. Accordingly, special caution should be used in interpreting even slightly abnormal eye conditions. For the proper examination of these eyes, perimetric tests of the visual fields not rough tests, are essential, and the visual acuity, changes in the blind spots and scotomas should be specially studied. If absolutely no abnormalities appear, the patient may be given his first injection of tryparsamide, 1 Gm, to be followed in two or three days by field and visual acuity tests. The tryparsamide injection may be repeated in a dosage of from 2 to 2.5 Gm on successive weeks, each injection being followed by repetition of the ophthalmologic examination. If the slightest abnormalities appear, the treatment should at once be discontinued. Heavy metal therapy may be employed as a preliminary (preferably with a bismuth compound), one course of from six to ten injections, the subsalicylate being used at weekly intervals. Apparently the inquirer plans to use something approximating the original technic of Lorenz and Loewenhardt, which combined the administration of mercuric salicylate intramuscularly with that of tryparsamide in broken courses, usually of ten injections each, with rest intervals of from four to eight weeks between courses. This method has been supported by subsequent reports of a favorable nature, but it has been departed from by observers of large experience such as Solomon and Bunker, both of whom have given tryparsamide over periods ranging from one to eight years with injection intervals of one week during the first year or two and longer intervals subsequently. While one cannot infer from the inquiry just how soon the inquirer intends to reexamine the patient's spinal fluid, it may be said that on tryparsamide therapy not much less than a year should elapse before an effort is made to draw a definite conclusion as to serologic results.

If the use of tryparsamide proves to be contraindicated either by preliminary examination or by ophthalmologic examinations repeated weekly during the first eight or ten injections of the drug it would be advisable to consider either intraspinal therapy by the unmodified Swift-Ellis technic or some form of fever therapy. Moore, who has been the most vigorous advocate of intraspinal therapy rates it superior to fever therapy. The method is an inconvenient and now relatively less accessible one for many patients. It should be emphasized that it is probably more effective in controlling the optic atrophy than in putting a stop to the progress of the tabetic dementia paralytica as a whole. The considerations that would enable one to judge of the patient's fitness for one or the other form of pyrexial treatment are not given by the inquirer (the cardiovascular condition and so on) but it may be remarked that malarial therapy is not usually well tolerated by patients carrying bladder infections, which may give rise to an ascending pyelitis and pyelonephritis. In place of malaria the use of typhoid vaccine either as the H antigen or the unchanged vaccine, in divided doses according to the technic of Nelson is an easily controllable method, giving satisfactory immediate results but still under investigation as to the permanence of the effects obtained. Physical methods of inducing fever may be specially available for this patient and their controllability (especially the Kettering hypertherm) may make them preferable to malaria. On the other hand, if the patient is of an age and in a general condition fit to take malaria without material risk it can still safely be rated as the most effective all around measure against this type of neurosyphilis.

It should be clearly realized both by the inquirer and by his patient that if a primary optic atrophy exists it may progress in spite of any form of treatment employed and it may seem to be arrested likewise by almost any form of treatment employed except tryparsamide. This drug may be regarded as positively contraindicated if any sign of primary optic atrophy can be identified. The same is true of acetarsone.

EFFECTS OF LIQUID PETROLATUM ON VITAMIN A

To the Editor—Please give me references to articles discussing the lower ability of the body to utilize vitamin A when mineral oil is administered.

VIRIAN ZELLER GROSS Newark N J

ANSWER—As brought out in the editorial in THE JOURNAL Aug 27 1927 page 694, it is important when considering the effect of liquid petrolatum on the absorption of vitamin A to distinguish between the actual vitamin and provitamin A such as carotene. The deleterious effect of liquid petrolatum on the absorption of provitamin A has been reported by several investigators. Thus Jennie I Rowntree (The Effect of the Use of

Mineral Oil upon the Absorption of Vitamin A, *J Nutrition* 3 345 [Jan.] 1931) verified the earlier report by Dutcher that liquid petrolatum interferes with the absorption of vitamin A from the intestinal tract of animals, and the effect appears to be dependent on the amount of vitamin A in the diet. Richard W. Jackson (The Effect of Mineral Oil Administration upon the Nutritional Economy of Fat-Soluble Vitamins. I. Studies with the Vitamin A of Butter Fat, *J Nutrition* 4 171 [July] 1931) showed that liquid petrolatum caused a considerable loss of vitamin A to the animal organism if the liquid petrolatum was mixed with the vitamin A (in the form of butter fat) prior to ingestion but not if the liquid petrolatum was administered separately from the butter fat. In later work Jackson (Effect of Mineral Oil Administration upon Nutritional Economy of Fat Soluble Vitamins. Studies with Vitamin A Factor of Yellow Corn, *J Nutrition* 7 607 [June] 1934, Effect of Mineral Oil Administration upon Nutritional Economy of Fat Soluble Vitamins. Studies with Vitamin D of Irradiated Ergosterol, *ibid* 7 617 [June] 1934) showed that the deleterious effect of the liquid petrolatum is greater with the vitamin A factor of yellow corn than with vitamin A obtained from animal sources. Dutcher, Harris Hartzler and Guerrant (The Assimilation of Carotene and Vitamin A in the Presence of Mineral Oil, *J Nutrition* 8 269 [Sept.] 1934) bring out the interesting fact that liquid petrolatum interferes with the absorption of carotene, which makes up the bulk of vitamin A of vegetable sources, but has a less marked detrimental influence on the absorption of vitamin A such as makes up most of the vitamin A potency of butter fat or cod liver oil. The two articles by Jackson in June 1934 also demonstrate this fact.

In general, therefore, it may be stated that in the amounts usually prescribed and under the conditions in which it is taken, the effect of liquid petrolatum on the absorption of vitamin A of the human diet would probably be negligible. On the other hand, experimental evidence shows clearly that petrolatum is a poor vehicle for vitamin A, particularly provitamin A, such as carotene, and that its use is not to be recommended.

HIGH ACIDITY OF URINE

To the Editor—What is the significance of a highly acid urine (over 40 degrees a degree being equivalent of 1 cc. of tenth normal acid per hundred cubic centimeters of urine) in adults? What conditions besides overconsumption of acid ash foods produce highly acid urines in adults? Has it definitely been proved to have any relation to the reaction of the blood or the reaction of the tissues? Are there any conditions for which the production of an alkaline urine is beneficial? Is it advisable through the use of diet (or diet and the administration of soda) to regulate the urine to a normal range of acidity or to a point of alkalinity? Please omit name.

M D Washington

ANSWER—The normal urine is acid when the entire twenty-four hour specimen of a person on a mixed diet is tested. This reaction is due to the presence of different acid and basic constituents but mostly depends on the relative amounts of mono-basic and dibasic sodium and potassium phosphates. The acidity runs quite parallel with the hydrogen ion concentration. The normal range of pH value is from 5.0 to 8.0, the average being around 6.0.

The kidneys assist the lungs in maintaining the neutrality and alkali reserve or buffer power of the blood. The total acid secreted daily by the kidneys is equivalent to from 200 to 500 cc. of tenth normal acid, or from 200 to 500 units. This acidity is due largely to acid phosphates and to a minor extent to organic acids.

Many foods yield acid end products in metabolism. The sulfur of proteins and the phosphorus of lecithin are changed into acids. Vegetable and fruit acids undergo oxidation and give rise to alkaline carbonates. It is therefore obvious that the diet is one of the most important factors in affecting the reaction of the urine.

The reaction of the urine varies during the day. The acidity is usually highest in the morning before breakfast and diminishes after a meal. Two or three hours after a meal the urine may even become alkaline, because of temporary absorption of the acid by the food in the stomach. The alkalinity may render the urine turbid from the precipitation of phosphates. This temporary change in reaction of the urine has been called the alkaline tide. An exclusive protein diet causes an increase of acidity, such an increase is seen also in conditions of acidosis, in some infectious diseases, after excessive exercise, and hot baths with free perspiration. After ingestion of large amounts of vegetables or fruits or alkaline waters there is a decreased acidity or alkalinity. It is generally advisable to regulate the diet to keep the urine within a normal range of acidity.

On a normal diet a total acidity of over 500 units in twenty-four hours indicates a tendency toward acidosis, and a total

under 100 units a tendency toward alkalosis. In many pathologic conditions, changes in the urinary reaction are found. The amount of acid secretion by the stomach, absorption of transudates or exudates, vomiting, acute infectious diseases, pyelitis and cystitis, as well as the diet, may influence the reaction of the urine. An alkaline urine is often found with bacterial infections of the urinary tract, often accompanied by pyuria. In such cases the use of sodium acid phosphate or ammonium chloride to render the urine acid for several days may be of value.

The study of the acidity of the urine is an aid in following the effects of dietary or drug treatment in the estimation of the alkali reserve, and in the treatment of urinary infections.

The artificial alteration of urinary reaction may be effected by various drugs. Mineral acids will increase the acidity, but their usefulness is limited. Sodium biphosphate and ammonium and calcium chloride are most often used. Bicarbonates, citrates and acetates are employed to reduce the acidity or to increase the alkalinity of the urine.

The production of an alkaline urine is beneficial in lithuria with a high uric acid content of the urine, and in cystinuria. An acid urine is of value in oxaluria because it increases the solubility of oxalates, and also in phosphaturia. Normally the kidneys secrete from 1 to 5 Gm. of phosphoric acid in the form of phosphates. At times the amount rises or the phosphates are precipitated by a change in reaction. In phosphaturia the urine is usually alkaline and cloudy when voided. The treatment should remove any infection present, lower the intake of calcium, and render the urine acid with acid sodium phosphate. The fluid intake should be increased.

POLYP COMPLICATING PREGNANCY

To the Editor—A few months ago a woman came to me for advice on account of having bleeding from the vagina. The patient was a multipara and was in her eighth month of pregnancy. She did not have any bleeding up to a few days after she was due in her eighth month. Examination revealed a small polyp at the cervix of the uterus. The polyp had a pedicle about an inch long which could be felt by the finger but could not be seen because the body of the polyp will not allow the pedicle to be seen. The patient was put on observation and meanwhile the literature at hand was looked up. De Lee and Williams in their respective books on obstetrics do not explain how to handle such cases and the patient was observed until labor. She kept doing well with the slight bleeding (it was necessary to use one or two napkins) every four or five days until one day just before labor set in she lost about 150 Gm. of blood. An examination made while she was bleeding showed that bleeding came from one surface of the polyp. It stopped almost immediately with pressure made with gauze while I was looking through the vaginal speculum. The day after this bleeding labor pains set in and a child weighing 9 pounds 4 ounces (4200 Gm.) was born six hours after the pain had started. Convalescence was uneventful and at present she is getting ready to be operated on for the polyp. This happened a few months ago. Now another patient has come to me. She is a primipara in good health well built 28 years old has been married for two years and missed her monthly period. A few days afterward she started to bleed slightly through the vagina. At first she thought that menstruation was going to set in but time went by her abdomen was getting large and bleeding persisted. Almost every morning she notices a small clot of blood which comes down through the vagina. Examination of the patient shows that she is normal in every respect (pelvic measurements blood pressure heart) except that a small bleeding polyp was found in the cervix. This polyp is almost exactly the same as the one in the other case. It is small and red and has a pedicle that can be felt by the finger but not seen by the eyes because the body of the polyp does not allow the pedicle to be seen. The question for me and the one for which I inquire is: Shall this patient be allowed to go on to term with the polyp to be operated on after delivery or shall the polyp be operated on now and the risk taken of starting up an infection in order to stop a slight bleeding or to prevent a larger bleeding later on? Please omit name.

M D Puerto Rico

ANSWER—A few years ago Heidler (*Arch f Gynak* 121 429 1924) reported a death which occurred after delivery and which he attributed to the removal of a cervical polyp six weeks before delivery. Necropsy revealed a small purulent hematoma at the site from which the polyp had been removed and the vessels around this area showed septic thrombi. Heidler believed that these pathologic conditions developed soon after removal of the polyp and that this infection was a latent one but was actuated by the vaginal manipulations and instrumental delivery the patient had. This author therefore strongly counseled against any manipulation of the cervix during pregnancy. On the other hand, there have been reports of large series of cases in which the electric cautery was used during pregnancy for cervical erosions and other conditions and in which, in spite of this treatment, miscarriages or other complications were not observed.

Cervical polyps often become infected. Furthermore, in pregnancy particularly, the blood which accumulates in the vagina

from a polyp may give rise to infection. Likewise, the trauma of labor may bruise the polyp and an infection may follow. Hence in the case cited it is probably best to remove the polyp by twisting the pedicle with a long curved clamp and then cauterize the base of the pedicle with an electric cautery. Such treatment has been carried out without any untoward results.

BRONCHIAL ASTHMA WITH INFECTION OF UPPER RESPIRATORY TRACT

To the Editor—My husband Dr. S. wishes me to write to you with regard to our 7 year old son. He has had asthma since he was 2 and gets it only during the winter months after he has first contracted a cold. He is desperately ill with it for about thirty six hours and then is better until he has another cold, his resistance becoming lower as the winter progresses. He has already had one attack. He often develops ear and gland trouble as well. We should like to take him to another climate for the winter in the hope that he may escape these attacks and that he will outgrow it eventually. My question is this: What locality in the United States would probably be most favorable for him? Do you think the warm climate of Florida would be best in spite of its dampness or would Arizona's drier climate with its cold nights be more likely to agree with this condition? Or are there even better places to go than these two? Any suggestions you have to offer will be very much appreciated.

— Michigan

ANSWER—The symptoms given would indicate that the boy has a bronchial asthma which is aggravated by infection of the upper respiratory tract. It is obvious of course that the colds are only contributory factors, even though very important. Basically the child has a tendency toward asthma otherwise the spells would not occur. It is important therefore to find out to what the child is sensitive besides the fact that he contracts these colds. No mention is made of an examination from an allergic point of view and certainly the patient should have the benefit of a thorough examination followed by complete protein sensitization tests.

These tests should be carried out by the cutaneous or scratch method at first, followed by intradermal tests if necessary. All this should be done before a change of climate is considered.

On the other hand if these tests have all been carried out and carried out thoroughly, preferably by one who is experienced in making such tests, and if no benefit has been derived from this examination and treatment based on the results of such an examination the question of change of climate may well be taken up. There is no one locality which is favorable to all asthmatic patients; some do well in Colorado, some in California, some in Florida, and probably the greatest benefit is derived by those who visit Arizona.

It should be emphasized that change of climate should not be carried out until a thorough search for the cause of trouble has been instituted.

HYPERTENSION IN PREGNANCY

To the Editor—Would you be kind enough to give your opinion of the following case. The woman is now 30 years of age. Five years ago she went through a pregnancy complicated by hypertension. The systolic pressure was from 180 to 210. The urine was consistently normal. There were no complaints and no edema. The eye grounds were normal. Physical examination was negative. She delivered a normal baby at term. The baby subsequently died of a respiratory infection. The blood pressure was already elevated when the patient was first seen by the doctor. It remained elevated post partum. Chemical examination of the blood was reported negative. The Wassermann reaction was negative. Subsequently the blood pressure remained high. The urine always was normal. The patient is now two months pregnant. The blood pressure is 230 systolic, 110 diastolic. The urine is normal. There are no complaints and no other abnormalities. Would you allow such a pregnancy to continue? What treatment would you institute if pregnancy is to continue? Kindly omit name.

MD New York

ANSWER—The patient apparently has an essential or primary hypertension. In view of her present blood pressure when only two months pregnant the probabilities are that if the pregnancy is permitted to continue the blood pressure will slowly increase and in the last trimester albumin will begin to appear in the urine. The baby will probably die in utero as a result of placental infarction or abruptio placentae perhaps even before it is viable.

While in rare instances such patients go to term or near it happily it is extremely unlikely that this one will give birth to a living child. If interruption of pregnancy is refused the patient should be placed on a balanced general diet which is salt poor and advised to spend a great part of the day in bed. Later on in pregnancy she should remain in bed constantly and phenobarbital may be given as a sedative. Interruption would be indicated to spare the kidneys and heart at thirty-two to thirty-four weeks if the fetus should still be alive at that time.

TIN PANS AND FOOD POISONING

To the Editor—We have recently had a rather widespread gastrointestinal disturbance thought to be due to food served here at the institution. At this meal we served ground meats. Some of this meat was kept for twenty-four hours in aluminum containers and some of it was kept in tin pans under proper refrigeration and it appeared that those served the meat that had been kept in the tin pans were the ones who had the intestinal disturbance. When the ground meat was prepared pickles, vinegar and hard boiled eggs were mixed with the meat after which this mixture was kept in the tin pans for about three hours when it was used for sandwiches. Will you please advise whether you think that the use of the tin pans could have been responsible for the gastro-intestinal disturbance.

J. D. RILEY, M.D. State Sanatorium, Ark.

ANSWER—This query is quite involved. In response to the direct query as to whether the tin pans would be responsible per se for the gastro-intestinal disturbances, the only answer possible is that this is most unlikely. In reconstructing such an outbreak from the meager information available one would think that somewhere in the preparation or handling of the meat it became contaminated with certain bacteria, either through human or other animal sources. Moreover, whatever the contaminating bacterial organisms may have been, opportunity for them to grow and produce a bacterial poison in sufficient amounts to cause the gastro-intestinal disturbance mentioned must have been present.

This of course assumes that the clinical picture was that of the ordinary food poisoning outbreak, namely, nausea, vomiting, abdominal pain and diarrhea appearing usually from three to six hours after consumption of the causative food and that the chemical analysis of the food was entirely negative.

The clinical picture, if chemicals were involved, however, might have been similar but the incubation period would have been almost immediate. It is, indeed, unfortunate that no bacteriologic examination was made of the suspected food. In retrospect therefore, this outbreak may have been due to the fact that the food was contaminated somewhere during its preparation, either through the source of a human carrier or from some other animal source the bacterial organism being one of the group ordinarily associated with outbreaks of food poisoning in man.

Certainly the reference to tin pans could be entirely eliminated as a direct factor for it is further assumed that the pans mentioned were properly cleansed before being used.

FRÖHLICH'S SYNDROME AND OBESITY

To the Editor—A girl aged 14 years weighing 185 pounds (84 Kg.) was brought to me to help her reduce. Her blood pressure was 110 systolic, 80 diastolic, pulse 80 and her basal metabolic rate —35. The urine was normal, menstruation was normal and she did not have headaches, dizziness or tiredness. I put her on thyroid 2 grains (0.13 Gm.) a day and increased it to 6 grains (0.4 Gm.) a day and once a week gave her anterior pituitary 2 cc. for about four weeks. At the end of five months she lost 15 pounds (7 Kg.) and her basal metabolic rate was —16. The blood pressure was 120/80 but her pulse went up to 120 per minute. When medication was discontinued her weight again went up to 183 pounds (83 Kg.). The distribution of fat is that of Fröhlisch's syndrome. Advice as to the treatment will be appreciated. Please omit name.

MD Ohio

ANSWER—The problem resolves itself into two distinct phases: the treatment of Fröhlisch's syndrome proper and the treatment of the obesity.

The present status of the treatment of Fröhlisch's syndrome is unsatisfactory. Thyroid and/or various pituitary preparations have been used with varying results. For a recent review of this subject see chapters VIII and XIV of *Glandular Physiology and Therapy*, published by the American Medical Association, Chicago, 1935. Fortunately most cases of Fröhlisch's syndrome probably undergo spontaneous regression at adolescence. The simple correction of the obesity, by whatever means has seemed almost as effective a treatment of Fröhlisch's syndrome as any.

As regards the treatment of the obesity in this case the low basal metabolic rates justify the use of thyroid. However the amount of thyroid prescribed should be governed by the appearance of symptoms of overdose rather than by the desired rate of loss in weight. It is also well to consider the possibility that the basal metabolic rate of —16 (after intensive thyroid medication and at the time when both blood pressure and pulse rate were raised) may actually represent a normal or supernormal metabolic rate for this patient. A recalculation of that metabolism test on the basis of ideal weight rather than actual weight (active tissue plus much inert fat) would give a fairer estimate of the state of affairs.

Loss or gain in body weight is determined by the balance between the caloric expenditure in the form of muscular work

and heat and so on and the caloric intake in the form of food. The suggested treatment, therefore, is to adjust the thyroid medication in accordance with the principles outlined, and then prescribe a diet with a caloric value less than the energy expenditure under those conditions.

AMYOTONIA CONGENITA

To the Editor—At present I have under my care a 5 weeks old female infant with amyotonia congenita. This child was apparently normal at birth but has rapidly developed the characteristic signs of this disease within the past ten days so that at present there is atrophy of the left deltoid muscle and the lower extremities are becoming involved. This is the third consecutive child born of the same parents within seven years. Each of the other two infants died of amyotonia. Two years ago the mother had one spontaneous abortion. The blood Wassermann reaction on both parents was negative. During this last pregnancy the mother received weekly injections of a derivative of physostigmine and in the last ten days the baby was likewise injected with this drug without any resulting improvement. Both other babies were studied histopathologically and a full report on the first case was published in the *American Journal of Diseases of Children* (41: 591 [March] 1931). In both other babies the blood calcium, blood phosphorus and blood cholesterol were elevated. There were also a terminal hyperemia and edema of the brain. Briefly the pathologic condition consisted of an absence of anterior horn cells of the cord with a progressing degeneration of the few anterior horn cells left. I should like to know (1) whether there is any newly discovered treatment for this condition and (2) whether high voltage roentgen therapy over the spine will prove efficacious. Because of the rapidly fatal course of this disease I should greatly appreciate a prompt reply. Kindly omit name.

M D New York

ANSWER—I Hurwitz and Gerstle (Amyotonia Congenita with Familial Incidence *Arch Neurol & Psychiat* 33: 1317 [June] 1935) suggest the use of ammoniac acid over long periods. Three months of treatment in their case did not change the neurologic status. Other drugs such as ephedrine, physostigmine and its derivative are being used also without encouraging results. In view of the paucity of the anterior horn cells and the atrophy of those present when seen at necropsy, any drug therapy would appear to be of doubtful value.

2. No reports are known of the effects of high voltage roentgen therapy.

DEATH FOLLOWING INTRAVENOUS IODIDE

To the Editor—Is it advisable to give a patient having angina pectoris with electrocardiogram tracings showing damage to the heart muscle an intravenous injection of sodium iodide 30 grains (2 Gm.)? This was done and within forty-eight hours the cardiac condition became worse, decompensation occurred and despite all efforts the patient died. Does the sodium iodide given in dosage as mentioned have an absorbent or solvent action on the scar tissue previously laid down by former attacks of probably minor occlusion of minor vessels? What is your opinion of the intravenous use of iodide for conditions other than syphilis? Please omit name.

M D California

ANSWER—As death is liable to occur at just this time after an attack of coronary thrombosis and in just this manner when iodide is not given it is impossible to say that the iodide has been the cause of the fatality, however intravenous iodide may cause pulmonary edema in some persons and hence may have been a contributory factor in the fatality. It should be definitely understood, however, that iodide is not indicated at this time. Iodide given intravenously may have alternative value in other conditions besides syphilis but it is difficult to define these indications precisely. With quite a number of astute practitioners it is the practice to "give iodide when in doubt and sometimes good results are obtained in this manner but as iodides are so well absorbed from the gastro-intestinal tract there seems to be little reason for giving them by vein.

CONGENITAL MYOTONIA

To the Editor—I recently saw a 2 year old girl with a typical case of congenital myotonia (Oppenheim's disease). The standard textbooks give little information about the disease and I would appreciate your opinion as to the pathology, treatment and prognosis. Please omit name.

M D New York

ANSWER—Fairly adequate descriptions of amyotonia (myotonia) congenita are found in the newer textbooks of neurology and pediatrics. The article in Grinker's Neurology is particularly good. Many exhaustive articles have appeared in neurologic journals. The pathology is discussed at some length by R. R. Grinker (*The Pathology of Amyotonia Congenita* *Arch Neurol & Psychiat* 18: 982 [Dec.] 1927) and by E. S. Gurdjian (*Myotonia Congenita* *ibid* 24: 52 [July] 1930). Both articles are well illustrated and contain clinical and anatomic descriptions. The disease exists at birth. The chief feature is extreme hypotonia, so that the legs may actually be wrapped around

the neck. The weakness is profound. The tendon reflexes are absent or very weak. The change in the nervous system consists of scarcity in the anterior horn cells. There is no inflammatory reaction. The striped muscle fibers are abnormally small. The smooth muscles are not involved. There is a tendency to gradual improvement, but some degree of hypotonia usually persists. No specific treatment is known. The disease often closely resembles the Werdnig-Hoffmann type of muscular atrophy. This disease does not exist at birth but develops during the first few years of life and is more severe and progressive with early death. The alterations in the nervous system are more profound.

PERIPHERAL NEURITIS AND CHROME COMPOUNDS

To the Editor—A young woman has developed a peripheral neuritis of both the upper and the lower extremities following an alleged mild head cold. One of her duties is to wash blueprints as needed an hour or so daily. The prints are soaked (in a well ventilated room) in potassium bichromate (1 drachm to 5 gallons) lifted automatically out of this solution to drain off and then placed in a cold water bath and dried. Physical examination is essentially negative. She has a rather flushed face, congested throat and pyorrhea around a decayed tooth. Could this work be responsible for her condition? M D Connecticut

ANSWER—Potassium bichromate as used in the trade specified is frequently the cause of 'chrome holes' in the skin and chrome dermatitis, occasionally a perforated nasal septum may be encountered. Chrome vapors conceivably might lead to the acceleration of infectious processes about the gums and respiratory tract. However the direct association of a peripheral neuritis with potassium bichromate in limited exposure is scarcely warranted. Occasionally workers become sensitized to chrome compounds so that the quantity of damage resulting is far out of proportion to that expectable from trivial exposure. Sensitization to chrome is discussed by Adelaide R. Smith (*Chrome Poisoning with Reference to Manifestations of Sensitization* *THE JOURNAL*, July 11, 1931 p. 95). In the case described mention is made not only of skin lesions but also of asthma, nephritis, glycosuria, myositis and fever. These manifestations occurred on reexposure. *Occupation and Health* of the International Labor Office, specifies in discussing chromates. In the case of the mouth chromates may cause irritations, small yellowish ulcerations which heal slowly, and a type of pharyngitis regarded as characteristic. Further, the statement is made that most experts admit that chromates exercise a local effect and that a general effect is scarcely likely. In the absence of a proved sensitization to chrome compounds and in the absence of obvious local evidences of injury it is doubtful whether the peripheral neuritis mentioned in the query can be traced to chrome as the cause.

URETHRORECTAL FISTULA

To the Editor—A man aged 23 has a chronic stricture of the urethra which because of neglect has resulted in being complicated with two fistulas. One is at the junction of the urethra and the scrotum the other is inside the rectum. When urine is passed it comes out mostly through the rectum and the lower opening. There is some passed through the distal opening with only a small amount coming through the urethral opening. I opened an abscess about two weeks ago which resulted in the stricture above. What procedure would you recommend to close these openings? I am now using hydrogen peroxide injections. I have the stricture opened fairly well to and beyond the first opening but there is still some discharge from this fistula. I have used other medicines but would prefer your advice in this matter.

M D Texas

ANSWER—Urethrorectal fistula is seldom caused by stricture of the urethra alone but usually results from an abscess in the prostate. The urethroperineal fistula is probably the result of a perirethral abscess which in turn may have been secondary to stricture. Urethrorectal fistulas do not usually heal as a result of treatment of the urethra alone, and an open operation dissecting the fistulous tract and freeing the urethra is usually necessary. The chances for the anterior fistula to close following adequate dilation of the urethra and drainage are better although surgical urethrotomy may be necessary. Operation for urethral fistula of course is not possible unless the inflammation has subsided. This should be accomplished by various means such as urethral lavage and instillations of such solutions as silver salts, potassium permanganate, and other antiseptics. Local applications of heat may also be of value. If the gonococcus is present, hyperpyrexia must also be considered.

After the anterior fistula has been treated and the urethral stricture dilated urethroscopic examination may be possible to determine the relationship of the posterior fistula to the prostatic urethra. Local treatment consisting of lavage and dilation should be directed toward this area and if the fistula does not close a plastic operation may be indicated. Such opera-

tions, however, are not easy and often result in failure to close the fistula. If operation is undertaken, it would be advisable to institute preliminary suprapubic drainage in order to avoid the necessity of an inlying urethral catheter to keep the wound dry.

RADIUM TREATMENT OF CAVERNOUS ANGIOMA

To the Editor—A baby about 9 months old, was brought to me with a cavernous angioma about the size of a pigeon egg situated exactly between the inner canthi of the eyes over the nasal bone extending upward toward the glabella. Superimposed on this cavernous angioma is a naevus vasculosis. I have seen cases like it before but never in this location. Usually I have found that they respond to heavily filtered distant radium treatment. Can radium be safely used in this location with the eyes covered with lead and can my plaque, namely a 10 mg plaque be regarded as strong enough? The child has already had a few doses with apparently no effect the last dose being radium 10 mg distance 5 mm above the lesion the radium superimposed on a leaden bridge which is 0.5 mm thick with a time exposure of three hours with out effect on the birthmark. The lesion is so disfiguring to the child that something has to be done and if my technic is faulty I wish I might have your opinion. Please omit name and initials.

M D, Massachusetts

ANSWER—Generally speaking the treatment as outlined is good, though probably it does not afford sufficient irradiation. A better opinion or suggestions could be given if the doctor had given more details as to the exact size of the lesion, its elevation and also the size of the plaque (full strength?)

The average pigeon egg measures slightly more than 1 by 1½ inches. Assuming that the lesion is about 1½ inches in diameter and one-fourth inch in elevation and a full strength plaque is used, the screening is satisfactory, though 1 or 2 mm of rubber or distance might be better. The plaque is not large enough to cover a lesion of such dimensions. It might be well to divide the surface of the lesion into approximately four areas and irradiate each of these for about two hours. Overlapping of the areas should be avoided.

The treatment should be repeated at intervals of approximately six weeks until about five treatments have been given. It is well then to wait four or five months and if further treatments are indicated they may be given then.

ROLE OF PITUITARY IN LIVER FUNCTION

To the Editor—The wife of one of the members of our staff is 58 years old. During the past month the stools have been gray and though she has never developed frank jaundice the skin and the sclerae have at times a sallow muddy appearance. There is no pain abdominal tenderness or palpable evidence of tumor. There has been nausea but no vomiting. The blood sugar is consistently low between 80 and 95. Even after dextrose, 5 per cent intravenously from 400 to 500 cc twice or three times during the day there is no sugar in the urine. She has always been a heavy consumer of sweets. Since the onset of this illness she has been troubled with uncontrollable generalized itching of the skin and mucous membranes particularly in the vagina and the ear canals, which disappears when she is given large amounts of intravenous dextrose. There have been no signs of bites or allergic reaction. The blood counts and blood picture are normal. The icterus index is 14.6 the blood urea nitrogen 7.6. A malignant condition has been suspected but no evidence found. Apparently the liver is just not functioning. This might be considered a subacute hepatitis. Does the pituitary gland enter into liver function? Will you please give a recent bibliography on this subject? Please do not publish name.

M D West Virginia

ANSWER—Few references appear in the recent literature bearing directly on the control of liver function by the pituitary gland. However, a recent paper (Soskin, Samuel Mirsky, I. A. Zimmerman, L. M. and Crohn, Nathan. Influence of Hypophysectomy on Gluconeogenesis in the Normal and Depancreatized Dog, *Am J Physiol* 114:110 [Dec.] 1935) clearly shows that the hypophysis is at least one important factor in controlling the formation of blood sugar by the liver.

CALCIUM AT MENOPAUSE

To the Editor—Is there any rational basis for the use of calcium in the treatment of symptoms occurring at the menopause? Please omit name.

M D, New York

ANSWER—In the literature there are so few references to the therapeutic use of calcium for menopausal disturbances that it seems not to be considered of especial value in this respect.

Climacteric hypertension and menopausal bleeding from the uterus are two conditions in which calcium lactate or calcium gluconate might appear to be indicated. Climacteric hypertension usually responds fairly readily however to more familiar and simple methods of treatment. In the presence of menopausal bleeding disturbance in calcium metabolism with prolonged clotting time of the blood is probably one of the least likely and most remote of the several recognized causative

factors, whereas early cancer is so dangerous a possibility that it must first be rigidly sought for and excluded before one resorts to anything so uncertain in its indications and effects as calcium therapy for such bleeding.

Abraham Cantarow in his monograph on Calcium Metabolism and Calcium Therapy (Philadelphia, Lea & Febiger, 1931) makes no reference to the use of calcium in disturbances of the menopause.

INCUBATION OF MAGGOTS IN CORPSE

To the Editor—Can you give me the length of time for the incubation of maggots in a dead (human) body death having occurred during the recent warm weather? Also their relative rate of growth? The maggots in this case were from 1 to 1.5 cm in length. I am working with the county coroner on this case and will be called on to testify as to the approximate time of death. If you do not have this information I would appreciate it greatly if you could refer me to the proper source to obtain it.

H. H. HARRIS M.D. Rockwell City Iowa

ANSWER—The length of time for the development of maggots from ova on the dead human body is from twelve to twenty hours in warm weather. This time varies according to the degree of warmth the surrounding moisture and the condition of the corpse. The maggot may reach its full grown size, which is 1.5 cm long, in between twenty and twenty-four hours after incubation at 85°C in a dry bulb and at 55°C in a wet bulb. Flies are likely to deposit ova on necrotic tissue, exudate, pus and blood. In the case stated, the length of the maggots is no criterion of the approximate time of death, since ova may be deposited early or late after death, depending on whether or not flies have access to the body. Textbooks on zoology dealing with the metamorphosis of the Diptera will be found helpful.

PREGNANCY IN SYPHILIS

To the Editor—A married man the father of one child came under my observation three years ago about three days after the appearance of a chancre. The first Wassermann test was negative but the one several days later was 4 plus. I administered about thirty intravenous and intramuscular injections. No secondary symptoms appeared. No further clinically demonstrable signs of syphilis appeared within these three years. Five Wassermann tests within this period were consistently negative. One blood Wassermann test of his wife two years ago was negative. The couple is anxious for another baby and they want my advice. I had previously warned them against the possibility of transmitting the disease to the offspring. Under the existing conditions what would be the proper advice to give? Please omit name.

M D Ohio

ANSWER—A spinal fluid Wassermann test should be made of the husband and one or more blood Wassermann tests of the wife. Of course if a positive test is obtained in either intensive treatment should be instituted and no pregnancy should be initiated until at least five years after repeated Wassermann tests have become negative. If the spinal fluid Wassermann test of the husband and the blood Wassermann test of the wife are negative, the couple may have another baby. However, in order to be on the safe side the wife should have a full course of antisyphilitic treatment throughout the pregnancy but the doses should be smaller than normal. The suggestion concerning the prophylactic treatment during gestation should be made to the wife in the proper manner in order to avoid arousing an undesirable psychic effect.

COMPARISON OF TESTS FOR SYPHILIS

To the Editor—How does the Wassermann test compare with modifications such as the Kahn, the Kline and the Eagle? Kindly give them in the order of relative value. Please omit name.

M D Florida

ANSWER—The Kahn, Kline and Eagle tests are not modifications of the Wassermann test. These tests are not based on the principle of complement fixation but on the principle of precipitation. The relative value of various modifications of the Wassermann test in comparison with precipitation tests is apparent from the result of the recent evaluation study of tests for syphilis carried out by the United States Public Health Service with the cooperation of the American Society of Clinical Pathologists. The report of this study appeared in *THE JOURNAL*, June 8, 1935, page 2083. The results given in this report indicate that of the thirteen methods employed the Kahn stand out test with serum and with spinal fluid was the most dependable and that the Kline test ranked next in dependability. Also the results of these two precipitation tests were superior to any of the Wassermann methods employed in this evaluation study.

Florida June Examination

Dr William M Rowlett, secretary, Florida State Board of
Medical Examiners, reports the examination held in Jackson-
ville, June 15-16, 1936 One hundred and sixteen candidates
were examined, 94 of whom passed and 22 failed The follow-
ing schools were represented

Vermont June Examination

Dr W Scott Nay, secretary Vermont State Board of Medical Registration, reports the written examination held in Burlington, June 24-26 1936. The examination covered 12 subjects and included 90 questions. An average of 75 per cent was required to pass. Thirty candidates were examined all of whom passed. The following schools were represented:

Louisiana June Report

Dr Roy B Harrison secretary Louisiana State Board of Medical Examiners, reports the written examination held in New Orleans, June 4-6 1936. The examination covered 12 subjects and included 100 questions. An average of 75 per cent was required to pass. Ninety-seven candidates were examined 96 of whom passed and 1 failed. Four physicians were licensed by reciprocity. The following schools were represented:

Book Notices

Minor Surgery By Frederick Christopher S.B. M.D. F.A.C.S. Associate Professor of Surgery at the Northwestern University Medical School Chicago. With a foreword by Allen B. Kanavel M.D. F.A.C.S. Professor of Surgery at the Northwestern University Medical School. Third edition. Cloth. Price \$10. Pp 1030 with 709 illustrations. Philadelphia & London W. B. Saunders Company 1936.

This edition has been considerably amplified by the addition of a number of newer methods of treatment, most of which have been well established from their use by a number of surgeons. The opening chapters include a general discussion and treatment of wounds, infections, injuries and circulatory disturbances. Tumors, injuries, fractures, dislocations, infections and deformities of the various regions of the body are taken up systematically. The male and female genito-urinary organs and the anus and rectum are considered in separate chapters. Minor surgical technique and the duties of a surgical intern conclude the book. Illustrations are numerous and well chosen. They add materially to the value of the text. Numerous authorities for preferred treatment and modern points of view are given credit and in some instances brief excerpts are taken from current literature. A practical approach is made to the problems of minor surgery by frequently giving not only the author's preferred treatment but also widely used methods from leading clinics. It is explained by the author that what seems to be minor surgery at first may rapidly develop into major surgery even with the most expert early treatment. From this conception one must appreciate that the subjects included here are of much more than minor importance both to the patient and to the physician. In fact it is in this highly diversified and borderline field which strictly should not be called minor surgery, that experience is so necessary in the prevention of dangerous complications, which may require the most expert treatment or even complicated major surgery. The author offers those who meet surgical conditions which at first do not appear to be of a serious nature an opportunity to learn how such conditions may be best treated. Every hospital resident should read this book and every practitioner should profit through its study.

Plague: A Manual for Medical and Public Health Workers By Wu Lien Teh M.A. M.D. Director, Welshengshui National Quarantine Service. J. W. H. Chun M.B. B.C. Senior Quarantine Officer Shanghai. R. Pollitzer M.D. Microbiologist Shanghai Quarantine Station and C. Wu M.B. B.S. Chief Technical Expert, Welshengshui National Quarantine Service. Cloth. Price \$4.15. Pp 347 with 103 illustrations. Shanghai China, Welshengshui National Quarantine Service 1936.

It has remained for these workers in China to furnish probably the most comprehensive survey of plague in any language, certainly the most satisfactory in English. The work is a thoroughly modern treatise on the subject, mentioning even the focus of rodent plague that was discovered only in 1935 in Montana. The book, as might be expected, is particularly full on the history of the disease in China, although the authors reject the view, so often expressed, that the province of Yunnan is an endemic focus. A list of Chinese epidemics going as far back as 224 B.C. is given. Among pioneer workers are listed S. B. Grubbs and the late J. J. Kinyoun both of the U.S. Public Health Service the former for his ship ratproofing work and the latter for his work in California in 1900. The highly controversial question as to the discovery of the causative organism of plague is disposed of by crediting Kitasato with first having seen the organism now known as *Pasteurella pestis* and Yersin with first having secured it in pure culture. The authors agree with early workers as to the great value in the diagnosis of the bubonic type of plague in man that is derived from a careful study of the gross pathology of the disease.

The authors consider outbreaks of the pneumonic type of plague to have their origin in cases of the bubonic type in which lung lesions secondary pneumonia have developed but admit that not all the factors leading to the origin and spread of the pneumonic type are well understood and that a 'pneumotropism' must be considered as a possibility. There are facts in connection with the history of pneumonic plague in the United States that furnish some supportive evidence for

the latter view. The opinion is expressed that while serum therapy is not spectacularly successful, some benefit is derived from it. Bacteriophage therapy, so much written about a few years ago, is not considered of material value. In consideration of prophylactic measures, stress is laid on the importance of an educational campaign whenever antiplague procedures are necessary, even when the work is to be carried out among an ignorant population. Rat proofing is an antiplague measure is favorably regarded, and instructions in detail are given for its accomplishment. Bacterial viruses for rat destruction are not considered as important as chemical poisons. The difficulty of mass vaccination is considered and the measure is looked on with some favor, though the reader is warned that it is not to be expected to control an epidemic but rather to be used along with other and more directly effective measures. Under the head of measures against rural rodents, the statement is made with respect to the California ground squirrels that "the problem of the extermination of the pest has exercised the attention of the United States Health authorities for nearly thirty years and remains to be solved," a statement with which any one familiar with the problem will agree and one that probably is applicable to sylvatic plague anywhere. The prophylaxis of the pneumonic type of the disease is regarded more hopefully than is usually the case. This is a subject on which the authors speak with final authority on account of their large experience with this type of plague. Their injunction is that those sick of pneumonic plague must be hospitalized early (during the first twenty-four hours of illness) and that contacts of the sick are to be isolated promptly. The importance of early isolation of the sick lies in the very low, or absent, infectiveness of the patient during this period. The book is one that every research worker in plague and every administrative authority dealing with the disease will find useful—almost indispensable.

Studies in Brucella Infections. Michigan State College of Agriculture and Applied Science. Agricultural Experimental Station. Section of Bacteriology. Technical Bulletin No. 140. Paper. Pp. 51. East Lansing, Michigan, 1936.

This bulletin contains five papers, on nonspecific agglutination in the Brucella group, the chemical examination of an avirulent strain of *Brucella abortus*, a study of *Brucella abortus*-infected tissues as immunizing agents against *Brucella* infection in the guinea pig, a method for measuring the opsonocytaphagic power of the blood of cattle for *Brucella*, and undulant fever—specific treatment with brucellin and procedures for diagnosis. These reports record the continuation of the splendid studies on brucellosis made by Huddleson and his collaborators at Michigan State College.

The first study reveals that partially or completely dissociated strains of *Brucella* are unreliable as antigens for the agglutination test. There are long intervals during which dissociated strains are heat stable. The thermo agglutination test serves only as an approximate means of detecting rough and dissociated variants of *Brucella*. It cannot be depended on entirely as a routine test for the selection of normal cultures for use as antigens in the agglutination test.

The second paper describes the occurrence and properties of various cellular fractions of an avirulent strain of *Brucella abortus* compared with the composition of normally virulent strains. The principal differences were found to consist in serologic dissimilarities between the protein fractions and in the absence in the nonpathogenic strain of a conjugated protein constituent which is largely responsible for the toxicity and serologic properties of the virulent strain.

The third study was made to determine the value of *Brucella abortus* infected tissue as an immunizing agent against *Brucella* infection in the guinea pig. The spleens of infected guinea pigs and infective fetal exudate from fetal membranes treated to render them noninfective were studied. The results showed conclusively that when infected guinea-pig spleen and exudate from the fetal membranes of an aborted bovine fetus are treated with either chloroform or solution of formaldehyde to render them noninfective they are without value as immunizing agents against experimental *Brucella abortus* infection in the guinea pig.

The fourth report describes a method for determining the degree of immunity in cattle against *Brucella* infection. The

method involves the measuring of the phagocytic power of the polymorphonuclear leukocytes in an opsonocytaphagic system.

The fifth paper describes the results obtained in the treatment of 100 cases of brucellosis (undulant fever) in human beings with brucellin, a fraction of *Brucella* cells obtained by growing the organisms in peptic digest liver broth. The bacteria-free active agent is recovered from the liver broth filtrate. Of the 100 patients who were treated with brucellin, twenty-three were under 11 years of age. A small number were laboratory workers who contracted the disease in line of duty. From information obtained by physicians in charge of the nonlaboratory cases there was convincing evidence that more than 75 per cent contracted the disease through the ingestion of raw infective dairy products. In the cases of children and infants there was no evidence which would indicate that the source of infection was any other than raw infective milk. There were twenty-nine cases in which agglutinins could not be demonstrated in the blood in a dilution of 1:20 or above. Eighteen of these, or 62 per cent, were in children under 11 years of age. The diagnosis in these cases was based on a positive allergic skin test and opsonocytaphagic blood test or a positive blood culture. The authors believe that the further use of these diagnostic methods, in addition to the agglutination test, will dispel the long held assumption that children are not as susceptible to the disease as are adults. The intradermal testing was done with a standardized *Brucella* nucleoprotein suspensoid known as "Brucin." The authors have outlined in detail the procedure to be followed in using brucellin as a therapeutic agent. Of the seventy cases in which the duration of symptoms was less than 121 days before treatment with brucellin, recovery occurred in fifty-one (73 per cent) within twenty-two days after the first injection, and in eighteen (26.1 per cent) after the twenty-second day period, one (1.4 per cent) failed to respond to treatment. Of the thirty cases in which the duration of symptoms was more than 120 days before treatment, recovery occurred in seventeen (56.6 per cent) within twenty-two days after the first injection and in ten (33.3 per cent) after the twenty-two day period, two terminated fatally and one failed to respond to treatment. If the six cases that failed to respond to treatment and the two in which death occurred are excluded it was found that the average duration of illness per case before treatment was 159.3 days. The average duration of illness per case after treatment was begun was 18.2 days.

An Epitome of Obstetrical Diagnosis and Treatment in General Practice. By Bethel Solomons, M.D., F.R.C.P., F.C.O.G., Gynaecologist, Dr. Stevens Hospital, Dublin. Volumes I and II. Second edition. Cloth. Price 2s. 6d. per volume. Pp. 184, 65, 140. London: John Bale Sons & Danielsson Ltd. 1936.

The amount of useful information which the author has included in these two booklets is amazing. The books were written for general practitioners, hence all the advice given is of a practical nature. The first volume is divided into two parts, the first of which deals with normal pregnancy, normal labor and the uncomplicated puerperium. The second part is concerned with abnormal pregnancy and includes the toxemias, uterine hemorrhages, ectopic pregnancy, diseases of the ovum and diseases in pregnancy. In the second volume the author takes up abnormal labor, the abnormal puerperium and obstetric operations. In discussing the conduct of labor, the author says:

There is no need to wear masks or gowns, but the doctor should not blow or cough into the vagina. Since the use of a mask entails no trouble and but little expense it should be used during every delivery, because droplets from the mouth may reach the vulva and vagina not only during blowing and coughing but also while the physician is talking. The author favors the use of episiotomy where indicated and its repair with large, through and through silk worm sutures. In the treatment of eclampsia, Solomons favors the use of purgatives, colonic lavage and gastric lavage, procedures that have largely been given up in this country. For the treatment of accidental hemorrhage (abruptio placentae) the author recommends puncture of the membranes, solution of posterior pituitary and treatment of collapse especially with saline solution. He believes that the best therapy for placenta praevia is version, regardless of whether the cervix is completely dilated or not, but he

BOOK NOTICES

JOUR. A. N. A.
Nov. 14, 1936

properly emphasizes that after the version the patient should be left to deliver herself. Cesarean section is reserved for some cases of placenta praevia, the classic operation being the one of choice. The sections dealing with the conduct of labor are particularly commendable. In the treatment of postpartum hemorrhage, Solomons advocates the use of a hot intra-uterine douche, but this procedure has so many disadvantages that it may well be omitted from the treatment of postpartum bleeding. Chloroform is recommended, although the author definitely points out its limitations. The author's vast experience as an obstetrician and gynecologist is evident by the sound advice given in every chapter. The booklets will prove valuable not only to general practitioners but also to medical students, because they completely summarize the actual practice of obstetrics.

Clinical Heart Disease By Samuel A. Levine, M.D., F.A.C.P., Assistant Professor of Medicine, Harvard Medical School, Cloth, Price \$5.50. Pp. 445 with 87 illustrations. Philadelphia & London: W. B. Saunders Company, 1936.

One who is familiar with Dr. Levine's numerous contributions to the subject of heart disease has no difficulty in recognizing that much in this volume is virtually what he has published elsewhere. The book, however, is not merely a random collection of reprints. The old material has been worked over and collected into what may be viewed as a collection of essays, each with a direct bearing on the topic of the clinical features of heart disease. The chapters or essays are arranged in a somewhat casual order yet in such a way that each chapter or group of chapters contains a fairly complete presentation of one topic—like a short story. Thus there are three consecutive chapters devoted to acute rheumatism and rheumatic heart disease, one chapter of some fifty pages is on angina pectoris and coronary thrombosis, fourteen pages are given to acute and subacute endocarditis, thirty to the treatment of congestive heart failure. The longest chapter, more than 100 pages, is the one on clinical electrocardiography. There are two short but interesting chapters, one on the clinical significance of the systolic murmur, the other on acute cardiovascular emergencies. The book is not suited to the needs of the undergraduate, whose guide should be a text more comprehensive than this with more consideration of pathologic anatomy, etiology, and historical background. Nor is it for the research worker. The author's purpose, however, was to write a book that might help the general practitioner solve some of the difficult problems presented by heart disease. This purpose has been well fulfilled. It is a pleasure to note that emphasis is put on the frequent possibility of reaching a diagnosis by history and study of symptoms and signs without the appeal to the laboratory or the instrument of precision. It is also a pleasure to state that the author's views seem in general to be sound. If occasionally he is a little nonorthodox, he makes himself responsible. This preservation of individuality is in no sense offensive, it is, rather, refreshing.

Aural Therapy in Relation to Deafness By Professor D. F. Fraser, M.D., D.Sc., B.Sc., With a foreword by Sir James Purves-Stewart, K.C.M.G., C.B., M.D., Second edition. Cloth, Price 7s. 6d. Pp. 45 with 10 illustrations. London: Sterling Medical Publishing Co. [n. d.]

This short treatise, with a foreword by Sir James Purves-Stewart and an introduction "by an unnamed professor on the faculty of medicine at an English University," devotes a chapter to varieties of deafness in which the author speaks of congenital and acquired as well as deafness secondary to generalized infections such as measles, scarlet fever, "rheumatism" and some forms of catarrh of the nose and throat. The second chapter deals with causes of deafness and also briefly discusses the anatomy of the ear. Among the causes of impaired hearing mentioned are cerumen, injury to the drum membrane, and obstruction of the eustachian tube. A rather striking statement is that another form of deafness is due to otosclerosis which is a rheumatic condition for just as people with rheumatism find their knuckles swell so the bones of the head may swell and be distorted. In view of all the research that has been done on the etiology of otosclerosis this theory certainly appeals to one as rather strange. In the third chap-

ter the diagnosis of deafness is discussed. The apparatus used is the audiograph, which is similar in many ways to the various types of audiometers used in this country. A number of graphs are shown and one type of deafness is termed "neurotinnital deafness," with "otosclerosis" in parenthesis. The fourth chapter deals with treatment by hearing aids, and the author emphasizes the fact that the aids should be prescribed to suit the individual requirements of the patients, depending on the type of hearing impairment present. The next chapter describes the treatment of certain forms of impaired hearing by means of a "thermocatheter," used, however, in the external auditory nerve canal. The principle is that an oil with a low melting point is placed in the small cup of the instrument called thermocatheter, the inside of which can be warmed by an electric current. When the contents of the cup have reached the proper temperature the fatty ointment begins to flow out of the little cup down the meatus to the drum head. Here it does its work without waiting to be absorbed first into the blood and then carried round the circulation in order to reach the ear. The author states that in cases of senile deafness and "of deafness associated with rheumatic and gouty conditions, this form of direct medication is very helpful and should be persisted in for some length of time." In the sixth and final chapter the author states that by the use of audiometric measurements, changes in hearing are detected which were overlooked when only tuning forks were used. This brochure is unique in some of the points it emphasizes also in the use of certain terms, such as "neurotinnital deafness" and in its description of otosclerosis as a rheumatic condition.

L'année électro radiologique Par Morel Kahn avec la collaboration de MM. G. Appell, Duclaux et al. Deuxième année (1934-1935). Paper, Price 40 francs. Pp. 266 with 38 illustrations. Paris: Masson & Cie, 1936.

This is an annual report divided into three parts, roentgen diagnosis, therapeutic radiology and electrotherapy. The subjects considered in each chapter contain a clinical discussion and a special description of the techniques of roentgen examination, which are well illustrated, and the treatment with roentgen radium or electric modalities. The subjects of the first part are pneumoconiosis, tuberculosis of the granules froides, diverticulitis of the gastro intestinal tract, amebic colitis, diseases of the pancreas, vasog tumors of the hypophysis. The chapter on radiation therapy includes the application to disturbances of the sympathetic system, which are made either centrally over the plexus dolorosa or regionally or cutaneously over the puncta dolorosa. Total body irradiations are next discussed. They are used in general of the blood, of the reticulo-endothelial system and in general in permanent and paroxysmal hypertension in the angims and in arteriosclerosis of the extremities are given. The treatment of secondary glandular carcinoma is the most difficult problem in the treatment of cancer. Prophylaxis is discussed from surgical and radiologic standpoints. The best treatment appears to be a combination of surgery, radium and roentgen rays. A description of radium therapy in cutaneous angiosarcomas follows. Finally the researches on artificial radioactivity are reported including irradiations with light rays and electric currents. Next a discussion of fever therapy is given. An interesting article is assigned to the treatment of benign uterine hemorrhages caused by myomas which may be successfully treated with radium roentgen rays or electrolysis with copper or silver. Submucous polyps are destroyed by electrocoagulation. Functional hemorrhages indicate interstitial electrolysis and diathermy of the hypophysis. A discussion of the treatment of diffuse peritonitis recommends evacuation of the purulent material and direct exposure to ultraviolet rays. The treatment of injuries by light rays as sun and heat concludes the review. An annex reports the scientific proceedings of the national and international congresses of radiology held during 1934-1935. The annual is a valuable contribution. It has a recommendable advantage by reporting only those investigations in which original and good work has been done.

Your Breath and Your Health By Louis M Pearlman M.D. Cloth Price \$1 Pp 128 with 8 illustrations New York Academy Publishing Company 1936

After an introduction by Barnet Joseph and a preface by the author, this little book is divided into three parts. The first is a physiologic survey of the sense of smell, metabolism, respiration and the blood circulation. The second part deals with the local causes of bad breath, particularly as regards the mouth, teeth, tonsils, sinuses, nose and ear infections. The third portion concerns itself with the systemic or constitutional causes of bad breath. This includes diseases of metabolism, infections and neuroses. Foul breath, or "factor ore" as it is known medically, is a subject that well warrants attention. The public mind has been aroused by advertisements of certain well known preparations to be used as mouth washes and gargles, in the effort to remove the so-called halitosis. Many people believe that bad breath is due to some disturbance of the stomach. Otolologists have, of course, known for a long time that conditions in and about the mouth and throat are most common causes of this disagreeable condition, and particularly the caseous plugs which form in the tonsil crypts. This little book is evidently intended for the layman and as such should prove exceedingly enlightening and lead many to seek medical attention to relieve foul breath. The work is systematically arranged and the illustrations are simple and easily understood.

Die Tuberkulose Therapie des praktischen Arztes mit diagnostischen Bemerkungen Von Prof. Dr. Kurt Klare Arzt Direktor der Prinzregent Luitpold Kinderheilstätte Scheidegg und Dr. Hans Heinrich Knödel Chefarzt der Heilstätte Harzgerode Ninth and tenth edition Paper Price 8 marks Pp 111 with 41 illustrations Leipzig Curt Kabitzsch 1936

This book attempts to give to the clinician a short survey of the facts necessary for understanding the distribution, course, prophylaxis, diagnosis and treatment of tuberculosis. The authors, both working in large tuberculosis sanatoriums, do not enter deeply into the theories and the manifold problems of the disease but concentrate strictly on that which is necessary for practical work. In the chapter on prophylaxis and general treatment the social questions and the special conditions in Germany with her well organized tuberculous "fuersorge" system are mainly referred to. The results of the tuberculin tests, blood picture, sedimentation test and sputum examination are evaluated and the general treatment, as well as chemotherapy, and the problems of nutrition are discussed. Therapeutic measures for fever, cough and pulmonary hemorrhage are given. Much space is devoted to the indications and descriptions of surgical procedures, especially pneumothorax, the excellent results of which are emphasized by instructive illustrations. The indications for isolation of the patient from the family and for hospitalization also are stated. In pregnancy the authors feel that artificial interruption is necessary only on rare occasions. A special chapter deals with tuberculosis in childhood, where hereditary and constitutional factors are greatly stressed, and finishes with a short survey of the extrapulmonary forms of childhood tuberculosis. The general practitioner may get some quick information from this book but little of value is presented to the physician familiar with any standard textbook on the subject.

Annual Report for the Year 1935 Central Narcotics Intelligence Bureau Egyptian Government Paper Price P.T. 10 Pp 104 with illustrations Boulak Cairo Gort Press 1936

This is an exhaustive report on the activities of the Central Narcotics Intelligence Bureau of the Egyptian government for the year 1935. Smuggling trafficking, seizures, prosecutions and judgments narcotic addiction, adulteration of narcotic drugs the social effects of narcotic addiction, and legislation in Egypt and other countries are discussed, and elaborate tables are given on practically all the important aspects of the narcotic problem. Hashish seems to be largely used by the drug addicts of Egypt. Cocaine and the derivatives of opium other than diacetylmorphine apparently play a minor part. Traffic seems to be carried on according to usual methods, such as through concealment in the soles of shoes in the interior of cases, and between the false walls of containers of various kinds, but the reported case in which opium was concealed in the gullets of birds is probably unique. If the data given in this report are accepted at face value it may be

assumed that narcotic drug addiction is on the wane in Egypt but even so there remains plenty to do and the problem of treatment and cure of narcotic addicts is as yet unsolved. The director of the bureau recommends that the Egyptian government send a mission of carefully selected doctors to the United States to study methods of treatment prevailing in this country. His idea as to the basic method to be pursued in suppressing illicit traffic, as stated at Geneva in May 1935, is set forth in the report.

As I have said before important narcotic seizures do not fall into one's lap like ripe plums nor is information to be had for nothing from Sunday school teachers and other honest folk.

To fight the illicit traffic good information must be obtained from the inside and must be paid for while anticontraband services must be well funded well paid and well rewarded.

Of this record and report the Central Narcotics Intelligence Bureau of Egypt may well be proud.

The Practitioners Library of Medicine and Surgery Volume X Dermatology and Syphilology Supervising Editor George Blumer M.A. M.D. David P. Smith Clinical Professor of Medicine Yale University School of Medicine Associate Editor C. Guy Lane M.D. Instructor in Dermatology and Syphilology Harvard Medical School Cloth Price \$10 Pp 1043 with illustrations New York & London D. Appleton Century Company Incorporated 1936

In this volume thirteen eminent dermatologists collaborate to present a complete textbook of dermatology and syphilology. The opening chapter is a general discussion of common conditions affecting the skin as well as general methods of diagnosis and treatment. Then follow infections of the skin various forms of dermatitis, tumors, toxic dermatoses, other dermatoses, abnormalities, diseases of the nails and hair and of the lips and mucous membranes, pigmentary disturbances, endocrine manifestations, neuroses and syphilis. The section on syphilis, by Dr. Joseph Earle Moore, is essentially a condensation of the more extensive volume on the subject made available independently. There are hundreds of pictures such as are necessary in any textbook of dermatology, and a good index to complete the volume. Each of the chapters is supplemented by a brief bibliography. The book is a commendable volume and fits well into the system of which it is a part.

Les atrophies gastriques dans les anémies idiopathiques et les métanémies Par Robert Lehmann Paper Pp 119 with illustrations Paris Librairie E. Le François 1936

Lehmann has studied the gastroscopic appearance of the stomach by the Schindler technic in nineteen patients and correlated his observations with the radiologic, clinical and hematologic data in each case. In four cases of pernicious anemia he found "zonal" atrophic gastritis associated with hunterian glossitis and total gastric achylia. In one instance he observed the simultaneous regression of the gastritis and glossitis with liver therapy. In five cases of hypochromic anemia no atrophy and "zonal" atrophy of the stomach were found once each and diffuse atrophy three times. One of these patients was reexamined after iron therapy and showed regression of the atrophy. Three of four patients with aplastic and pseudo-aplastic anemia showed diffuse atrophy. A patient without anemia but with zonal atrophy reexamined after iron therapy showed definite improvement in the appearance of the mucous membrane, and another patient with macrocytosis but no anemia showed a disappearance of diffuse atrophy following liver therapy. Lehmann's conclusions are rather more definite than justified by his limited number of observations. His belief that "zonal" atrophy responds to liver therapy and diffuse atrophy to iron therapy should however be provocative of further studies.

Illustrations Contributaires to Public Health Being the Names Carved on the New Building to House the Departments of Health Hospitals and Sanitation and the Office of the Chief Medical Examiner A Souvenir Prepared for the Dedication Exercises on Tuesday November 26 1935 By Charles Frederick Bolduan M.D. Department of Health City of New York Cloth Pp 33 with 28 illustrations Privately printed New York The Author 1936

This book was prepared as a souvenir for the dedication of the new building to be devoted to public health in New York City. On the various façades of the building the names of great contributors to medicine have been carved. The purpose of the souvenir booklet is to provide thumb-nail biographic sketches of those whose names have merited this honor. There are also some excellent photographs of these great contributors to the advancement of public health.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Typhoid Fever Liability of Municipality—Ogden City owns and operates a water supply system, including sources of supply, by means of which it supplies water to its inhabitants. A major portion of the water is obtained from artesian wells. When necessary, however, additional water is obtained from a canyon stream known as Wheeler Creek. In 1928 the state sanitary engineer reported that the latter source of supply would be "subject to human contamination" and recommended that the water be chlorinated. The city purchased a chlorinator and contracted for the erection of a building to house it. The chlorinator was not used, however, until after July 11, 1929. In the meantime the city continued to use water from Wheeler Creek. During the latter part of June and the early part of July, 1929, fifteen known cases of typhoid fever developed in the city. In the present proceedings, the legal representatives of two of the typhoid patients who died sued the city, alleging that the deaths were caused by typhoid fever contracted through drinking contaminated water negligently furnished by the city. From a judgment in favor of the city, the plaintiffs appealed to the Supreme Court of Utah.

According to the evidence, test samples of water from Wheeler Creek, taken during the summer of 1928 and on July 1, 1929, showed the presence of coli bacilli. A test sample taken from the city mains on June 15, 1929, was negative for coli bacilli, but another sample taken July 14, 1929, was positive. Expert witnesses testified that the presence of coli bacilli in the water indicated contamination with either human or animal fecal matter and that their presence constituted a warning that typhoid germs might also be present. Water so contaminated is regarded as unfit for human consumption. Expert witnesses for the plaintiffs testified that the water supply was probably the source of the typhoid infection. On behalf of the city, it was shown that five of the persons who contracted typhoid fever had eaten at a certain restaurant, a waitress in which later had developed typhoid fever, and that eight others had frequented another place which was also frequented by a typhoid carrier. It was shown, furthermore, that a number of summer residents at a resort at the mouth of Wheeler Canyon were supplied with water from Wheeler Creek in June and July, 1929, and that none was known to have been ill. Expert witnesses for the city excluded the city water as a probable source of infection, basing their opinions in part, on the fact that thirteen of the persons contracting the disease had been in contact with other possible sources of infection. They pointed to the fact, too, that only a comparatively small number of cases developed among the 40,000 people using the city water and that the percentage of mortality was comparatively high. In epidemics attributed to contaminated water, they testified, the numbers of cases are usually greater and the percentage of mortality is low on account of the dilution of the bacteria in the larger supply of water. Where there is direct infection, however, the masses of typhoid bacteria are greater, resulting in higher mortality.

In cases of this kind, said the court, involving infection by germs of microscopic size, it is frequently impossible to establish by definite proof the source of infection. The plaintiffs, by circumstantial evidence, attempted to prove that the illness was caused by drinking the city water, which in 1928 and in July, 1929, was found to be polluted by coli bacilli. There was no direct evidence that it was so contaminated early in June when the two inhabitants involved in this case contracted the disease. There was no showing of typhoid germs in the water at any time. If all other probable sources of the infection are eliminated, the court said, a reasonable inference might be drawn that the water caused the illness. The city attempted to show, by circumstantial evidence, that there were other probable sources of infection. Neither party was able to show any preexisting typhoid case from which the germs might have come. The mere fact that the city water carried coli bacilli

at the time the disease was contracted, if that had been proved, would not necessarily, without considering other facts, be proof that the typhoid germs which caused the disease came from the water. At most, the evidence of the presence of coli bacilli was strongly suspicious. The owner and manager of the summer hotel, whose guests were furnished water directly from Wheeler Creek at about the same point as the city's intake, and the city health commissioner, whose information was based on the records in his office, were properly permitted to testify that no sickness had occurred among approximately 100 guests at the hotel during the summer season of 1929. These witnesses were competent. Any limitation as to their knowledge would affect only the weight of their testimony. Since the presence of typhoid germs in the stream was not shown, evidence that none of the guests of the summer hotel who drank the raw water became ill tended to prove, although not conclusively, that the water did not contain typhoid germs.

The case, in the opinion of the court, was properly submitted to the jury, and after reading the entire record the court concluded that the case was fairly tried and that the jury was adequately instructed as to the law. The judgment of the trial court in favor of the city was therefore affirmed.—*Stoker v. Ogden City, McFarland v. Same (Utah)*, 54 P. (2d) 849.

Criminal Abortion Civil Liability of Physician Who Performs an Illegal Abortion—On grounds of public policy, said the Supreme Court of Oklahoma, a woman may not recover damages from a man who induces her to submit to an operation which produces an abortion where she is of age and voluntarily submits to the operation. In arriving at this conclusion, the court followed the reasoning of the Court of Appeals of the District of Columbia in *Hunter v. Wheate*, 53 App. D. C. 206, 289 F. 604, 31 A. L. R. 980, a case in which a woman sued a physician for the negligent performance of an abortion. In that case the court said:

It has long been the law that where an action is founded upon an unlawful contract the court will not interfere to relieve either of the parties thereto in an action against the other from the results thereof.

This rule applies whether the act is performed in the execution of a contract or not. In other words, it applies to transactions as well as to contracts, and hence the suggestion of appellee that the recovery here was upon the second count in the declaration as for a tort regardless of the contract is of no avail. If the act out of which the cause of action arises is immoral or illegal, the courts will not grant relief.

So in the present case, the Supreme Court of Oklahoma held that where parties to an immoral or illegal transaction are in pari delicto with each other, each is estopped as to the other to take advantage of his own moral turpitude, illegal act or criminal conduct for the purpose of recovering damages for injury sustained as a consequence of their joint wrongdoing.—*Bauman v. Lunsford (Okla.)*, 54 P. (2d) 666.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1926 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Requests as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Sensitivity to Tuberculin at Different Age Periods—

According to Stewart and Dyson, Mantoux tests with old tuberculin and purified protein derivative in doses of unequal potency agree in showing that, as a rule, children are more sensitive to tuberculin than adults and that this difference between the two age groups is due to the occurrence among adults of a disproportionately large percentage of patients with relatively small areas of reaction to tuberculin. The suggestion is offered that the difference in allergy observed between the two age groups is the product of a general tendency for sensitiveness to tuberculin to diminish slowly as the postinfection time elapses. The sensitiveness to tuberculin-protein induced in the tissues by tuberculous infection is an extremely variable and moderately unstable immunologic change.

Studies in Whooping Cough.—Hematologic studies by Daughtry-Denmark indicate that, with a severe cough, a marked increase in the number of leukocytes with more than 60 per cent lymphocytes indicates whooping cough. However, the absence of such a blood picture by no means excludes the disease, for, although it is not a well known fact, normal leukocyte and differential counts do not disprove the presence of whooping cough. In a series of 240 patients who received Sauer's vaccine, four blood counts being made in each case, there was an increase in lymphocytes. Haemophilus pertussis has agglutinated spontaneously both with normal serum and with the serum of patients with whooping cough. Agglutination has never been complete and the test is worthless in the diagnosis of whooping cough. The pertussis bacillus has not been universally accepted as the etiologic agent. The present investigation has shown that, although hematologic studies are of value only when the results are positive and that agglutination tests are without value, the complement fixation test may be relied on for the early diagnosis of whooping cough, that is, before the whoop develops. Sauer's vaccine was administered to 150 children. Complement fixation was secured one week later in 92 per cent and was complete in 61 per cent.

All those who received as much as 14 cc of vaccine had complete complement fixation. This proves that Sauer's vaccine is effective in producing complete fixation. Thirty-seven children who received Sauer's vaccine in May 1933 were exposed to whooping cough. Seven of these contracted the disease, but in each case it was mild. Seven children who were vaccinated in September 1934 and were exposed to whooping cough remained well. Twenty-eight children in whose blood complete fixation was secured by the use of Sauer's vaccine were directly exposed to whooping cough and did not contract the disease. In several cases the exposure was immediate. This indicates that the vaccine becomes effective as soon as complement fixation is secured, instead of three months after administration, as has been suggested. The author's studies have demonstrated that children who have whooping cough have complete complement fixation during the disease but may have no fixation a few months later. The same condition is true of vaccine. The immunity conferred by vaccination may last as long as that conferred by the disease.

Nonprotein, Urea and Rest Nitrogen During Pregnancy.—According to Cadden and Faris, it is generally agreed that normal pregnancy is accompanied by a decrease in blood urea nitrogen. A survey of the literature, however, reveals great disagreement among various investigators as to absolute figures observed during gestation, reported average values ranging from 68 to 125 mg per hundred cubic centimeters of blood. Before reliance can be placed on any abnormalities found in the urea nitrogen content of the blood, as has been reported in certain of the toxemias of pregnancy, it becomes essential that the normal pregnancy values be established. For accurate estimation of blood urea nitrogen by any method involving the use of urease it is essential that certain factors, such as the hydrogen ion concentration, the type of buffer used and the temperature, be carefully regulated. The authors determined the nonprotein, urea and rest nitrogen in 163 blood specimens obtained from normal pregnant women at different periods of gestation during labor and on the eighth day post partum. They found that the nonprotein nitrogen of the blood decreases during the first six months of pregnancy from the average nonpregnant values of approximately 30 to 24 mg per hundred cubic centimeters of blood. During the last four months of pregnancy the nonprotein nitrogen increases steadily until one week post partum, when it averages 33 mg per hundred cubic centimeters of blood, being about 26 mg at term. The urea nitrogen concentration diminishes during the first six months from the usual nonpregnant value of about 14 mg to a value of 6 mg per hundred cubic centimeters of blood and then maintains a constant level until the eighth, or ninth month, when it begins to rise, having an average value of 7.12 mg at term and 11 mg per hundred cubic centimeters of blood on the eighth day post partum. Owing to the fact

that the nonprotein nitrogen falls and rises more rapidly than the urea nitrogen, the rest nitrogen falls during the first six months of pregnancy to a value of 18.02 mg per hundred cubic centimeters of blood and then increases during the latter part of pregnancy, being 19.18 mg at term. It is further increased during the first week post partum, reaching a value of 21.39 mg on the eighth day of the puerperium. Although it is quite evident that a change in the rest nitrogen is not necessarily accompanied by a change in the urea nitrogen over nonprotein nitrogen ratio, figures show that the urea nitrogen to nonprotein nitrogen ratio is decreased during pregnancy, being 0.25 during the sixth or seventh month and 0.27 at term. The normal nonpregnant value for this ratio is approximately 0.5.

Fetal Heart Tones in Ablatio Placentae—In reviewing cases of ablatio placentae, it would seem to Richardson that the greatest practical value in studying the significance of fetal heart tones would be derived by classifying them in accordance with their degree of separation. Since both extreme and intermediate variables of rate and area separation are represented in these cases, they might be accepted as a standard of future investigation. Taking as a basis a normal case with average fetal heart tones of from 136 to 140 and the placenta completely attached, the separating of from one fourth to one third of the area would lead one to expect the fetal heart tones to be from 160 to 170, while with one half separation and fetal heart tones of from 180 to 190 the time factor considered, the fetus passes from a compensation phase into a phase of asphyxia. When the fetal heart tones decrease with three-fourths separation of placenta from 90 to 70, fetal death will occur before, at or immediately after complete detachment. This process may involve five minutes or five hours and will obviously present some variations, depending on the elapsed time occupied by any phase along this uniform line of events. With this basis one can observe the acceleration of the fetal heart rate and thereby arrive at a diagnosis of the approximate, and usually quite exact, area of placenta that has become separated. Such an evaluation renders the wide application of these figures obvious. To secure all the information obtainable from variations in the fetal heart rate, especially in labor, the rate should be observed at definite and frequent time intervals, say at intervals of fifteen or thirty minutes, making evident the response of the fetal organism to the primary embarrassment of ablatio placentae before other signs of this complication are present, and also before this accident has reached a stage critical to mother or fetus. By securing this earlier information it would be evident that, in by far the greater number of cases, ablatio placentae is not an abrupt process at all but insidious in its course and that it usually presents time for more adequate and satisfactory treatment than is usually given. Earlier diagnosis narrows the differential value between ablatio placentae and placenta praevia.

Mapharsen in Treatment of Early Syphilis—During the last twenty months Kulchar and Barnett have given 1,270 injections of mapharsen to fifty-six patients with untreated primary or secondary syphilis. Nine were in the seronegative primary stage, eleven in the seropositive primary stage and thirty-six in the secondary stage when treatment was started. The treatment schedule consisted of courses of ten weekly injections of iodobismutol given twice a week in the first course and once a week in subsequent courses. Standard doses of mapharsen, 60 mg for men and 40 mg for women, were used. The dose of iodobismutol was 2 cc. The rate of disappearance of lesions under mapharsen therapy was observed in twenty cases. In ten patients primary lesions healed in from four to thirty days, the mean being thirteen days. The average time of involution of secondary syphilides in ten patients was the same. This interval corresponds to an average of two injections of mapharsen and is less than the twenty-three days reported by Cannon and Karetz as the average period of involution using neoarsphenamine. Wassermann reactions were done before starting treatment and at the end of each course. From this comparison it appears that the rate of serologic reversal is slower with mapharsen than with arsenphenamine. In thirty patients Wassermann reactions were obtained after the completion of at least twenty injections each of mapharsen and iodobismutol. The final reactions were negative in twenty-five, weakly positive in two, and strongly positive in three. The cerebrospinal fluid was examined in twenty-one patients after at least six months of regular treatment. In fifteen the fluid was normal. Of the six abnormal fluids two were of the group I (cells or protein increased), three of the group II (Wassermann reaction partially positive), and one of the group III type (paretic formula). The patient in whom the group III fluid was found developed clinical signs of early dementia paralytica after receiving one year of regular treatment. Because of the small number of spinal fluids examined, the apparent high incidence of positives (29 per cent) may not be significant. Pruritus, skin eruptions and immediate reactions, including nitritoid crises, were slightly more frequent with neoarsphenamine than with mapharsen. All other types of reaction, particularly nausea, vomiting, diarrhea and headache, are more common following mapharsen. Venous thromboses, often severe and extensive, occurred following nearly 1 per cent of the 1,270 injections of mapharsen, while none followed the use of neoarsphenamine. Of the thirty-three patients receiving two or more courses of mapharsen, all but four experienced some reaction to the drug. The period of observation is too short and the number of patients too small for a complete clinical appraisal of mapharsen. Serologic fastness and relapse, central nervous system involvement and treatment reactions, however, are evidently not avoided in early syphilis by the use of mapharsen.

Kline Exclusion Test in Diagnosis of Syphilis—Rein asserts that, in the recent evaluation plan for the serodiagnosis of syphilis, the Kline exclusion heated serum test was the most sensitive of all tests in group A (less than 1 per cent false

positive reactions in 468 presumably nonsyphilitic persons) By means of this test more persons with primary and latent syphilis (with varying amounts of treatment) were detected than by any other test (in group A) This is particularly important in the control of syphilis, especially in outpatient departments and clinics and immediately before transfusions to prevent the transmission of syphilis As a secondary consideration, the low cost of materials and the rapidity and ease of performance of the slide tests deserve the highest regard

Iron Hematoxylin-Aniline-Blue Staining Method — Koneff's method permits the demonstration of most types of tissue simultaneously and with sufficient differentiation to form a judgment of the total histologic make-up of the organ. The method will also demonstrate clearly certain pathologic changes. The staining procedure may be used after any of the common fixatives. Sections are mordanted in 5 per cent aqueous solution of iron and ammonium sulfate (violet crystals) for five to ten minutes, and rinsed quickly in distilled water, and then stained in Harris's hematoxylin for from three to fifteen minutes. They are again washed in distilled water and placed in a mixture of 0.1 Gm of aniline blue (Grübler), 2 Gm of oxalic acid, 15 Gm of phosphomolybdic acid and 30 cc of distilled water. This solution simultaneously differentiates the hematoxylin and stains with aniline blue. Proper nuclear and cytoplasmic differentiation is observed after about fifteen minutes. For this purpose the sections are washed in distilled water and examined under the microscope. If differentiation and staining are incomplete, the sections are returned to the staining solution for a longer time. Tissue that has been stored for a long time in 80 per cent alcohol or as celloidin blocks in glycerin alcohol requires from forty-five to sixty minutes' staining time, while recently fixed material usually requires from fifteen to twenty-five minutes and is then washed in distilled water, differentiated and dehydrated in two changes of absolute alcohol, cleared in xylene and mounted in balsam. If euparal is used as the mounting medium, the xylene may be omitted. When staining loose celloidin sections, 95 per cent alcohol is substituted for absolute alcohol and the sections are mounted in euparal. Clearing in creosote is not necessary unless the sections are mounted in balsam.

Revival of Human Hearts—Kountz points out that the method of perfusion of the heart has not advanced since the days of Langdon, who isolated a heart, inserted a cannula

into the aorta and perfused the coronary vessels by backflow of the perfusing solution through the aorta. This method was satisfactory as a means of determining the viability of the heart but would not suffice to keep hearts viable for a period sufficiently long to permit physiologic observation. In general the hearts were found to dilate in a short period if the pressure in the aorta was raised sufficiently to permit perfusion of the coronary system. Therefore a cannula was constructed that would permit the development of different pressures in the ventricle and in the coronary arteries. Cannulas were inserted into the coronary arteries through the aorta. A large cannula was then introduced over the coronary ones through the aorta and past the aortic valves. Different pressures were maintained in the two systems by individual reservoirs. The pressure in the cannulas of the coronary arteries was maintained at about 120 mm of mercury, whereas that in the ventricle was varied according to the contractility of the heart. One could thus perfuse hearts for a period or could make heart-lung preparations that would last for several hours. The hearts of 127 persons who had died of various conditions have been studied. Sixty-five have been revived to the point of ventricular contraction. Of these, forty-eight developed regular cardiac mechanism and beat for a period of at least two hours. Fifteen heart-lung preparations have been made, and cardiac contractions against a blood pressure of 120 mm of mercury have been maintained for as long as four hours. The functions of the other hearts were studied by perfusion of the coronary vessels. The time after death and the nature of the disease had definite influence on the viability of the heart. The causes of death ranged from heart disease to death by accident. In general, in those patients dying from chronic illness revival could as a rule be accomplished more easily than in those succumbing to acute infection. The hearts of persons who died of tuberculosis revived more easily than those of any other group whose death was due to a single cause. The hearts of children were usually more responsive than those of adults. The greatest difficulty was encountered in the hearts of those who had succumbed to diseases of the heart itself. Congenitally defective hearts were relatively easy to revive. The longer the period after death the greater likelihood there was of thrombosis in blood vessels and the greater the probability of dilatation of the heart when the experiment was started. In addition to cutting the bundles, the surface of the heart was electrically stimulated and the localization and nature of extrasystoles were determined. Four general types of extrasystoles were observed.

Lymphosarcoma and Hodgkin's Disease—Ginsburg says that lymphosarcoma and Hodgkin's disease invade every organ and tissue of the body. There are no pathognomonic clinical signs of lymphosarcoma and Hodgkin's disease, hence extraglandular involvement of either disease has frequently been overlooked and mistaken for non-neoplastic conditions. Both diseases are characterized by marked invasion, proliferation, replacement and compression of organs and tissues, necrotization, ulceration, toxemia, cachexia and febrile reaction. Both diseases may spontaneously run an acute, a subacute or a chronic course. The only method of differentiation is on the basis of morphologic microscopic criteria, which are not always conclusive. The etiology of lymphosarcoma and Hodgkin's disease is obscure. Gordon's claim for a filtrable virus as the cause of Hodgkin's disease still needs confirmation. There is no specific method of treatment for either disease. Chemotherapy, vaccine and toxin treatment, surgery and irradiation are purely palliative methods which in selected cases, have produced favorable results with freedom from clinical evidence of disease for many months and years. Both lymphosarcoma and Hodgkin's disease invade, infiltrate and destroy organs and tissues not only by direct extension but also by lymphogenous and hematogenous metastases as in epithelial cancer, hence early recognition is essential for successful irradiation or any other form of local treatment. In doubtful cases in which a biopsy is unobtainable, the radiotherapeutic test may be greatly helpful not only in arriving at a diagnosis but also in relieving the patient. The clinical course, the prognosis, the mode of death, the results of chemotherapy, vaccines, toxins, radium, roentgen therapy and surgery as observed in lympho-

sarcoma and in Hodgkin's disease run closely parallel. Hodgkin's disease varies in no fundamental clinical characteristics from lymphosarcoma.

Convulsions Due to Hyperactive Carotid Sinus Reflex

—According to Weiss and his associates, a hyperactive state of the carotid sinus reflex can be responsible for clinical symptoms, including attacks of syncope and convulsions. Syncope and related manifestations result from cardiac slowing, primary depression of the blood pressure or a central reflex to the brain. The mechanism causing the reaction often appears in a mixed form. Spontaneous attacks can be induced by mechanical stimulation of the carotid sinus. Digitalis sensitizes the carotid sinus reflex mechanism. The routine pre-operative administration of this drug, particularly to elderly patients, is not without danger. Various morbid states play a part in sensitizing the carotid sinus reflex, and treatment of the disease, when efficacious, diminishes or abolishes the hypersensitive carotid sinus reaction. Both the vagal and the depressor type of reaction can be controlled by epinephrine and atropine. Atropine abolishes the vagal type but has no effect on the depressor type. The cerebral type is not benefited by these drugs. Surgical denervation of the carotid sinus abolishes spontaneous and induced attacks in suitable cases but does not influence any of the unrelated accompanying symptoms.

Hemorrhagic Purpura Following Administration of Neosarsphenamine

—In the syphilis clinic at the University of California since 1924 about 60,000 treatments with arsphenamine have been administered. Falconer and his co-workers found four recorded cases of hemorrhagic purpura. The data on three of the patients, the first observed in 1931 and the other two from 1932 to 1935, constitute the material for their report. These three patients showed two distinct types of sensitivity to neosarsphenamine. The first patient became increasingly sensitive until a crisis occurred in the form of a severe reaction followed by hemorrhagic purpura. He was sensitive in 1931 during the first course of neosarsphenamine treatment, for he recalled at least two occasions when he had mild hemorrhagic manifestations. Apparently no nitritoid reaction preceded the bleeding. The fact that he received no arsenicals and no treatment of any kind for a year did not suffice to abolish the sensitivity, as was evidenced by the severe reaction after the fourth dose of neosarsphenamine in the second series of treatments. The other two patients belong to a group probably small, that present an initial sensitivity to neosarsphenamine. The second patient presented marked hypersensitivity to the drug from the standpoint of a toxic reaction of the platelets and capillaries. This case, and the cases reported by other investigators, illustrate that sensitivity is not dependent on the amount of the drug previously administered. The second patient had not received any arsphenamine previous to Sept. 28, 1933, when she received her first dose of neosarsphenamine. After the second dose of 0.15 Gm purpuric manifestations appeared. She had a nitritoid reaction after each dose. When she reported to the

hematologic clinic one week after receiving the second dose, although the purpuric spots were still well marked, the platelets had returned to a normal number and the bleeding time was normal. The marked sensitivity to neosarsphenamine presents a sharp contrast to the entire lack of any untoward reaction from mapharsen. This applies to both the second and the third patient and certainly suggests that the sensitivity is not to arsenic as such but to some oxidation product not present in mapharsen. The question as to whether mapharsen can be safely used after the occurrence of hemorrhagic purpura is answered in the affirmative by the results in the authors' two cases but requires further observation.

Shock. Definition and Differentiation.—Moon defines shock as a circulatory deficiency, not cardiac or vasomotor in origin, characterized by a decreased volume of blood and cardiac output and by hemoconcentration. Hemoconcentration appears early, is easily determined and is seen in cases of moderate severity before variations in the blood pressure occur. When the syndrome is fully developed, lowered blood pressure and lowered basal metabolism, diminished renal excretion and an increased cardiac rate are associated features. Each of these associated features may occur in conditions other than shock, but their combination with the circulatory deficiency described seems to constitute a definite entity. Shock is simulated clinically by hemorrhage, syncope and rapidly developing cardiac failure. It presents pathologic features resembling those of passive congestion. The circulatory phenomena of shock result from a disparity between the volume of the blood and the capacity of the blood vessels. Any loss of fluid, such as that caused by hemorrhage following trauma or local loss of fluid as in burns, will contribute to this disparity, and its importance will be proportionate to the amount of blood and/or fluid lost. Primary shock is essentially similar to syncope, and it has not been shown that these conditions are accompanied by a decreased volume of blood or by hemoconcentration. Primary shock and syncope appear to be transient vasomotor phenomena in which no qualitative changes occur in the capillary walls or in the blood. Shock simulates exsanguination clinically, while its pathologic features resemble those of passive congestion. The similarity to passive congestion accounts for the failure of pathologists to recognize the visceral changes of shock. In the absence of cardiac disease, the diagnosis of congestive circulatory failure as a cause for death is more accurate than that of congestive heart failure. The visceral engorgement characteristic of shock is not designated accurately either as active congestion or as passive congestion. It seems necessary to formulate a suitable term. "Acute venous congestion" is suggested as appropriate.

Tissue Responses to an Avirulent Tubercle Bacillus (BCG).—Rosenthal attempts to answer the questions of what the reaction in remote parts of the body is, particularly in the susceptible tissue in the sense of Besredka, when an avirulent organism (BCG) which tends to remain localized is injected, and whether tubercles in various organs develop similarly. An attempt also is made to correlate the humoral and the tissue responses. Following the intracardiac injection of avirulent tubercle bacilli (BCG) there developed not only a specific reaction with tubercle formation in various organs but a generalized histiocytic response manifest most prominently in the septal cells of the lungs, Kupffer cells of the liver, endothelial and reticulum cells of the kidneys and spleen and histiocytes of the

endocardium and epicardium This generalized response of the reticulo-endothelial system is ascribed to submicroscopic forms of the tubercle bacilli (BCG) as shown by cultural studies The formation and regression of the tubercle have been traced The number of bacilli and the organs involved determined to a large extent the proliferative or exudative character of the nodule The infiltration of the tubercle by lymphocytes was associated with the healing of the process The changes in the blood reflected those of the tissues The fate of the bacilli (BCG) differed in the various organs

Modification of Frank-Goldberger Blood Estrogen Test—The method for extracting estrogenic substance from blood that Neustaedter now uses is as follows About 40 cc of blood is transferred from a syringe to a petri dish containing from 30 to 40 Gm of anhydrous disodium sulfate, mixed thoroughly with a glass rod, fanned until the mass has the consistency of fudge, transferred to a mortar and ground to a very fine powder as the mixture dries, then the powder is returned to the petri dish for storage if the procedure must be interrupted at this point If the mixture does not harden, more disodium sulfate is added The red powder is transferred to a 250 cc. Erlenmeyer flask and 100 cc. of ether is added, stoppered tightly with rubber and agitated for twenty minutes in a shaker The flask is rested on a specially constructed board at an angle of 45 degrees to separate the ether from the sludge by sedimentation. The supernatant fluid is decanted and centrifugated The process is repeated twice. The centrifugated ether is evaporated to dryness in an evaporating dish before an electric fan The lipid residue is dissolved in 6 cc of benzene to which 0.6 cc. of olive oil is added The benzene is fanned off The olive oil, which now contains the lipid extract, is sterilized by autoclaving at 15 pounds for fifteen minutes This extract may be kept for several days if rubber stoppered and stored in the dark The extract is injected into mature, castrated female mice in divided doses On the first day three injections are given at intervals of four hours Two injections at the same interval are made on the following day The extract is introduced into the mouse dorsally and subcutaneously Beginning on the third morning, vaginal smears are prepared twice daily for four days The smears are made with a small bent glass tube drawn to a fine tip By means of a rubber bulb, a drop of water is repeatedly injected and reaspirated from the vaginal canal so that a uniform and typical sample of vaginal secretion is secured The specimen is transferred to a clean slide, dried fixed and immersed in aqueous thionin (1 per cent) for one

minute, excess stain is removed with water The vaginal smear is examined for an estrous reaction

Basophilic Cells of Hypophysis and Blood Pressure—Rasmussen considers two types of basophilic cells in the human hypophysis It is reaffirmed that those extending into the nervous lobe are derived from the pars intermedia Tinc-
torially the posterior lobe basophils are essentially like those found in the anterior lobe A slight difference in color may be obtained sometimes Morphologically, the ones in the posterior lobe do not as a rule attain the size of the basophils of the anterior lobe, nor are they as vacuolated In pituitary basophilism those of the posterior lobe do not show the hyaline changes to the same extent that these changes occur in the basophils of the anterior lobe The relationship of the basophilic cells of the hypophysis to elevated blood pressure is far from proved Several recent observations show no correlation between excessive invasion of basophils into the nervous lobe and eclampsia The trend of the evidence in essential hypertension is in the same direction There are more basophils in both the anterior lobe and the posterior lobe in men than in women The accumulation of basophilic cells in the posterior lobe increases slowly with age and, while blood pressure also tends to rise with age, one is not necessarily the cause of the other Three cases of pituitary basophilism are added to those already described by Crooke, showing the characteristic hyaline change in the cytoplasm of the basophils of the anterior lobe, regardless of whether there was a pituitary adenoma, an adrenal neoplasm or neither The last patient had enough inflammation and edema in the adrenals to account for much, if not all, of the enlargement of these glands These hyaline changes occur only rarely and then only to a slight degree in essential hypertension, eclampsia or other cases of high blood pressure unaccompanied by the other characteristics of pituitary basophilism

Histologic Changes Following Injections for Cure of Hernia—Rice and Mattson find that fibrous tissue is produced in the human being following the injection of irritating solutions intended for the cure of hernia Such changes are characteristic of an inflammatory reaction in which the production of the connective tissue predominates Solutions that produce less of the exudative reaction seem scientifically more rational Clinical trial has proved the method to be effective in carefully

selected cases, and histologic investigations seem to establish a scientific rationale for the method. At the end of fifteen hours the reaction was mostly exudative. Polymorphonuclear and round cells were found in the exudate. Proliferations of the fixed connective tissue cells appeared on the first day. By the fifth day, most of the polymorphonuclear cells had disappeared. Fibroblasts appeared on the third day. Fibrous tissue was found in dense bundles after fourteen days. At the end of the forty-second day, fibrous tissue was very dense.

Virucidal Substances in Patients with Poliomyelitis.—According to Harmon and Harkins, since poliomyelitis seems to be an exclusive disease of the nasopharynx and nervous system in man, the irregular extraneural migration of virus is thought to explain the irregularity of production of neutralizing antibody. Infection can be blocked by peripheral nerve section or by section of the olfactory tracts. Chemical blockage of infection at the nasopharyngeal port of entry appears to have been demonstrated recently. The latter method may have some value in prophylaxis of the human disease. The specific virus neutralizing substance in poliomyelitis is unique in that a greater number of adults without history of contact or infection possess this substance than do convalescents from the disease. The average concentration of immune substance in normal adults is equal to or greater than that carried by convalescents. The importance of an actual attack of poliomyelitis in the production of this substance is minimized by serologic studies. Convalescent and other specific serum therapy should be continued, as there is no evidence that it is not of value. On the other hand, symptomatic improvement following serum administration is almost universal. There are indications that preparalytic poliomyelitis in man is a naturally milder type of the disease than the cases seen after paralysis is present. At present specific vaccination is considered to be too dangerous to be applied to man without careful supervision in a controlled study in non-epidemic months.

Control of Rhus Dermatitis—During the summer of 1935 Blank and Coca were enabled to make a suitably controlled study of the influence of injections of poison ivy extract on the incidence of ivy dermatitis in the CCC Veterans Camp MC-64, Morristown, N J. The men spent their active working days in areas which abound with the poison ivy and poison sumac plants, and contacts were unavoidable. The exposed men all working under approximately the same conditions in areas contaminated with ivy and sumac, were to be listed in three groups (1) to receive four injections at weekly intervals of

0.5 cc. of almond oil containing 10 per cent by volume of acetone and 0.1 per cent of solids extracted from poison ivy leaves with acetone and freed from chlorophyll, (2) to receive four weekly injections of 1 cc. of a similar extract containing 0.66 per cent of the poison ivy solids, and (3) to receive no prophylactic injections. As the men presented themselves with ivy dermatitis they were in rotation to be treated with the two extracts and almond oil with 10 per cent of acetone. The prophylactic and therapeutic injections were begun on June 17, and shortly after this there was a decline in the number of cases and in the number of days lost on account of ivy dermatitis, which continued steadily until the first of August, when the incidence of this condition reached zero. There were no cases in the month of August and only one in September, in a man who had not received any injection of ivy extract. Of the untreated men of the third group, 66½ per cent became affected with ivy dermatitis, whereas among the two treated groups of equally exposed men only 20 per cent and 7 per cent respectively were affected. The percentage of the affected controls corresponds closely with the percentage of adults who have been found by skin test with strong extracts of poison ivy to be sensitive to this plant. It is seen also that protection was established in a greater proportion of the group that received the larger dose than it was in those receiving only one-twelfth that dose.

Use of Blister Fluid for Passive Transfer Test.—Parlato undertook the present study for the purpose of determining whether the fluid contents of burn blisters contained skin sensitizing antibodies and whether they may be comparable to the reagents of artificially produced blisters and those of the blood serum. An attempt was made to determine whether the reagents of the burn blister fluid from a patient having burn blisters could be exhausted. One of the sensitized skin sites of one receptor was given repeated injections of cat epithelium extract. Within two days there occurred a reduction and then a lack of reactivity not only to the 0.001 but also to the 0.01 solution. At this point the site was tested with horse epithelium producing a positive result, indicating that the exhaustibility of the antibodies was specific. After a rest of eleven days, the same site reacted to the cat hair extract 0.01 solution. The work of Spain and Newell on the reagent content of artificially produced blister fluid has been confirmed. In some carefully selected cases, the artificial blister fluid could be used for performing the Prausnitz-Küstner test.

Role of Potassium in Epinephrine Action—After reviewing the earlier literature on this subject Camp and Higgins present a further analysis of this action of potassium. They made experiments on more than 100 dogs. On the basis of these studies they reach the following conclusions: 1 Potassium effects all the changes in the systems studied that are produced by epinephrine. 2 Potassium action is obtained after decerebration, bilateral adrenalectomy, atropine and ergotoxine. 3 Potassium is responsible for the typical changes ascribed to epinephrine. 4 Potassium is liberated from the heart by vagus stimulation. 5 One of the functions of the adrenal glands is to maintain a constant distribution of potassium.

H A Buchtel and E N Cook, Rochester Minn—p 603

Treatment of Urinary Infections by Ketogenic Diet—Buchtel and Cook have recently sent questionnaires to 200 patients who had been dismissed from the clinic a year or more previously with sterile urine following treatment by means of the ketogenic diet. The average length of time since dismissal in these cases was two years. They chose patients consecutively from two groups, one group made up of patients who had been treated in 1931 and 1932, and the other made up of patients treated in the last months of 1933 and early months of 1934. This was done to see whether the changes made in the management of the diet made any difference in the end results. Patients in the first group had been kept on the diet longer, usually from three to four weeks, whereas those in the latter group had been kept on the diet usually only until two sterile cultures of the urine were obtained on successive days. In addition, the diet used in the latter group of cases contained a higher ratio of fatty acid to dextrose. Of the 161 replies received there was recurrence of the bacillary infections in only forty two instances. Once recurrence has developed, use of the ketogenic diet at home has a definite place in the treatment. Patients can follow the diet at home quite well, especially if it has previously been followed under supervision. A ketogenic

diet for home use that has been quite successful has a 4 to 1 ketogenic-antiketogenic ratio, which is the same as is used now at the clinic. It can be prepared and followed quite easily and has proved to be an adequate means of treatment. Fourteen of the forty-two patients who suffered from recurrence of urinary infection followed this home diet. All reported benefit; three said they were cured, eight that they were markedly benefited and three reported moderate relief of symptoms. Two additional patients reported control of their symptoms by the use of acidifying drugs alone.

Juvenile Tuberculosis of Kidney—Mathe emphasizes the importance of suspecting tuberculosis of the kidney in children presenting chronic cystitis, persistent pyuria and relapsing pyelitis. It occurs in infants, children and adolescents more frequently than it is believed. In fact, many patients with adult renal tuberculosis had earlier silent tuberculous lesions of the kidney in childhood which escaped attention. But with more widespread interest in urology in children and by a careful systematic routine urologic study of suspected cases, made possible by the use of the more recently perfected smaller caliber child cystoscopes, diagnosis will be made in more cases and the patients will be given the same chance for the surgical relief that has been carried out so successfully in adults. Six cases of unilateral juvenile renal tuberculosis occurring in children and adolescents are reported. The group comprises 10.3 per cent of fifty-eight patients in whom nephrectomy was performed for tuberculosis. Four are living and well eight years, six years, eleven months and three months after operation. In reviewing 4,698 cases of unilateral renal tuberculosis the author found that this disease occurred in 565 subjects (12 per cent) aged from 1 to 20 years and that 0.42 per cent (twenty cases) occurred in infants aged from 1 to 5 years. 1.08 per cent (fifty-one cases) occurred in children aged from 5 to 10 years and 10.5 per cent (494 cases) occurred in adolescents aged from 10 to 20 years. The necropsy statistics show that the incidence is much higher (from 25 to 30 per cent)

Although clinical quiescence and autonephrectomy have been overenthusiastically hailed as spontaneous healing of renal tuberculosis, nephrectomy is the treatment of choice in the unilateral type in children as well as in adults and, if this operation is performed early enough, it is followed by a great percentage of cures.

Dextrose Tolerance as Diagnostic Aid in Jaundice—Jacobi believes that any case of jaundice in which after the administration of 100 Gm of dextrose orally there is a flat blood sugar curve, the principal feature of which is the return of the blood sugar to a normal fasting level at the end of the two hour period denotes a jaundice of toxic origin. In such cases operative intervention will be of no value and may add considerably to the already existing liver damage. Any case of jaundice in which, after the administration of 100 Gm of dextrose orally, there are sugar curves the principal feature of which is the failure of the blood sugar level at the end of the two hour period to return to the normal level, indicates that the case is due either to some obstructive lesion of the common duct, such as stricture, calculus, suppuration or carcinoma or to some such liver involvement as cirrhosis, abscess or carcinoma. As a rule other factors both clinical and laboratory help materially in further clarifying the situation. It is in this type of case of jaundice that early operation is definitely indicated with the most satisfactory results obtained, of course, in cases due to calculus obstruction. Obstructive jaundice produced by carcinoma of the head of the pancreas or of the common duct certainly calls for the performance of a cholecystectomy as an indicated palliative procedure. Cases of liver abscess with jaundice also give this obstructive curve. In the jaundice due to cirrhosis and carcinoma of the liver, the outlook is so hopeless, especially in the latter, that not much in the way of damage can be added to an already hopeless situation, even the performing of a laparotomy.

Acute Conditions of Gallbladder—In reviewing the varied pathologic lesions found in 129 cases in which the diagnosis was gallbladder or biliary duct disease, it became apparent to Taylor that they should not all be classified under the single heading of acute conditions of the gallbladder. The principal lesion in most of these cases is vascular, from an occlusion or partial occlusion of the venous return from this viscus. Infection plays a secondary part or, in many cases, may be completely absent. This feature contrasts sharply with the usual lesion of acute appendicitis in which the reverse is true. The 129 cases have been grouped according to morphologic observations in the gallbladder as acute edematous, acute suppurative and acute gangrenous. In analyzing the signs and symptoms of patients from these separate groups, it was found that there was no definite criterion by which they could be differentiated. There was a marked overlapping of signs and symptoms of patients with the acute edematous type, from which no complications might be expected, with the other two more serious groups. But one aid in making this differentiation was noted the white blood cell count. This in general, varied directly with the severity of the lesion. However it was mis-leading and bore no relation to the pathologic condition in more than 10 per cent of the cases. The clinical features of the disease often bear no relation to the severity of the pathologic process. The mortality for the entire series was 16.3 per cent. Patients operated on the first four days after acute onset gave a mortality of approximately 5 per cent. Of those operated on five or more days after onset, 23.8 per cent died. The perforating and gangrenous lesions have a higher incidence in those of advanced years. Therefore, age is no excuse for delaying operation. More than half the cases may be expected not to improve or become worse while being observed in the hospital. No case is so urgent that preoperative administration of adequate amounts of dextrose solution can be neglected. It would seem best to remove an occasional edematous gallbladder in the doubtful case, rather than run the risk of the more radical policy of watchful waiting.

Midline Cerebellar Tumors ("Medulloblastoma")—Winkelman and Eckel report three unusual cases of midline cerebellar tumor with dissemination through the spinal fluid. In the first case the patient had a definite remission for a period of nearly two years after decompression and high voltage

roentgen therapy. There gradually developed the signs and symptoms of local recurrence and progression, as well as diffuse involvement of the central nervous system. At necropsy there was marked distention of the fourth ventricle by the tumor with invasion into the surrounding structures, and complete filling up of the entire cerebral ventricular and subarachnoid spaces by the tumor tissue. Secondary invasions into the adjacent cerebral tissue were noted throughout. In the second case complete extirpation of the local cerebellar lesion had been done two years prior to the onset of a peculiar picture of spinal cord disease with root involvement. Necropsy showed marked overfilling of the spinal subarachnoid space with tumor cells of the medulloblastic type with invasion into the spinal cord substance. The spinal cord itself was enlarged to nearly five times its usual diameter. Loosening of tissue cells and dropping into the spinal subarachnoid space were probably the beginnings of the new growth within the spinal cord. In the third case the clinical course was typical. Local recurrence was present with complete distention of the fourth ventricle and invasion into adjacent structures. Here again the distended spinal subarachnoid space was filled with tumor tissue with invasion into spinal cord substance at various points. Compression of the spinal cord was present in addition. Scattering of tumor cells into the subarachnoid space as the result of operative manipulation probably accounts for much of the wide dissemination that occurs within the subarachnoid space, and especially within the spinal canal. Cure of the local lesion in medulloblastoma is not sufficient to eradicate the tumor cells completely from the central nervous system. Care must be taken not to loosen portions of the tumor and permit them to drop into the subarachnoid space.

Simple Method for Infant Feeding—In his search for a common-sense way of treating the great majority of babies in the summer months that can easily be handled by the average family physician and can be carried out by the average mother in moderate financial circumstances, it occurred to Hilden that about half of the whole world lived almost entirely on rice and that ages on ages in the world's experience had definitely proved that rice as a food was especially well adapted to the people who lived in the hot climates of the world. Therefore he selected condensed milk, added to it the required amount of boiled water to make it the right strength for any given infant and added to this one fourth of its quantity of boiled rice in the form of a thin gruel about as thick as cream. The quantity of this mixture for each feeding is regulated to suit the age and weight of the infant. This makes a practically sterile diet, easily digested highly nutritious and sufficiently balanced to meet the requirements in the great majority of cases. In addition to this diet the child is allowed a little orange juice two or three times a day. When oranges cannot be secured a little tomato juice may be substituted. For the last twenty years the diet has given the author far better results than any other method of infant feeding that he has ever tried.

48: 399-472 (Aug/Sept) 1936

*Lymphogranulomatosis Benigna in Light of Prolonged Clinical Observations and Autopsy Findings. J. Schaumann—p. 399

Necropsy in Benign Lymphogranulomatosis—Schaumann gives detailed reports of four necropsies in cases of the disease. Three of them had been thoroughly studied clinically. In the fourth the diagnosis was arrived at subsequent to death. The observations show the genetic identity of lupus pernio, Boeck's nodular and Boeck's disseminated milium sarcoid type, and likewise the occurrence of the disease without skin manifestations. The dermatologic diagnosis in case 1 was lupus pernio, in case 2 disseminated milium sarcoids (isolated or grouped in arcs and rings) and in case 3 Boeck's nodular sarcoid transformed into lupus pernio, and in all three cases there was found to be present benign lymphogranulomatosis. In case 4 there were no skin lesions, benign lymphogranulomatosis was an accidental discovery in the necropsy on a patient who had died of influenza. The author believes that benign lymphogranulomatosis is a generalized disease with predilection for the lymphohematopoietic apparatus, without or with skin manifestations, and that the disease is probably tuberculous. The disease may cause death in its character as benign lymphogranulomatosis, as a result of the advanced destruction of the hematopoietic apparatus, owing to its localization in vital organs or to cardiac asthenia caused by the increased resistance which the pulmonary lesions offer to the work of the heart. The most usual cause of death is possibly a classic tuberculosis arising in the course of benign lymphogranulomatosis.

Radiosensitivity of Tumors—Mottram avers that cells forming the margins of carcinomatous cell masses are more sensitive to gamma radiation than the central cells. A reasonable explanation for this is that the marginal cells have a more abundant oxygen supply, being near the blood vessels, and are for this reason more radiosensitive, since cells under anaerobiosis are radioresistant. If this be the case, carcinomas having small masses of cells should be more radiosensitive than those with large masses of cells. This deduction is considered, and evidence in its favor discovered. The question of the importance of the macrophage reaction to be seen in tumors regressing after irradiation is discussed, and it is concluded that they play no more important part than the phagocytosis of cells killed by radiation. Repeated doses of radiation should be spaced so as always to catch the tumor in a radiosensitive state, and irradiation should be withheld during times of radioresistance, following previous irradiation. The growth of tumors will supply a measure of their radiosensitivity during life, growth corresponding with sensitivity, and regression with resistance.

Action of Gamma Rays on Auerbach's Plexus—Colwell and Gladstone applied a composite radium applicator made up of several containers, to the abdomen of young rats narcotized with ether and urethane for two hours. Four of the tubes, each containing 13.3 mg of radium element, had a wall thickness of 1 mm. of platinum; the wall thickness of the rest (five) was 0.5 mm of platinum. The total radium content

of the applicator was 123.2 mg of radium element. At the end of the exposure the rat was given a subcutaneous injection of physiologic solution of sodium chloride and replaced in its cage. A control rat was similarly narcotized and given the physiologic solution. Twenty-four hours later the animals were killed with ether, and when the abdomen was opened the intestine of the irradiated animal was found to be swollen and the peritoneal surface reddened. Portions of the intestine were removed, placed in Bouin's fluid and, after the usual preliminaries, sections were stained in hematoxylin and eosin. Specimens from the intestine of the control animal (which appeared normal) were similarly treated for comparison. The condition of the nerve cells in the control specimens was, like that of the secretory epithelium and other tissues, quite good. In the irradiated specimens the ganglion cells are unequally or feebly stained, the outlines of the cell bodies are irregular and the granules ill defined or absent. The cell body is frequently shrunken and surrounded by a clear space. The nucleus is often irregular in outline and feebly stained. The nucleolus is often reduced to an irregular speck or may have disappeared completely, and the chromatic material is often broken down into minute granules or appears to have undergone solution. The majority of the nerve cells appear to be irreparably damaged. With the dosage employed, the nerve cells of the intrinsic sympathetic nervous system of the small and large intestine are extensively and badly damaged. Though a few cells seem to have escaped, the general destructive effects due to the irradiation are evident in the nerve cells as well as in the intestinal epithelium, lymphoid tissue, vascular system and unstriated muscle.

Examinations as Path to Freedom. C. M. Wilson—p. 449

Leptospiiral Jaundice, Following Bathing Injury—Lendrum reports a severe case of icterohemorrhagic spirochetosis. The disease was reproduced with typical lesions in guinea-pigs from two separate specimens of urine and from infected guinea-pig tissue. The typical guinea-pig lesions leave no doubt as to the diagnosis. In sections made from the infected guinea-pigs, several suggestive fields were seen in the liver, kidneys and lungs but could not be definitely identified. The source of infection appeared to be from the canal mud through the skin by means of the break caused by a splinter, the skin being an accepted port of entry. The patient always entered the water by diving. The patient, questioned afterward, was positive that he had never swallowed any of the water and stated that he had bathed in the same canal, at about the same site, on many previous occasions, the only difference on this occasion being that the splinter entered his foot. If the skin is accepted as the port of entry, the incubation period of the present case was only two days. The disease was typical. There was the sudden onset of headache, limb pains, vomiting and fever, followed by "red eyes" and jaundice, with an associated pyelonephritis. There was no herpes or sore throat. The pains of the limbs were distressing, they came at first in spasms and later whenever he was touched. He was unable to move his legs at one time, and the tendon reflexes were a long time in returning. The first symptom of relapse was on the seventeenth day. There was a return of all symptoms, pain being referred to the back rather than to the limbs, but there was no increase of jaundice. Albuminuria was present from admission until the forty-ninth day, except on the fifteenth, sixteenth and seventeenth days, just before the relapse, on which three days the urine was alkaline. Pleurisy developed on the eleventh day. Neutralization of the urine when looking for leptospirae is advocated by Morgan and Brown. Successful guinea-pig inoculations were performed, first with a urine which had been neutral in the twenty-four hour specimen immediately preceding, and the second with an alkaline urine. All

other urine inoculations were unsuccessful and were with an acid urine. The administration of potassium citrate or some such preparation is necessary if successful inoculations are to be made from urine. There was a progressive anemia up to the twenty-fifth day. The hemoglobin descended to 42. No high blood ureas were recorded. The highest figures were 48 mg per hundred cubic centimeters on the fifteenth day, and 50 mg during the relapse. The nephritis appears to leave no permanent effects. The boy is well and working at present. The mercury bichloride sulfosalicylic acid test for tuberculous meningitis appears to be not infallible, as a positive result was obtained from both specimens of cerebrospinal fluid examined.

Spondylolisthesis—Mercer asserts that, in spondylolisthesis, effective treatment is entirely mechanical, since the symptoms are due to a vertebral displacement which is producing overstretching and undue tension of the ligaments surrounding the vertebrae. The author places the patient on his back and raises the table at its lower end to produce an exaggerated Trendelenburg position. A long midline incision is made to just above the umbilicus. The abdominal contents are packed off from the area of operation, and a self-retaining retractor is inserted. The subluxated vertebra is inspected and its relation to the iliac vessels is ascertained. The gap between the sacrum and the slipping vertebral body is exposed by dividing the posterior peritoneum over it and ligating some small veins and the middle sacral artery, and freed of overlying fatty fibrous tissue with a gauze swab. An osteotome is driven in an anteroposterior direction into the lower margin of the fifth lumbar vertebra an eighth of an inch from its lower edge, and into the upper margin of the sacrum an eighth of an inch from its upper edge, producing a rectangular hole after the pieces of bone and the intervertebral disk have been removed. Autogenous bone grafts are taken from the crest of the ilium to wedge into this gap. The grafts are hammered tight into the gap between the sacrum and the fifth lumbar vertebra. To avoid springing out of the wedges, in addition to screwing the grafts in the operation is usually carried out with the patient in a posterior plaster shell. The patient remains in the shell for four months and then lies free from restraint in bed for another month. Thereafter he is allowed up in a Goldthwaite brace.

- *Diagnosis and Treatment of Bone Sarcoma. W. B. Coley—p. 49
 Disease of the Antrum of Highmore Operated on by Caldwell Luc Radical Operation. Review of One Hundred Consecutive Cases. W. S. Syme—p. 87

Diagnosis and Treatment of Bone Sarcoma—Coley points out that bone sarcoma has a predilection for youth and that the majority of cases occur between the ages of 15 and 30 years. The first symptom of bone sarcoma is usually pain and in the majority of cases pain is noticed some weeks or months before a swelling or a tumor is discovered. In a few cases of acute traumatic malignancy the sarcomatous tumor may begin to develop within a week or less but these cases are rare. The pain is apt to be worse at night, and in spite of occasional short remissions it usually increases steadily in severity. Continued pain in a bone that cannot be explained should always

call for roentgen examination. In the majority of malignant bone tumors, especially of the osteogenic type, the site of origin is one of the extremities. The joint is rarely involved in the early stages. The best explanation of this localization of bone sarcoma would seem to be that sarcoma is most likely to develop at those points which are most subject to trauma or strain. There is probably no bone in the body more likely to be injured than is the knee, hence the highest percentage of bone sarcomas develop in the femur, the most of these in the lower end, about the knee. In discussing the physical signs of bone sarcoma, the author says that a dilatation of the cutaneous veins nearly always occurs in sarcoma, but not in the early stages. Other factors to be regarded are the consistency, location, size and temperature of the tumor. After discussing the roentgen diagnosis and biopsy, particularly the dangers of the latter, the author shows that surgical treatment alone or combined with Coley's toxins is superior to irradiation. He takes up the therapeutic value of Coley's toxins (the toxins of erysipelas and *Bacillus prodigiosus*). He relates how he arrived at this method of treatment and cites the results that were obtained with the administration of the toxins of erysipelas and *Bacillus prodigiosus*.

Simple Method of Bronchoradiography—Since August 1935, when their attention was drawn to the article by Forester and Leroux describing the new pernasal method of administering iodized poppy-seed oil for visualizing the bronchial tree, Viswanathan and Kesavawamy have adopted this method in a modified form in sixty cases with satisfactory results. They were successful in all the cases except in one, in which the patient swallowed the whole quantity of the iodized oil, not allowing a drop to go into the bronchi. The method consists in the oil and previously to it the anesthetic being injected directly into one nostril with an ordinary glass syringe exclusive of any tip or catheter of any sort. The paraphernalia concomitant with an operation are no longer required, as is the case when the cricethoroid route is chosen for the injection. Only a 20 cc. syringe and a 2 cc. syringe, both without needles a piece of gauze and 1 per cent cocaine solution are required. There is no danger of injecting the oil into the cellular tissues nor is there any fear of breaking needles inside the trachea. The patient may swallow the iodized oil in which case a stomach wash may be needed.

Treatment of Lymphadenoma with Vaccine of Elementary Bodies—Warner points out that in a previous paper Gordon summarized the experimental evidence which strongly suggests that the "elementary bodies" which he has isolated are the causal agents of lymphadenoma. To establish this beyond doubt is at present impossible. Since the human species is the only one known to be infected with lymphadenoma, it is of interest to see how far, in the present state of knowledge, cases of lymphadenoma can be treated with a serum or vaccine prepared from these elementary bodies. For the past three years, work has been proceeding in collaboration with Gordon to test the value of his sensitized vaccine as a curative agent. The clinical material used has been subject to a careful scrutiny to ensure a correct diagnosis. The criteria to be fulfilled to ensure this have been 1. From a clinical standpoint, fairly typical cases, with lymphatic glandular enlargement, often pyrexia, and a blood count compatible with the diagnosis. 2. A histologic picture showing the changes characteristic of lymphadenoma. 3. A positive result to Gordon's intracerebral inoculation method. This test, when applied to lymphatic glands, is now becoming widely recognized as valuable proof of lymphadenoma, as a characteristic syndrome is produced in the rabbits. In discussing the effects of the vaccine the author cites several cases and says that the doses of the sensitized vaccine should be determined on the patient's reactions to them. In acute or recent cases the most satisfactory initial dose seems to be from 0.05 to 0.1 cc. of one twenty-thousandth vaccine, and depending on the amount of reaction obtained, this is either repeated or increased to from 0.1 to 0.2 cc. at the end of five, six or seven days. In any patient with pyrexia, or recent pyrexia, probably owing to the impossibility of obtaining complete sensitization of the elementary bodies in the vaccine, there is a maximal dosage which should rarely be exceeded. This varies in individual cases, but it is probably unwise to exceed a dose of 1 cc. in children or 2 cc. in adults. The optimal dose may be repeated weekly for long periods. In chronic cases an initial dose of 0.25 cc. is usually safe, and this may be increased usually by 0.25 cc. at the same intervals of time. If the vaccine is given early in cases which are not too advanced, the symptoms are greatly benefited.

Sterile Mating—Green-Armytage considers the following necessary in an investigation in every case of sterile mating: (1) a complete medical history of the life and habits of both husband and wife, (2) a complete physical examination of both parties, (3) an expert examination of the semen, (4) a β -H test of the reaction of the vagina and an investigation of the cervix, (5) a demonstration, preferably by roentgenogram, of patency of the tubes, and (6) an investigation of the premenstrual endometrium and endocrine factors. In discussing the examination of the male, the author stresses the importance of repeated examinations of the semen. He says that genital hypoplasia is by far the commonest single cause of primary sterility in women. It was responsible for 44 per cent of cases in his published series. Perhaps the most constant feature, however, is delayed onset of menstruation which later is irregular, painful or scanty. In women with this history, abortion is common. Treatment is disappointing, for it is not the ovary that is at fault but the anterior pituitary gland. In some cases the author found thyroid gland and calcium useful, but there seems little doubt that in the future, gonadotropic substances containing active anterior pituitary hormone will be the recognized means of treatment. After discussing the β -H of the vaginal secretion, the author gives his attention to tubal occlusion. Twelve years' experience with Rubin's insufflation test and salpingograms with iodized oil has confirmed the author's view of the rarity of sterility due to occlusion and has also convinced him that the salpingogram has much more

therapeutic and diagnostic value than insufflation. If obstruction is at the isthmus, operations, however careful are almost always useless, but if it is in the ampullary or fimbriated portion, there is at least a 20 per cent chance of success. Lastly the visible and invisible pattern of the endocrine glands must be considered. The sedentary city worker and many young women with menstrual irregularities have a low basal metabolic rate with subthyroidism, probably dietetic in origin. It is perhaps significant that the adoption of an infant, with its release of maternal feelings, is often sufficient to stimulate normal function and so cause conception. There is evidence, however, that certain women menstruate regularly, but without ovulation. In these cases the secretory or premenstrual phase, dependent on the hormone progesterin secreted by the corpus luteum, is absent. The treatment of this anovular menstruation is promising. The author gives four intramuscular injections of 100,000 units of theelin during the first two weeks of the cycle and three injections of gonadotropic substance of pregnancy urine (100 rat units) during the last ten days, beginning on the seventeenth day.

Gonorrhea in Women—Rorke states that, before one considers the discharge of a patient after treatment for gonorrhea, the films and cultures should be negative after three succeeding menstrual periods. She must also be free from signs or symptoms of gonorrhea and must have been off treatment for three or four weeks wholly before final testing after a provocative. The best provocative is alcohol—gin or other spirit taken the night before the films and cultures are taken in the morning. The local congestion resulting from the use of alcohol will astonish many practitioners. If this provocative is not possible, painting the urethra and cervix with 25 per cent strong protein silver and taking films and cultures thirty-six hours later make quite a fair provocative. The blood complement fixation test should also be made and be negative. Should it be positive, even if films and cultures are negative, it is necessary to consider the possibility of a focus of infection elsewhere. If the patient's "cure" is to be other than a mockery, it must be ensured that the husband or consort is clear of infection before the patient resumes relationships.

Ablation of Grafted Tumors and Metastases—Roussy and his collaborators have recently reported a study of the behavior of different tumors after ablation. For control purposes it was necessary to determine exactly the proportion of spontaneous metastases occurring with the various tumors without ablation. Thus, for Jensen's sarcoma they noted 81 per cent of spontaneous metastases, but actually for control purposes 25 per cent is a more accurate figure. These investigators then removed the tumor from more than 200 rats with grafted Jensen sarcomas. The removals were partial or total and were performed on tumors of different sizes, but in the majority of instances of large size. Total ablations were carried out on 143 rats. Sixty-three of these remained cured, thirty-one had local recurrences, thirty-five had recurrences and metastases and fourteen showed metastases alone. Thus, metastases were noted in 34 per cent of the total. Partial ablations were performed on sixty-seven rats, of which number thirty-eight developed metastases. On the whole, similar observations were made with other tumors, such as the Flexner-Jobling carcinoma and Murray carcinoma of the mouse. These investigations demonstrate that the origin of metastases after excision of grafted tumors depends on a number of factors including the operative act itself and the local and general disorders that it engenders, both of which are factors that favor the proliferation of cancerous cells. Furthermore, the removal of a tumor favors the proliferation of the remaining tumor cells, although the mechanism of this phenomenon remains unknown. It is probably complex and does not depend solely on the nutritive factor. It must also be realized that ablation can favor the production of metastases by prolonging the duration of evolution of a tumor. It is important, the authors believe, to determine the different behavior with regard to metastases of different types of grafted tumors. The results obtained can apply only to those tumors which were examined and cannot be carried over to other grafted tumors or spontaneous human cancers.

Spontaneous Transmission of Cancer—Balacesco and Tzovaru describe an ulcerated carcinoma of the breast transmitted spontaneously to the lips of a nursing infant, probably by the mechanism of grafting by direct contact. The histologic diagnosis of the cancer of the mother was a trabecular adenocarcinoma infiltrating the breast and having zones of scirrhous transformation. The connective tissue showed necrotic areas and ganglionic metastases. The histologic diagnosis of the tumor of the infant's lip was fusiform sarcoma. The second tumor, according to the authors, was obviously not of the same structural characteristics as the tumor of the mother. The interval elapsing before the development of the second tumor was about eleven months. The difference in character of the two tumors may lead to question as to the identity of origin. The question of transformation of an epithelioma into a sarcoma has served as the subject for prolonged discussions and controversies. It is probable, however that, along with the epitheliomatous evolution of grafted epithelial cells a sarcomatous evolution may also be produced, dependent either on the conjunctive element of the graft or on the stroma furnished by the tissues of the host. The latter explanation remains the choice of the authors.

Prostatic Hemorrhages—Pasteau believes that hemorrhage from the prostate occurs much more frequently than is generally believed. Traumatism is frequently responsible, but spontaneous hemorrhage is far from rare. The most important method of diagnosis of prostatic hemorrhage is furnished by catheterization. The most important aspect of treatment consists in avoidance of trauma so that the prostate may not be injured. However, once bleeding has set in, complete removal of the clot by aspiration becomes necessary. If bleeding continues in spite of these measures, suprapubic cystostomy must be performed.

- Parathyroids and Diabetes J Olmer and J E Paillas—p 1418

Sugar Therapy in Mushroom Poisoning—The marked hypoglycemia reported as occurring in mushroom (*Amanita phalloides*) poisoning led Binet and Marek to the experiments reported in this paper. The dry powder of the mushroom reduces its toxicity for a long time and it was this substance that served as the experimental injectable preparation. They used from 10 to 20 mg of dried mushrooms per kilogram of body weight of the animal by subcutaneous injection. When given orally, 0.1 Gm per kilogram of body weight was used. When rabbits were injected with this substance, no disturbance appeared for eight or ten hours, after which a profound asthenia set in. Frequently repeated convulsions would occur after this period. Death usually occurred about the twenty-fourth or thirty-sixth hour after the injection. Both in these animals and in dogs there was a marked fall in the blood sugar after the first four hours. The convulsions observed in the rabbits were apparently due to hypoglycemia, which therefore suggests a possible corrective method. To another series of rabbits given similar doses of dried mushrooms, sugar also was administered. After various trials the administration of 20 cc. of a 4 per cent solution of dextrose intravenously four or five times a day was adopted. The first dose was given eight or ten hours after the injection. With this method, nine out of twelve rabbits survived, although none of the untreated ones lived. Of the animals treated with sugar and living, there was a marked loss of weight later in spite of a rapid increase in quantity of food taken. All showed glycosuria and albuminuria between the third and sixth days, and three animals also showed an increase in blood urea. Although these observations were all of an experimental nature, the authors believe that the sugar method of treatment offers a safe and efficacious method of treating mushroom poisoning.

- Natural Self Protection and Regulation in Circulation E P Pick.—p 860
- Results of Bronchspirometry H C Jacobaeus—p 865
- *Influence of Allergy on Tuberculosis P Schwartz.—p 874

Influence of Allergy on Tuberculosis—Schwartz describes animal experiments in which it is proved that every infection with tubercle bacilli produces an increase in the sensitivity toward new specific infections. If the infected organism at the height of its sensitivity is exposed to hematogenic or exogenic dissemination of tubercle bacilli, there develops a shocklike symptomatology, which frequently leads to a fatal termination. However, if the organism survives the crisis that is produced by the hypersensitivity reaction, the crisis may be

the beginning of a process of healing. The author applies the experimental observations to human pathology. In giving his attention to the tuberculosis in children he takes up the primary complex, hematogenic dissemination and bronchial dissemination. He says that tuberculosis in adults occurs in the same forms as during childhood.

Polypeptidemia in Blood and Liver Diseases—Benedetti found normal polypeptidemia analogous to that reported in the literature (2.5 mg. per hundred cubic centimeters of blood) but a normal index of deamination of 0.08, which is lower than that previously reported, varying between 0.1 and 0.2. The author reports the results of determinations of polypeptidemia in blood and liver diseases and concludes that hyperpolypeptidemia appears in blood diseases if they are complicated by hepatorenal disturbances or fever or if they are associated with hemolysis. In grave forms of anemia secondary to hemorrhage and in those associated with hydremia, frequently there is a relative hypopolypeptidemia. In grave insufficiency of the liver, polypeptidemia is increased. In ascitic cirrhosis the improvement of circulation and digestive absorption, following paracentesis, associates itself with constant diminution of hyperpolypeptidemia. According to the author, polypeptides are not toxic substances but proteins, analogous to amino acids and useful to the organism. Hyperpolypeptidemia coexists with nervous, humoral and toxic symptoms in several diseases, but it is not the cause of the symptoms.

Zambri Pylororeaction in Pregnancy—The Zambri pylororeaction is based on the changes of saliva produced by addition of a coloring reagent prepared as follows: cochineal carmine 1 Gm., bioxiantroumone 7 Gm., trioxiantroumone 1 Gm., tincture of madder 13 Gm., and 95 per cent alcohol 100 Gm. One cubic centimeter of saliva is taken from a washed mouth directly into a graduate to which 15 or 20 drops of the reagent is added. The graduate is shaken, its mouth being covered with white paper. The saliva, in contact with the reagent, takes a color that may vary from light yellow to dark violet. The results of the test can be interpreted immediately after the test or later and do not change for several hours or days provided the tube is left in a dark place. The Zambri standard chromatic scale of the test has sixteen different shades. In the original test light shades (low figures in the scale) indicate a diminished vital resistance, whereas dark shades (high figures in the scale) indicate good vital resistance. The color changes in the test from dark to light indicate humoral variations in pathologic conditions. The test is of clinical value because the color scale in the saliva varies with the evolution of the disease to lighter shades on aggravation and to darker shades on improvement of the patients. Bolaffi made the test in normal and pathologic pregnancy, labor and the puerperium. He states that the reaction is reliable because it shows the real organic condition in all cases. In toxic forms of pregnancy, as well as in cardiac diseases and pulmonary tuberculosis complicating pregnancy, the variations of the color in the saliva correspond to the clinical evolution. The test shows sensitivity during labor in its color modifications to lighter shades if the woman is fatigued. A normal puerperium does not induce noticeable variations in the behavior of the test.

Behavior of Lactacidemia in Diabetes—Battistini and Herlitzka aimed at ascertaining the origin of hyperglycemia that follows administration of epinephrine in normal persons. They studied the behavior of lactacidemia in diabetes, before and after administration of epinephrine, and conclude that lactacidemia and glycemia in the arterial and venous blood are equal when the determinations are made with the patients at rest and with fasting stomachs. Following the administration of epinephrine, lactacidemia increases, especially in the venous blood, glycemia does not increase or increases slightly, especially in the venous blood, and the ratio between the molecular concentration of lactic acid and dextrose increases in relation to the intensity of lactacidemia. The slight hyperglycemia induced by epinephrine in diabetic patients, in comparison with that induced by the same test in normal persons, depends on the lowered reserves of carbohydrates in diabetic patients. It originates in a mobilization of dextrose from the muscles and perhaps also from dextrose stored in the liver. Dextrose mobilized by epinephrine becomes reactive and increases the amount of reactive dextrose in the blood of the patients. This mechanism explains hyperglycemia following administration of epinephrine in normal persons.

Lactacidemia in Renal Insufficiency—Cionini and Herlitzka determined the lactacidemia in a group of patients suffering from complete renal insufficiency. Their work aimed at verifying the role of lactacidemia in the pathogenesis of uremic acidosis. They conclude that lactacidemia is normal in patients suffering from complete renal insufficiency with moderate hyperazotemia and is increased in those presenting complete renal insufficiency with a high degree of hyperazotemia. In the latter group hyperlactacidemia is not intense and does not parallel the variations of hyperazotemia. As a rule, a lowering of the alkali reserve coincides with an increase of lactacidemia, but the variations of the latter do not parallel those of the former. Renal retention and possibly also anoxemia of the tissues due to circulatory insufficiency are the main factors involved in the development of lactacidemia in renal insufficiency. Hyperlactacidemia does not seem to play an important part in the development of uremic acidosis.

Simplification of Percutaneous Tuberculin Test—Verde performed the Pirquet and Mantoux reactions and the tuberculin plaster test in 165 children ranging in age between 2 months and 11 years. The tests gave positive results as follows: Pirquet 49 per cent, Mantoux 557 per cent and

tuberculin plaster test 51 per cent. The author concludes that the tuberculin plaster test has the following advantages over the Pirquet and Mantoux reactions: a simple technic, which permits rapid performance of the test by physicians and sanitarians, without having to resort to surgical instruments and without trauma or pain. The test is not followed by complications, pseudoreactions, abnormal reactions or infection. The results show sensitivity of the skin early in the development of tuberculosis, so that the test can be used not only in early diagnosis but also in preventing the disease. It is advisable to resort to the test as a preliminary to the Mantoux test, which can be made by physicians in cases selected from the results of the tuberculin plaster test.

Permanent Internal Derivation of Bile as Radical Surgical Treatment of Biliary Calculosis G. Baggio—p 1767

*Roentgen Treatment of Salivary Fistula G. Barbèra—p 1773

Roentgen Treatment of Salivary Fistula—Barbèra makes a critical study of the several operations for salivary fistula. He advises the suppression of the salivary secretions by high voltage roentgen irradiations on the area of the parotid gland by the following technic: limitation of the parotid field with lead material, focal distance 30 cm, hardness of rays 180 kilovolts, and high filtration of rays through a filter of 0.5 mm of copper and 3 mm of aluminum. The total dosage is 600 roentgens, given every other day as follows: 300 roentgens for the first irradiation and 150 for the second and third, respectively. The irradiations are measured by Hammer's instrument on the skin. Local painful swelling is relieved by applying the hot water bag on the irradiated area in the afternoon of the day on which the irradiation was given. The salivary secretion is controlled from the first roentgen treatment. After the third and last treatment it is definitely suppressed. The fistula spontaneously heals in two or three days after completion of the treatment and recurrence does not take place. Only exceptionally is a complementary operation necessary to cure the fistula, the diminished salivary secretion during the operation being an important factor for the result. He reports a case in which the satisfactory results of roentgen treatment, not followed by operation, were found to persist a long time after administration of the treatment.

Ligamentopexis—Bertola performs extraperitoneal ligamentopexis by the transperitoneal route with the following technic: medial umbilicopubic laparotomy, opening of the subperitoneal layers by a 2 cm peritoneal incision (which is made on the peritoneum at the internal margin of the exit of the round ligament), exposure of the peritoneal aspect of the inguinal-abdominal region (especially at the point in which Cooper's ligament and Thompson's fascicle of ilio pubic fibers meet), separation of the round ligament from the surrounding tissues, mobilization of the segment of the round ligament included between the body of the uterus and the exit of the ligament through the peritoneal opening and fixation of the ligament (by means of a suture with chronic catgut No. 2) to Thompson's fascicle of ilio pubic fibers. The fixation is made at the level of the external edge of the anterior rectus muscle (Henle's ligament). The segment of round ligament between the point of its fixation and its exit through the peritoneal opening passes over the iliac vessels but does not compress them. According to the author, the advantages of ligamentopexis made by this technic are the preservation of the normal anatomic disposition of the uterus into the peritoneal cavity and the fact that the organ is firmly fixed. With the precaution of emptying the bladder before operating no complications set in.

Laurence-Biedl Syndrome—Maldonado Allende reports a typical case of Laurence-Biedl syndrome in a child aged 10 years. The patient's parents are cousins and in some members of both families there are endocrine dysfunctions. The author says that in the pathogenesis of the syndrome the insufficiency of the hypophysis in association with alterations of the hypothalamus plays the most important part. The alterations of those structures are the cause of the symptoms. Combined organotherapy of thyroid and hypophysis, administered for a long time, induces, according to the literature, improvement of many symptoms and, in some cases, the clinical recovery of the patient. In the author's case the thyroid treatment resulted in increasing the basal metabolism and improving the visual and psychic conditions of the patient.

*Occurrence, Differentiation and Experimental Transformation of Three Types of Diphtheria Bacilli K. L. Pesch—p 1202

Reticulocytosis During Spring—In the course of studies on normal persons, which were made during the spring, Grunke and Diesing observed reticulocyte values that were considerably above the values usually regarded as normal. It was decided to make tests during the different seasons. Tabular reports and a diagram indicate that the reticulocytes are nearly always increased during spring. The authors admit that they do not know the cause of this reticulocytosis which appears in the spring but they suggest that increased sun radiation, particularly ultraviolet radiation, may play a part.

Studies on Types of Diphtheria Bacilli—Pesch investigated the statements of Anderson and his collaborator to the effect that Löffler's diphtheria bacilli can be divided into three types (gravis, mitis and intermedius). He examined 2,610 pharyngeal and nasal smears and studied 332 diphtheria strains. Of these, 208 were from diphtheria patients, 115 from convalescent persons and nine from carriers. Studies on these 332 diphtheria strains corroborated the occurrence of three different types of diphtheria bacilli. These three types differ not only in the shape of their colonies, in hemolysis and in starch acidification but also in their growth on certain synthetic culture mediums and particularly in the type and rapidity of their increase in nutrient bouillon (curve of increase). Regarding the transformation of the types, the author says that after about four or six weeks in aerobic bouillon cultures there is always a complete transformation from the intermedius into the mitis type. This transformation could not be reversed even after daily transfer on new Löffler plates (continued for weeks) and after six guinea-pig passages.

Rare Indications for Cesarean Operation—Isbruch emphasizes that he does not wish to argue for a wider use of the cesarean operation, on the contrary, he considers it the task of the obstetrician to utilize and support the natural processes. However aside from the typical indications for the

cesarean operation there are cases in which it is not only the most rapid and simplest method for the obstetrician but also life preserving for the child and the least dangerous for the mother. The author describes five cases. In the first, a cervical transperitoneal cesarean operation was done because an intra-cervical myoma made delivery by the natural route impossible, even if the life of the child had been sacrificed. The cesarean operation preserved the life of mother and child and made possible the removal of the myoma. The second case concerns a woman in whom the first delivery had resulted in a complete perineal tear with persisting rectovaginal fistula and incontinence. The second delivery was spontaneous, but repeated operations did not completely counteract the incontinence. During the third pregnancy the woman demanded that at term a cesarean operation be performed so as to avoid renewed tearing of the perineum. This was done. The author admits that after plastic repair of the perineum it is usually possible to make room enough by lateral incisions, but in this case it was impossible. In the third case the cesarean operation was resorted to on account of an extremely severe vulval edema. The fourth case concerned a woman with vaginal stenosis and hypoplasia of the uterus. Since the uterine contractions involved the danger of rupture of the hypoplastic uterus, the cesarean operation was done following the premature rupture of the bag of waters six weeks before the end of term. The fifth case concerns a uterus bicornis. In this connection the author emphasizes once more that he does not consider cesarean section necessary for all such cases but stresses that in this case the pregnancy had developed in the weaker horn, which, as the operation revealed, would not have withstood the strain of the uterine contractions.

Treatment of Sequels of Epidemic Encephalitis — Weber recommends the administration of large doses of atropine for the treatment of postencephalitic parkinsonism. In a man he begins with three daily administrations of 0.25 mg of atropine (after the morning, noon and evening meal). He considers the oral administration in the form of drops or pills the best method, but, if the oral medication is not well tolerated, it can be given also by subcutaneous injection or in the form of rectal suppositories. The dose is gradually increased by 0.25 mg daily until the subjective and objective improvement shows no further progress, which is usually the case when a daily dose of from 6 to 8 mg has been reached. After this maximal dose has been given for several days, the dosage is gradually reduced. The author says that cumulation does not have to be feared, since atropine is excreted within a few hours. The medication usually has to be continued for a long time, because it does not cure the basic process but only improves the disturbances, so that even 50 per cent of the patients with the severe forms are improved to such an extent that they can work again. If the treatment is to be interrupted by intervals, the cessation should always be gradual so as to obviate withdrawal symptoms. In some cases the doses have to be increased to more than 8 mg daily, but 12 mg is usually the maximum. The author thinks it advisable to hospitalize these patients for a while in order to be able to determine the optimal dose.

Vitamin Deficiency and Gastro-Intestinal Disturbances —According to Stepp, some vitamins are extremely unstable and thus there is a possibility that in case of changes in the gastro intestinal tract they may be destroyed before they are utilized. On the other hand, their resorption may encounter difficulties, either because the resorptive action of the epithelium of the small intestine is reduced or because in case of acceleration of the peristalsis of the small intestine the retention in the intestine is too short for resorption. The author first directs attention to the significance of the antineuritic vitamin in the gastro-intestinal function, a deficiency in this substance produces

a disturbance in the motility. He discusses the pathologic changes developing in the gastro-intestinal tract as the result of vitamin A deficiency. The hydrochloric acid secretion is reduced. Diarrheas with mucosanguineous stools often appear, but they quickly respond to cod liver oil medication. In gastro-enteritis, in which the intestinal passage is usually greatly accelerated, vitamin A resorption may be interfered with. Regarding the deficiency in vitamin B₁ the author says that this substance is absolutely necessary for the normal tonus of the musculature of the gastro-intestinal tract and that it plays an important part in the processes of resorption. The lack of vitamin B₁ results in cessation of the hydrochloric acid production, loss of appetite, atony of the gastro-intestinal tract and a peculiar tendency of the intestine to inflammatory processes. As to the vitamins B₂ and B₄, he points out that their deficiency plays a part in pellagra, stomatitis, glossitis, diarrhea, colitis and intestinal hemorrhages. Moreover, in sprue and celiac disease, a deficiency of the B factors and of vitamin C plays a part. Vitamin C is stored in the small intestine and the author says that this storage is not merely a phase of the resorption, for it is observed also if the cevamic acid is administered intravenously. In tolerance tests with cevamic acid it was observed that, in patients with gastritis in whom hydrochloric acid was absent, the elimination of cevamic acid was much less than in normal persons. This is due either to destruction of the vitamin or to the fact that the vitamin reserves are extremely low. In discussing the treatment with vitamins, the author thinks that on the whole it is better to supply the vitamins in their natural state, that is, in the food, rather than in their pure form.

Blood Factors M and N and Determination of Paternity —Pietrusky shows that there are N receptors which, in the usual method of examination even if the absorption method is used, escape detection. He cites cases in which it is advisable to consider the possibility of a defective N receptor that has escaped detection. He made efforts to produce especially potent anti N serums in order to detect with these the defective N receptor. He dilutes a good anti N serum in a ratio of 1:100 and subjects it to four or five absorptions with fresh, washed A M blood corpuscles until it fails to react with M blood corpuscles even after one hour. Then it is concentrated in the vacuum to from one fifth to one tenth of the original quantity. This is followed by filtration and, in order to obtain a physiologic solution, it is subjected to dialysis. If in the purity test with blood corpuscles M it shows agglutination within the first thirty minutes, it is once more subjected to absorption with A M and to concentration. In this manner the author obtained an extremely sensitive anti N serum. A case in which the ordinary serums had failed could be completely cleared up with the new serum. The author emphasizes that the blood group analyses, on which legal decisions are based, should be made only by laboratories which are entirely competent for such work.

*Decapsulation and Denervation of Kidneys. S. K. Sen—p 1035

Decapsulation and Denervation of Kidneys —The discovery of the effect of sympathectomy on the blood pressure has reawakened, according to Sen, the interest in kidney decapsulation. In his material the author found a fall of blood pressure after decapsulation of a kidney and application of phenol to the renal blood vessels. The blood pressure, however, never failed to rise once more, so that a permanent result was not obtained. The removal of the thickened capsule in thirty-two cases of perinephritis was successful in relieving the pain and the condition itself. The author likewise saw successful application of decapsulation in sixteen out of eighteen cases of hematuria in focal nephritis and in hemorrhagic nephritis. Decapsulation was effective in four cases of ascending kidney infection. He concludes that the operation of decapsulation gives gratifying results when performed for a proper indication.

- *Excess of Vitamin C in Healthy and Diseased Subjects W Tomaszewski—p 773
- Experiment with Soneryl (a White Crystalline Hypnotic, Butyl Ethyl Barbituric Acid) as Somniferous Remedy A Erb—p 779

Treatment of Pyogenic and Necrotic Diseases of Lungs—Landau and his co-workers state that during the last twenty-five years pyogenic and necrotic diseases of the lungs have had three stages in their treatment. 1 Before the introduction of pneumothorax, pharmacologic remedies were applied by mouth, but the results were unsuccessful. Arsphenamine proved satisfactory in cases of syphilitic origin. 2 Pneumothorax was applied to the upper part of the lungs with fairly good results and in some cases to the lower lobes also with success. 3 Alcohol was introduced intravenously and aided in postponing conservative treatment (drugs and arsphenamine) and was especially beneficial when combined with pneumothorax. Following is a summary of their cases: (a) out of a group of thirty-six pyogenic patients treated with pneumothorax, twenty-two (61 per cent) recovered or were much improved, eleven showed no improvement and three died; (b) of forty-six necrotic patients treated with pneumothorax and alcohol, twenty-one (48 per cent) recovered or were much improved, fourteen were not benefited and eleven died; (c) of eighteen patients treated with alcohol, seven recovered and six improved (a total of thirteen or 72 per cent, benefited). Alcohol aids in healing after operation.

Excess of Vitamin C in Healthy and Diseased Subjects—Tomaszewski states that he has experimented with vitamin C in both healthy and diseased persons. Researches have been made on the mechanism of behavior of vitamin C in the body, especially in the blood. The normal elimination in twenty-four hours of healthy persons who have had plenty of vitamin C is in excess of from 18 to 30 mg. (Tillmann's method of dichlorophenolindophenol). In persons considered healthy but not receiving enough vitamin C examination discloses the results of hypovitaminosis. An organism oversupplied with vitamin C excretes the excess on the first day through the urine. Almost all the diseased patients on whom the research was made with the aid of an excess of vitamin C showed marked degrees of hypovitaminosis, depending on the kind of disease and method of treatment (such as an ulcer diet). A distinct lack of vitamin C has been noted in some cases of diseases of the blood and of the digestive organs and in chronic rheumatism. In patients with high temperatures there is great excretion, especially at the onset, and examination of the urine is of great value in demonstrating such cases. It is likely, therefore, that the reduction bodies in cases of high temperature are not altogether those of vitamin C but come partly from another source. In cases of diabetes, low excretion has been observed which must be ascribed to the strong dilution of the vitamin C in the urine. During pregnancy the amount of vitamin C is often diminished, probably because of increased

demand. Hypovitaminosis during pregnancy causes low resistance and is probably one of the causes of infection in the urinary tract during this time. Stages of low vitamin C or hypovitaminosis are not considered a disease, but, in cases of low general resistance, influence the time of recovery from various diseases.

Early Diagnosis of Sarcoma of Skeletal Musculature

On the basis of seventy-five cases of sarcoma of the skeletal musculature observed at the Oncologic Institute in Leningrad from 1927 to 1934, Shanin states that correct diagnosis can be made on clinical data aided in some of the cases by a histologic examination. The clinical diagnosis includes the study of the etiologic factors, the early signs of a swelling, its origin, the localization of the involved muscle or group of muscles, the relation of the swelling to the neighboring tissues and the differentiation from other pathologic processes involving skeletal muscles. Trauma and a preceding infection appear to be the predisposing factors in a certain number of the cases. The majority, however, give no history of either. Pain, in a number of cases the result of a residual myositis of a preceding trauma or infection, is one of the earliest symptoms. There may be likewise early involvement of a nerve trunk or of a blood vessel giving rise to pains, paresthesias, anesthesias or feeble pulsation in the involved arterial trunk below the tumor. Histologic diagnosis is particularly valuable in determining the prognosis. The author feels that the state of maturity and distribution of the muscular fibrous substances is of a greater prognostic significance as to malignancy in a given case than the quantitative and qualitative relationship of the stroma to the parenchyma of a sarcomatous tumor.

Isolated Traumatic Rupture of Pancreas—Bönnsdorff says that rupture of the pancreas as the only lesion is rare and presumably occurs, when the stomach is empty, through pressure of the pancreas against the spinal column by the object struck. The prognosis is grave. The phenomenon of primary shock, followed by improvement and then aggravation with simultaneous appearance of a tumor in the epigastrium is characteristic in a number of the cases of isolated rupture of the pancreas (Garre and Körte). The author's patient, a girl aged 8, fell from her bicycle about four and a half hours after a meal and hit the right side of the epigastrium against the handle bar. After a relatively free interval of three weeks, aggravation with almost incessant vomiting occurred and she was admitted for treatment a week later. Attention is called to the fact that a child could eliminate up to 800 cc of secretion, probably mostly pancreatic juice, daily for several weeks without impairment of digestion, and also to the increased diastase values in the urine considered by Usland of great diagnostic significance. There was no glycosuria in this case and no fatty necrosis. Authors agree that as far as possible the ruptured place should be sutured and drained (Usland). In this case the patient was well five weeks after simple drainage.
